Three-Dimensional Gravity Reconsidered

Edward Witten

School of Natural Sciences, Institute for Advanced Study
Princeton, New Jersey 08540

We consider the problem of identifying the CFT's that may be dual to pure gravity in three dimensions with negative cosmological constant. The c-theorem indicates that three-dimensional pure gravity is consistent only at certain values of the coupling constant, and the relation to Chern-Simons gauge theory hints that these may be the values at which the dual CFT can be holomorphically factorized. If so, and one takes at face value the minimum mass of a BTZ black hole, then the energy spectrum of three-dimensional gravity with negative cosmological constant can be determined exactly. At the most negative possible value of the cosmological constant, the dual CFT is very likely the monster theory of Frenkel, Lepowsky, and Meurman. The monster theory may be the first in a discrete series of CFT's that are dual to three-dimensional gravity. The partition function of the second theory in the sequence can be determined on a hyperelliptic Riemann surface of any genus. We also make a similar analysis of supergravity.

1. Introduction

Three-dimensional pure quantum gravity, with the Einstein-Hilbert action

$$I = \frac{1}{16\pi G}\int d^3x\sqrt{g}\left(R + \frac{2}{\ell^2}\right), \tag{1.1}$$

has been studied from many points of view (see [1-3] for some early developments and [4] for a recent review and references), but its status is fundamentally unclear. The present paper is devoted to a tentative attempt to reconsider it. Before giving an overview of the paper, we begin with an introduction to the problem.

The first thought about this theory is that at the classical level it is "trivial," in the sense that there are no gravitational waves, and any two solutions are equivalent locally. So perhaps it might be tractable quantum mechanically.

A second thought is that despite being "trivial," the theory actually is unrenormalizable by power counting, since the gravitational constant G has dimensions of length. So perhaps the quantum theory does not exist.

The claim about unrenormalizability, however, is fallacious, precisely because the classical theory is trivial. In three dimensions, the Riemann tensor R_{ijkl} can be expressed in terms of the Ricci tensor R_{ij}. In the case of pure gravity, the equations of motion express the Ricci tensor as a constant times the metric. So finally, any possible counterterm can be reduced to a multiple of $\int d^3x\sqrt{g}$ and is equivalent on-shell to a renormalization of the cosmological constant, which is parametrized in (1.1) via the parameter ℓ^2. A counterterm that vanishes on shell can be removed by a local redefinition of the metric tensor g (of the general form $g_{ij} \to g_{ij} + aR_{ij} + \ldots$, where a is a constant and the ellipses refer to local terms of higher order). So a more precise statement is that any divergences in perturbation theory can be removed by a field redefinition and a renormalization of ℓ^2.

1.1. Relation To Gauge Theory

The claim just made is valid regardless of how one formulates perturbation theory. But actually, there is a natural formulation in which no field redefinition or renormalization is needed. This comes from the fact that classically, $2+1$-dimensional pure gravity can be expressed in terms of gauge theory. The spin connection ω is an $SO(2,1)$ gauge field (or an $SO(3)$ gauge field in the case of Euclidean signature). It can be combined with the "vierbein" e to make a gauge field of the group $SO(2,2)$ if the cosmological constant is negative (and a similar group if the cosmological constant is zero or positive). We simply combine ω and e to a 4×4 matrix A of one-forms:

$$A = \begin{pmatrix} \omega & e/\ell \\ -e/\ell & 0 \end{pmatrix}. \tag{1.2}$$

Here ω fills out a 3×3 block, while e occupies the last row and column. As long as e is invertible, the usual transformations of e and ω under infinitesimal local Lorentz transformations and diffeomorphisms combine together into gauge transformations of A. This statement actually has a close analog in any spacetime dimension d, with $SO(d-1,2)$ replacing $SO(2,2)$. What is special in $d=3$ is that [5,6] it is also possible to write the action in a gauge-invariant form. Indeed the usual Einstein-Hilbert action (1.1) is equivalent to a Chern-Simons Lagrangian[1] for the gauge field A:

$$I = \frac{k}{4\pi}\int \mathrm{tr}^* \left(A\wedge dA + \frac{2}{3}A\wedge A\wedge A\right). \tag{1.3}$$

---

[1] Here tr^* denotes an invariant quadratic form on the Lie algebra of $SO(2,2)$, defined by $\mathrm{tr}^*\, ab = \mathrm{tr}\ a\star b$, where tr is the trace in the four-dimensional representation and $\star$ is the Hodge star, $(\star b)_{ij} = \frac{1}{2}\epsilon_{ijkl}b^{kl}$.

In dimensions other than three, it is not possible to similarly replace the Einstein-Hilbert action with a gauge-invariant action for gauge fields.[2]

In the gauge theory description, perturbation theory is renormalizable by power counting, and is actually finite, because there are no possible local counterterms. The Chern-Simons functional itself is the only gauge-invariant action that can be written in terms of A alone without a metric tensor; as it is not the integral of a gauge-invariant local density, it will not appear as a counterterm in perturbation theory. The cosmological constant cannot be renormalized, since in the gauge theory description, it is a structure constant of the gauge group.

As we have already remarked, the Chern-Simons description of three-dimensional gravity is valid when the vierbein is invertible. This is so for a classical solution, so it is true if one is sufficiently close to a classical solution. Perturbation theory, starting with a classical solution, will not take us out of the region in which the vierbein is invertible, so the Chern-Simons description of three-dimensional gravity is valid perturbatively. The fact that, in this formulation, the perturbation expansion of three-dimensional gravity is actually finite can reasonably be taken as a hint that the corresponding quantum theory really does exist.

However, nonperturbatively, the relation between three-dimensional gravity and Chern-Simons gauge theory is unclear. For one thing, in Chern-Simons theory, nonperturbatively the vierbein may cease to be invertible. For example, there is a classical solution with $A = \omega = e = 0$. The viewpoint in [6] was that such non-geometrical configurations must be included to make sense of three-dimensional quantum gravity nonperturbatively. But it has has been pointed out (notably by N. Seiberg) that when we do know how to make sense of quantum gravity, we take the invertibility of the vierbein seriously. For example, in perturbative string theory, understood as a model of quantum gravity in two spacetime dimensions, the integration over moduli space of Riemann surfaces that leads to a sensible theory is derived assuming that the metric should be non-degenerate.

There are other possible problems in the nonperturbative relation between three-dimensional gravity and Chern-Simons theory. The equivalence between diffeomorphisms and gauge transformations is limited to diffeomorphisms that are continuously connected to the identity. However, in gravity, we believe that more general diffeomorphisms (such as modular transformations in perturbative string theory) play an important role. These are not naturally incorporated in the Chern-Simons description. One can by hand supplement the gauge theory description by imposing invariance under disconnected diffeomorphisms, but it is not clear how natural this is.

---

[2] In $d = 4$, it is possible to write the Hamiltonian constraints of General Relativity in terms of gauge fields [7]. This has been taken as the starting point of loop quantum gravity.

Similarly, in quantum gravity, one expects that it is necessary to sum over the different topologies of spacetime. Nothing in the Chern-Simons description requires us to make such a sum. We can supplement the Chern-Simons action with an instruction to sum over three-manifolds, but it is not clear why we should do this.

From the point of view of the Chern-Simons description, it seems natural to fix a particular Riemann surface Σ, say of genus g, and construct a quantum Hilbert space by quantizing the Chern-Simons gauge fields on Σ. (Indeed, there has been remarkable progress in learning how to do this and to relate the results to Liouville theory [8-11].) In quantum gravity, we expect topology-changing processes, such that it might not be possible to associate a Hilbert space with a particular spatial manifold.

Regardless of one's opinion of questions such as these, there is a more serious problem with the idea that gravity and gauge theory are equivalent non-perturbatively in three dimensions. Some years after the gauge/gravity relation was suggested, it was discovered by Bañados, Teitelboim, and Zanelli [12] that in three-dimensional gravity with negative cosmological constant, there are black hole solutions. The existence of these objects, generally called BTZ black holes, is surprising given that the classical theory is "trivial." Subsequent work [13,14] has made it clear that three-dimensional black holes should be taken seriously, particularly in the context of the AdS/CFT correspondence [15].

The BTZ black hole has a horizon of positive length and a corresponding Bekenstein-Hawking entropy. If, therefore, three-dimensional gravity does correspond to a quantum theory, this theory should have a huge degeneracy of black hole states. It seems unlikely that this degeneracy can be understood in Chern-Simons gauge theory, because this essentially topological theory has too few degrees of freedom. However, some interesting attempts have been made; for a review, see [4].

The existence of the BTZ black hole makes three-dimensional gravity a much more exciting problem. This might be our best chance for a solvable model with quantum black holes. Surely in 3+1 dimensions, the existence of gravitational waves with their nonlinear interactions means that one cannot hope for an exact solution of any system that includes quantum gravity.[3] There might be an exact solution of a 1+1-dimensional model with black holes (interesting attempts have been made [16]), but such a model is likely to be much less realistic than three-dimensional pure gravity. For example, in 1+1 dimensions, the horizon of a black hole just consists of two points, so there is no good analog of the area of the black hole horizon.

1.2. What To Aim For

So we would like to solve three-dimensional pure quantum gravity. But what would it mean to solve it?

First of all, we will only consider the case that the cosmological constant Λ is negative. This is the only case in which we know what it would mean to solve the theory.

Currently, there is some suspicion (for example, see [17]) that quantum gravity with $\Lambda > 0$ does not exist nonperturbatively, in any dimension. One reason is that it does not appear possible with $\Lambda > 0$ to define precise observables, at least none [18] that can be measured by an observer in the spacetime.[4] This is natural if a world with positive Λ (like the one we may be living in) is always at best metastable – as is indeed the case for known embeddings of de Sitter space in string theory [20]. If that is so, then pure gravity with $\Lambda > 0$ does not really make sense as an exact theory in its own right but (like an unstable particle) must be studied as part of a larger system. There may be many choices of the larger system (for example, many embeddings in string theory) and it may be unrealistic to expect any of them to be soluble.

Whether that is the right interpretation or not, we cannot in this paper attempt to solve three-dimensional gravity with $\Lambda > 0$, since, not knowing how to define any mathematically precise observables, we do not know what to try to calculate.

For $\Lambda = 0$, above three dimensions there is a precise observable in quantum gravity, the S-matrix. However, in the three-dimensional case, there is no S-matrix in the usual sense, since in any state with nonzero energy, the spacetime is only locally asymptotic to Minkowski space at infinity [3]. More relevantly for our purposes, in three-dimensional pure gravity with $\Lambda = 0$, there is no S-matrix since there are no particles that can be scattered. There are no gravitons in three dimensions, and there are also no black holes unless $\Lambda < 0$. So again, we do not have a clear picture of what we would aim for to solve three-dimensional gravity with zero cosmological constant.

---

[3] An exact solution or at least an illuminating description of the appropriate Hamiltonian for near-extremal black holes interacting with external massless particles is conceivable.

[4] At least perturbatively, the de Sitter/CFT correspondence gives observables that can be measured by an observer who looks at the whole universe from the outside [19,18]. These observables characterize the wavefunction of the ground state.

With negative cosmological constant, there is an analog, and in fact a much richer analog, of the S-matrix, namely the dual conformal field theory (CFT). This is of course a *two*-dimensional CFT, defined on the asymptotic boundary of spacetime. Not only does AdS/CFT duality make sense in three dimensions, but in fact one of the precursors of the AdS/CFT correspondence was the discovery by Brown and Henneaux [21] of an asymptotic Virasoro algebra in three-dimensional gravity. They considered three-dimensional gravity with negative cosmological constant possibly coupled to additional fields. The action is

$$I = \frac{1}{16\pi G}\int d^3x\sqrt{g}\left(R+\frac{2}{\ell^2}+\ldots\right), \tag{1.4}$$

where the ellipses reflect the contributions of other fields. Their main result is that the physical Hilbert space obtained in quantizing this theory (in an asymptotically Anti de Sitter or AdS spacetime) has an action of left- and right-moving Virasoro algebras with $c_L = c_R = 3\ell/2G$. In our modern understanding [15], this is part of a much richer structure – the boundary conformal field theory.

What it means to solve pure quantum gravity with $\Lambda < 0$ is to find this dual conformal field theory. We focus on the case $\Lambda < 0$ because this is the only case in which we would know what it means to solve the theory. Luckily, and perhaps not coincidentally, this is also the case that has black holes.

1.3. A Non-Classical Restriction

This formulation of what we aim to do makes it clear that we must anticipate a restriction that is rather surprising from a classical point of view. In contemplating the classical action (1.4), it appears that the dimensionless ratio ℓ/G is a free parameter. But the formula for the central charge $c_L = c_R = 3\ell/2G$ shows that this cannot be the case. According to the Zamolodchikov c-theorem [22], in any continuously varying family of conformal field theories in $1+1$ dimensions, the central charge c is constant. More generally, the same is true for the left- and right-moving central charges c_L and c_R.

So the central charges of the dual CFT cannot depend on a continuously variable parameter ℓ/G. It must be [18] that the theory only makes sense for specific values of ℓ/G.

Of course, the c-theorem has an important technical assumption: the theory must have a normalizable and $SL(2,\mathbb{R}) \times SL(2,\mathbb{R})$-invariant ground state. (The two factors of $SL(2,\mathbb{R})$ are for left- and right-moving boundary excitations.) This condition is obeyed by three-dimensional gravity, with Anti de Sitter space being the classical approximation to the vacuum. The desired $SL(2,\mathbb{R}) \times SL(2,\mathbb{R})$ symmetry is simply the classical $SO(2,2)$ symmetry of three-dimensional AdS space.

The statement that ℓ/G cannot be continuously varied is not limited to pure gravity. It holds for the same reason in any theory of three-dimensional gravity plus matter that has a sensible AdS vacuum. For example, in the string theory models whose CFT duals are known, ℓ/G is expressed in terms of integer-valued fluxes; this gives a direct explanation of why it cannot be varied continuously.

1.4. Plan Of This Paper

Now we can describe the plan of this paper.

We aim to solve three-dimensional gravity with negative Λ, at some distinguished values of ℓ/G at which it makes sense.

We do not have any rigorous way to determine the right values. However, in section 2, taking at face value the Chern-Simons description of three-dimensional gravity, we will use it to motivate certain values of ℓ/G. The values that emerge – with the help of a small sleight of hand in the choice of the gauge group for the Chern-Simons theory – are interesting. They are the values at which c_L and c_R are integer multiples of 24, and complete holomorphic factorization of the dual CFT is conceivable.

Not wishing to look a gift horse in the mouth, we will assume that these are the right values to consider. Relying on holomorphic factorization, to describe the solution of the theory, we must describe a sequence of holomorphic CFT's with $c = 24k$, $k = 1, 2, 3, \ldots$.

For $k = 1$, it is believed [23] that there are precisely 71 holomorphic CFT's with the relevant central charge $c = 24$. Of these theories, 70 have some form of Kac-Moody or current algebra symmetry extending the conformal symmetry. In the AdS/CFT correspondence, these theories are dual to three-dimensional theories describing gravity plus additional gauge fields (with Chern-Simons interactions). To describe pure gravity, we need a holomorphic CFT with $c = 24$ and no Kac-Moody symmetry.

Such a model was constructed nearly twenty-five years ago by Frenkel, Lepowsky, and Meurman [24], who also conjectured its uniqueness. The motivation for constructing the model was that it admits as a group of symmetries the Fischer-Griess monster group $\mathbb{M}$ –

the largest of the sporadic finite groups. (The link between the monster and conformal field theory was suggested by developments springing from an observation by McKay relating the monster to the j-function, as we explain more fully in section 3.1.) Arguably, the FLM model is the most natural known structure with $\mathbb{M}$ symmetry. A detailed and elegant description is in the book [25]; for short summaries, see [26,27], and for subsequent developments and surveys, see [28-30]. Assuming the (unproved) uniqueness conjecture of FLM, we propose that their model must give the CFT that is dual to three-dimensional gravity at $c = 24$.

For $c = 24k$, $k > 1$, we need an analog of requiring that there is no Kac-Moody symmetry. A plausible analog, expressing the idea that we aim to describe pure gravity, is that there should be no primary fields of low dimension other than the identity. A small calculation shows that at $c = 24k$, the lowest dimension of a primary other than the identity cannot be greater than $k + 1$, and if we assume that this dimension is precisely $k + 1$, then the partition function is uniquely determined. Conformal field theories with this property were first investigated by Höhn in [31,32] and have been called extremal CFT's; see also [33].

It is not known[5] if extremal CFT's exist for $k > 1$. If such a CFT does exist, it is an attractive candidate for the dual of three-dimensional gravity at the appropriate value of the cosmological constant. The primaries of dimension $k + 1$ and above would be interpreted as operators that create black holes. The dimension $k + 1$ agrees well with the minimum mass of a BTZ black hole. This statement may sound like magic, since the value $k + 1$ is determined from holomorphy and modular invariance without mentioning black holes; but the result is not so surprising if one is familiar with previous results on the AdS/CFT correspondence in three dimensions [34].

Section 3 of this paper is devoted to describing the partition function of an extremal CFT and discussing how such a theory could be related to three-dimensional gravity. In both sections 2 and 3, we consider also the case of three-dimensional supergravity. More precisely, we consider only minimal supergravity, corresponding to $N = 1$ superconformal symmetry for the boundary CFT. In this case, holomorphic factorization is conceivable at $c = 12k^*$, $k^* = 1, 2, 3, \ldots$. Here there is a little ambiguity about exactly what we should mean by an extremal superconformal field theory (SCFT), but pragmatically, there are good candidates at $k^* = 1, 2$. The $k^* = 1$ theory was constructed by Frenkel, Lepowsky, and Meurman, who also conjectured its uniqueness. Its discrete symmetries were understood only recently in work by Duncan [35]. For $k^* = 2$, the extremal SCFT was constructed by Dixon, Ginsparg, and Harvey [26], by modifying the orbifold projection that had been used [24] in constructing the $k = 1$ extremal CFT. Interestingly, the extremal SCFT's with $k^* = 1, 2$ both admit[6] an action of very large discrete groups related to the Conway group. This is a further indication that unusual discrete groups are relevant to three-dimensional gravity and supergravity. In fact, we find some hints that supergravity may have monster symmetry at $k^* = 4$ and baby monster symmetry at $k^* = 6$.

---

[5] Höhn's definition of an extremal CFT allowed holomorphic factorization up to a phase, so that c may be a multiple of 8, not 24. As a result, he discussed several examples of extremal theories that we will not consider here. These examples have k non-integral and less than 2.

Regrettably, we do not know how to construct new examples of extremal conformal or superconformal field theories. Section 4 is devoted to a calculation that aims to give modest support to the idea that new extremal theories do exist. We consider an extremal CFT with $k = 2$ and show that its partition function can be uniquely determined on a hyperelliptic Riemann surface of any genus (including, for example, any Riemann surface of genus 2). The fact that a partition function with the right properties exists and is unique for any genus is hopefully a hint that an extremal $k = 2$ CFT does exist.

We make at each stage the most optimistic possible assumption. Decisive arguments in favor of the proposals made here are still lacking. The literature on three-dimensional gravity is filled with claims (including some by the present author [6]) that in hindsight seem less than fully satisfactory. Hopefully, future work will clarify things.

Advice by J. Maldacena was essential at the outset of this work. I also wish to thank J. Duncan, G. Höhn, G. Nebe, and J. Teschner for descriptions of their work and helpful advice; T. Gannon, R. Griess, J. Lepowsky, and A. Ryba for correspondence about the monster group and related matters; and many colleagues at the IAS and elsewhere, especially A. Maloney, G. Moore, and S. Shenker, for helpful comments.

2. Gauge Theory And The Value Of c

The goal of the present section is to determine what values of the cosmological constant, or equivalently of the central charge c of the boundary CFT, are suggested by the relation between three-dimensional gravity and Chern-Simons gauge theory.

---

[6] The fact that they have essentially the same symmetry group was pointed out by J. Duncan, who also suggested the identification of the $k^* = 2$ theory.

Before proceeding to any calculation, we will dispose of a few preliminary points. The first is that [36], as long as the three-dimensional spacetime is oriented, as we will assume in this paper, three-dimensional gravity can be generalized to include an additional interaction, the Chern-Simons functional of the spin connection ω:

$$\Delta_0 I = \frac{k'}{4\pi}\int_W \mathrm{tr}\left(\omega\wedge d\omega + \frac{2}{3}\omega\wedge\omega\wedge\omega\right). \tag{2.1}$$

Here we think of ω as an $SO(2,1)$ gauge field (or an $SO(3)$ gauge field in the case of Euclidean signature). Also, tr is the trace in the three-dimensional representation of $SO(2,1)$, and k' is quantized for topological reasons (the precise normalization depends on some assumptions and is discussed in sections 2.1 and 2.4). Equivalently, instead of ω, we could use the $SO(2,2)$ gauge field A introduced in eqn. (1.2), and add to the action a term of the form

$$\Delta I = \frac{k'}{4\pi}\int_M \mathrm{tr}\left(A\wedge dA + \frac{2}{3}A\wedge A\wedge A\right), \tag{2.2}$$

where now tr is the trace in the four-dimensional representation of $SO(2,2)$. Provided that the conventional Einstein action (1.1) is also present, it does not matter which form of the gravitational Chern-Simons interaction we use, since they lead to equivalent theories. If one adds[7] to ω a multiple of e, the Einstein action (1.1) transforms in a way that cancels the e-dependent part of (2.2), reducing it to (2.1) (while modifying the parameters in the Einstein action).

For our purposes, the $SO(2,2)$-invariant form (2.2) is more useful. This way of writing the Chern-Simons functional places it precisely in parallel with the Einstein-Hilbert action, which as in (1.3) can similarly be expressed as a Chern-Simons interaction, defined with a different quadratic form. We will use the fact that all interactions can be written as Chern-Simons interactions to constrain the proper quantization of all dimensionless parameters, including ℓ/G.

We start with the fact that the group $SO(2,2)$ is locally equivalent to $SO(2,1)\times SO(2,1)$. Moreover, we will in performing the computation assume to start with that $SO(2,1)\times SO(2,1)$ is the right global form of the gauge group. (Then we consider covering groups[8] that are only locally isomorphic to $SO(2,1)\times SO(2,1)$.) Thus, by taking suitable linear combinations of ω and e, we will obtain a pair of $SO(2,1)$ gauge fields A_L and A_R. These have Chern-Simons interactions

---

[7] This operation is invariant under diffeomorphisms and local Lorentz transformations because ω and e transform in the same way under local Lorentz transformations – a statement that holds precisely in three spacetime dimensions.

$$I=\frac{k_L}{4\pi}\int \mathrm{tr}\,\left(A_L\wedge dA_L+\frac{2}{3}A_L\wedge A_L\wedge A_L\right)-\frac{k_R}{4\pi}\int \mathrm{tr}\,\left(A_R\wedge dA_R+\frac{2}{3}A_R\wedge A_R\wedge A_R\right). \tag{2.3}$$

Both k_L and k_R are integers for topological reasons, and this will lead to a quantization of the ratio G/ℓ that appears in the Einstein-Hilbert action, as well as the gravitational Chern-Simons coupling (2.2). The minus sign multiplying the last term in (2.3) is convenient; it will ensure that k_L and k_R are both positive.

2.1. Quantization Of Parameters

For completeness, we begin by reviewing the quantization of the Chern-Simons coupling in gauge theory. The basic case to consider is that the gauge group is $U(1)$. The gauge field A is a connection on a complex line bundle $\mathcal{L}$ over a three-manifold W, which for simplicity we will assume to have no boundary. Naively speaking, the Chern-Simons action is

$$I=\frac{k}{2\pi}\int_W A\wedge dA \tag{2.4}$$

with some coefficient k. If the line bundle $\mathcal{L}$ is trivial, then we can interpret A as a one-form, and I is well-defined as a real-valued functional. If this were the general situation, there would be no need to quantize k.

However, in general $\mathcal{L}$ is non-trivial, A has Dirac string singularities, and the formula (2.4) is not really well-defined as written. To do better, we pick a four-manifold M of boundary W and such that $\mathcal{L}$ extends over M. Such an M always exists. Then we pick an extension of $\mathcal{L}$ and A over M, and replace the definition (2.4) with

$$I_M=\frac{k}{2\pi}\int_M F\wedge F, \tag{2.5}$$

where $F=dA$ is the curvature. Now there is no Dirac string singularity, and the definition of I_M makes sense. But I_M does depend on M (and on the chosen extension of $\mathcal{L}$, though we do not indicate this in the notation). To quantify the dependence on M, we consider two different four-manifolds M and M' with boundary W and chosen extensions of $\mathcal{L}$. We can build a four-manifold X with no boundary by gluing together M and M' along W, with opposite orientation for M' so that they fit smoothly along their common boundary. Then we get

---

[8] For an early treatment of coverings in the context of Chern-Simons theory with compact gauge group, see [37]

$$I_M - I_{M'} = \frac{k}{2\pi}\int_X F\wedge F. \tag{2.6}$$

Now, on the closed four-manifold X, the quantity $\int_X F\wedge F/(2\pi)^2$ represents $\int_X c_1(\mathcal{L})^2$ (here c_1 is the first Chern class) and so is an integer. In quantum mechanics, the action function I should be defined modulo 2π (so that $\exp(iI)$, which appears in the path integral, is single-valued). Requiring $I_M - I_{M'}$ to be an integer multiple of 2π, we learn that k must be an integer. This is the quantization of the Chern-Simons coupling for $U(1)$ gauge theory.[9]

Now let us move on to the case of gauge group $SO(2,1)$. The group $SO(2,1)$ is contractible onto its maximal compact subgroup $SO(2)$, which is isomorphic to $U(1)$. So quantization of the Chern-Simons coupling for an $SO(2,1)$ gauge field can be deduced immediately from the result for $U(1)$. Let A be an $SO(2,1)$ gauge field and define the Chern-Simons coupling

$$I = \frac{k}{4\pi}\int_W \mathrm{tr}\left(A\wedge dA + \frac{2}{3}A\wedge A\wedge A\right), \tag{2.7}$$

where tr is the trace in the three-dimensional representation of $SO(2,1)$. Then, in order for I to be part of the action of a quantum theory, k must be an integer. The reason that the factor $1/2\pi$ in (2.5) has been replaced by $1/4\pi$ in (2.7) is simply that, when we identify $U(1)$ with $SO(2)$ and then embed it in $SO(2,1)$, the trace gives a factor of 2.

Coverings

So we have obtained the appropriate quantization of the Chern-Simons coupling for gauge group $SO(2,1)$. However, this is not quite the whole story, because $SO(2,1)$ is not simply-connected. As it is contractible to $SO(2)\cong U(1)$, it has the same fundamental group as $U(1)$, namely $\mathbb{Z}$. Hence it is possible, for every positive integer n, to take an

---

[9] There is a refinement if the three-manifold W is endowed with a spin structure. In this case, k can be a half-integer, as explained in [38]. This refinement is physically realized in the quantum Hall effect with filling fraction 1. That effect can be described by an electromagnetic Chern-Simons coupling with $k = 1/2$; the half-integral value is consistent because the microscopic theory has fermions and so requires a spin structure.

n-fold cover of $SO(2,1)$. The most familiar of these is the two-fold cover, $SL(2,\mathbb{R})$. In addition, $SO(2,1)$ has a simply-connected universal cover.

We want to work out the quantization of the Chern-Simons interaction if $SO(2,1)$ is replaced by one of these covering groups. Again, it is convenient to start with $U(1)$. To say that the gauge group of an abelian gauge theory is $U(1)$ rather than $\mathbb{R}$ means precisely that the possible electric charges form a lattice, generated by a fundamental charge that we call "charge 1." Dually, the magnetic fluxes are quantized, with $\int_C F/2\pi \in \mathbb{Z}$ for any two-cycle C. Replacing $U(1)$ by an n-fold cover means that the electric charges take values in $n^{-1}\mathbb{Z}$, and dually, the magnetic fluxes are divisible by n, $\int_C F/2\pi \in n\mathbb{Z}$. As a result, for a four-manifold X, we have $\int_C F\wedge F/(2\pi)^2 \in n^2\mathbb{Z}$. So, in requiring that the Chern-Simons function (2.4) should be well-defined modulo 2π, we require that $k \in n^{-2}\mathbb{Z}$. This is the appropriate result for an n-fold cover. In the case of the universal cover, with $U(1)$ replaced by $\mathbb{R}$, the magnetic fluxes vanish and there is no topological restriction on k.

These statements carry over immediately to covers of $SO(2,1)$, whose covers are all contractible to corresponding covers of $U(1)$. So for an n-fold cover of $SO(2,1)$, we require

$$k \in n^{-2}\mathbb{Z}, \tag{2.8}$$

and for the universal cover of $SO(2,1)$, k is arbitrary and can vary continuously.

Diagonal Covers

There is more to say, because three-dimensional gravity is actually related to $SO(2,1)\times SO(2,1)$ gauge theory, not just to gauge theory with a single $SO(2,1)$. So we should consider covers of $SO(2,1)\times SO(2,1)$ that do not necessarily come from separate covers of the two factors.

As $SO(2,1)\times SO(2,1)$ is contractible to $SO(2)\times SO(2) = U(1)\times U(1)$, we can proceed by first analyzing the $U(1)\times U(1)$ case. We consider a $U(1)\times U(1)$ gauge theory with gauge fields A, B and a Chern-Simons action

$$I = \frac{k_L}{2\pi}\int_W A\wedge dA - \frac{k_R}{2\pi}\int_W B\wedge dB. \tag{2.9}$$

To define I in the topologically non-trivial case, we pick a four-manifold M over which everything extends and define

$$I_M = \int_M \left(\frac{k_L}{2\pi} F_A\wedge F_A - \frac{k_R}{2\pi} F_B\wedge F_B\right), \tag{2.10}$$

where F_A and F_B are the two curvatures. This is well-defined mod 2π if

$$I_X = \int_X \left(\frac{k_L}{2\pi} F_A \wedge F_A - \frac{k_R}{2\pi} F_B \wedge F_B \right) \tag{2.11}$$

is a multiple of 2π for any $U(1) \times U(1)$ gauge field over a closed four-manifold X.

In $U(1) \times U(1)$ gauge theory, the charge lattice is generated by charges $(1,0)$ and $(0,1)$, and the cohomology classes $x = F_A/2\pi$ and $y = F_B/2\pi$ are integral. For a cover of $U(1) \times U(1)$, we want to extend the charge lattice. To keep things simple, we will consider only the case that will actually be important in our application: a diagonal cover, in which one adds the charge vector $(1/n, 1/n)$ for some integer n. In this case, x and y are still integral, and their difference is divisible by n: $x = y + nz$ where n is an integral class. We have

$$I_X = 2\pi(k_L - k_R) \int_X y^2 + 2\pi k_L \int_X (n^2 z^2 + 2nyz). \tag{2.12}$$

The condition that this is a multiple of 2π for any X and any integral classes y, z is that

$$\begin{aligned} k_L &\in \begin{cases} n^{-1}\mathbb{Z} & \text{if } n \text{ is odd} \\ (2n)^{-1}\mathbb{Z} & \text{if } n \text{ is even} \end{cases} \\ k_L - k_R &\in \mathbb{Z}. \end{aligned} \tag{2.13}$$

These are also the restrictions on k_L and k_R if the gauge group is a diagonal cover of $SO(2,1) \times SO(2,1)$ with action (2.3). For example, the group $SO(2,2)$ is a double cover of $SO(2,1) \times SO(2,1)$, and this cover corresponds to the case $n = 2$ of the above discussion. So for $SO(2,2)$ gauge theory, the appropriate restriction on the Chern-Simons levels is

$$\begin{aligned} k_L &\in \frac{1}{4}\mathbb{Z} \\ k_L - k_R &\in \mathbb{Z}. \end{aligned} \tag{2.14}$$

For a general n-fold diagonal cover, one should use (2.13).

It is also possible to form a "universal diagonal cover," corresponding roughly to the limit $n \to \infty$ in the above formulas. With this gauge group, there is no restriction on k_L, but $k_L - k_R$ is an integer. In terms of three-dimensional gravity, to which we return next, this corresponds to letting ℓ/G be a freely variable parameter, while the gravitational Chern-Simons coupling k' defined in eqn. (2.2) is an integer. As explained in section 1.3, although this is the state of affairs classically in three-dimensional gravity, it cannot be the correct answer quantum mechanically.

2.2. Comparison To Three-Dimensional Gravity

So far, we have understood the appropriate gauge theory normalizations for the Chern-Simons action

$$\begin{aligned} I =& k_L I_L + k_R I_R \\ =& \frac{k_L}{4\pi}\int \mathrm{tr}\left(A_L\wedge dA_L + \frac{2}{3}A_L\wedge A_L\wedge A_L\right) - \frac{k_R}{4\pi}\int \mathrm{tr}\left(A_R\wedge dA_R + \frac{2}{3}A_R\wedge A_R\wedge A_R\right). \end{aligned} \tag{2.15}$$

Our next step will be to express A_L and A_R, which are gauge fields of $SO(2,1)\times SO(2,1)$ (or a covering group) in terms of gravitational variables, and thereby determine the constraints on the gravitational couplings. We have

$$I = \frac{k_L + k_R}{2}\left(I_L - I_R\right) + (k_L - k_R)\frac{(I_L + I_R)}{2}. \tag{2.16}$$

The term in (2.16) proportional to $I_L - I_R$ will gave the Einstein-Hilbert action (1.1), while the term proportional to $(I_L + I_R)/2$ is equivalent to the gravitational Chern-Simons coupling (2.2) with coefficient $k' = k_L - k_R$.

The spin connection $\omega^{ab} = \sum_i dx^i \omega_i^{ab}$ is a one-form with values in antisymmetric 3×3 matrices. The vierbein is conventionally a one-form valued in Lorentz vectors, $e^a = \sum_i dx^i\, e_i^a$. The metric is expressed in terms of e in the usual way, $g_{ij}dx^i\otimes dx^j = \sum_{ab}\eta_{ab}e^a\otimes e^b$, where $\eta = \mathrm{diag}(-1,1,1)$ is the Lorentz metric; and the Riemannian volume form is $d^3x\sqrt{g} = \frac{1}{6}\epsilon_{abc}e^a\wedge e^b\wedge e^c$, where ϵ_{abc} is the antisymmetric tensor with, say, $\epsilon_{012} = 1$. All this has an obvious analog in any dimension. However, in three dimensions, a Lorentz vector is equivalent to an antisymmetric tensor; this is the fact that makes it possible to relate gravity and gauge theory. It is convenient to introduce ${}^*e_{ab} = \epsilon_{abc}e^c$, which is a one-form valued in antisymmetric matrices, just like ω. We raise and lower local Lorentz indices with the Lorentz metric η, so $\frac{1}{2}\epsilon^{abc}\epsilon_{bcd} = -\delta_d^a$, and $e^c = -\frac{1}{2}\epsilon^{abc}\,{}^*e_{bc}$.

We can combine ω and ${}^*e$ and set $A_L = \omega - {}^*e/\ell$, $A_R = \omega + {}^*e/\ell$. A small computation gives

$$I_L - I_R = -\frac{1}{\pi\ell}\int \mathrm{tr}\,{}^*e(d\omega + \omega\wedge\omega) - \frac{1}{3\pi\ell^3}\int \mathrm{tr}\,({}^*e\wedge{}^*e\wedge{}^*e). \tag{2.17}$$

In terms of the matrix-valued curvature two-form $R^{ab} = (d\omega + \omega\wedge\omega)^{ab} = \frac{1}{2}\sum_{ij} dx^i \wedge dx_j R_{ij}^{ab}$, where R_{ij}^{ab} is the Riemann tensor, and the metric tensor g, this is equivalent to

$$I_L - I_R = \frac{1}{\pi\ell}\int d^3x\sqrt{g}\left(R + \frac{2}{\ell^2}\right). \tag{2.18}$$

Remembering the factor of $(k_L+k_R)/2$ in (2.16), we see that this agrees with the Einstein-Hilbert action (1.1) precisely if

$$k_L+k_R=\frac{\ell}{8G}. \tag{2.19}$$

The central charge of the boundary conformal field theory was originally computed by Brown and Henneaux [21] for the case that the gravitational Chern-Simons coupling $k'=k_L-k_R$ vanishes. In this case, we set $k=k_L=k_R=\ell/16G$. The formula for the central charge is $c=3\ell/2G$, and this leads to $c=24k$. For the case $k'=0$, the boundary CFT is left-right symmetric, with $c_L=c_R$, so in fact $c_L=c_R=24k$.

In general, the boundary CFT has left- and right-moving Virasoro algebras that can be interpreted (for a suitable orientation of the boundary) as boundary excitations associated with A_L and A_R respectively. So the central charges c_L and c_R are functions only of k_L and k_R, respectively. Hence the generalization of the result obtained in the last paragraph is

$$(c_L,c_R)=(24k_L,24k_R). \tag{2.20}$$

2.3. Holomorphic Factorization

In conformal field theory in two dimensions, the ground state energy is $-c/24$. More generally, if there are separate left and right central charges c_L and c_R, the ground state energies for left- and right-movers are $(-c_L/24,-c_R/24)$. Modular invariance says that the difference between the left- and right-moving ground state energies must be an integer. In the above calculation, $(c_L-c_R)/24=k_L-k_R$. According to (2.20), this is an integer provided that the gravitational Chern-Simons coupling $k'=k_L-k_R$ is integral.

Holomorphic factorization requires that the left- and right-moving ground state energies should be separately integral, so that there is modular invariance separately for left-moving and right-moving modes of the CFT. Thus, for holomorphic factorization, c_L and c_R must both be integer multiples of 24. This is the only constraint, since holomorphic CFT's with $c=24$ do exist (and have been classified [23] modulo a conjecture mentioned in section 1.4).

According to (2.20), the condition for c_L and c_R to be multiples of 24 is precisely that k_L and k_R must be integers. As in our discussion of eqn. (2.7), this is the right condition if the gauge group is precisely $SO(2,1)\times SO(2,1)$ rather than a covering group.

It is possible to give an intuitive explanation of why this is the right gauge group if the boundary CFT is supposed to be holomorphically factorized. The Virasoro algebra is, of course, infinite-dimensional, but it has a finite-dimensional subalgebra, generated by $L_{\pm 1}$ and L_0, that is a symmetry of the vacuum. It is customary to refer to the corresponding symmetry group of the vacuum as $SL(2,\mathbb{R})$, but in fact, in a holomorphic CFT, in which all energies are integers, the group that acts faithfully is really $SO(2,1)$. So a holomorphically factorized CFT has symmetry group $SO(2,1)\times SO(2,1)$, and it is natural that this is the right gauge group in a gauge theory description of (aspects of) the dual gravitational theory.

Now let us consider some other possible gauge groups. One possibility is to take a double cover of each factor of $SO(2,1)\times SO(2,1)$, taking the gauge group to be $SL(2,\mathbb{R})\times SL(2,\mathbb{R})$. The appropriate restriction on the gauge theory couplings was determined in (2.8) (where we should set $n=2$) and is that k_L and k_R take values in $\frac{1}{4}\mathbb{Z}$. Hence the central charges c_L and c_R are multiples of 6. In particular, $SL(2,\mathbb{R})\times SL(2,\mathbb{R})$ gauge theory would allow us to consider values of the couplings that contradict modular invariance of the boundary CFT.

There is perhaps a more intuitive argument suggesting that $SL(2,\mathbb{R})\times SL(2,\mathbb{R})$ is not the right group to consider. If the gauge group is $SL(2,\mathbb{R})\times SL(2,\mathbb{R})$, then upon taking the two-dimensional representation of one of the $SL(2,\mathbb{R})$'s, we get a two-dimensional real vector bundle over W which generalizes what in classical geometry is the spin bundle. Thus, this would be a theory in which, in the classical limit, W is a spin manifold, endowed with a distinguished spin structure (or even two of them). That is appropriate in a theory with fermions, but not, presumably, in a theory of pure gravity.

We similarly lose modular invariance and have difficult to interpret geometric structures if we consider other non-diagonal covers of $SO(2,1)\times SO(2,1)$. So let us discuss the diagonal covers of $SO(2,1)\times SO(2,1)$ that were considered at the end of section 2.1. We know that the universal diagonal cover is not right, since then ℓ/G could vary continuously. This leaves the possibility of an n-fold diagonal cover for some n. The best-motivated example is perhaps the two-fold cover $SO(2,2)$, which is the symmetry of Anti de Sitter spacetime (as opposed to a cover of that spacetime). In this case, according to (2.14), k_L and k_R can take values in $\mathbb{Z}/4$, as long as $k'=k_L-k_R$ is integral. For the boundary CFT, this means that c_L and c_R can be multiples of 6 (with their difference a multiple of 24). For example, let us consider a hypothetical CFT of $(c_L,c_R)=(6,6)$. The ground state energies are $(-1/4,-1/4)$. As these values are not integers, the symmetry group of the ground state is not $SO(2,1)\times SO(2,1)$, but a four-fold diagonal cover, which is a double cover of the gauge group $SO(2,2)$ that was assumed. Such a CFT cannot be holomorphically factorized, since the left- and right-moving ground state energies are not integers; it cannot even be holomorphically factorized up to a phase.[10] The structure is considerably more complicated than in the holomorphically factorized case. Similar remarks apply to other diagonal covers.

Pragmatically, the most important argument against trying to describe three-dimensional gravity via a cover of $SO(2,1) \times SO(2,1)$ may be simply the fact that no good candidates are known. For example, no especially interesting bosonic CFT (as opposed to a superconformal field theory) seems to be known at $c = 6, 12$, or 18, which are values that we would expect if we use the gauge group $SO(2,2)$. By contrast, at $c = 24$, which is natural for $SO(2,1) \times SO(2,1)$, the Frenkel-Lepowsky-Meurman monster theory is a distinguished candidate, as we mentioned in section 1.4 and will explain in more detail in section 3.

The simplest possible hypothesis is that the right gauge group to consider in studying three-dimensional pure gravity is $SO(2,1) \times SO(2,1)$, with integral k_L and k_R and holomorphic factorization of the boundary CFT. It would be highly unnatural to overlook the fact that $SO(2,1) \times SO(2,1)$ gauge theory leads to precisely the values of the central charge at which the drastic simplification of the boundary CFT known as holomorphic factorization is conceivable. Moreover, the fact that the classical action (2.15) of the gauge theory is a sum of decoupled actions for A_L and A_R – related respectively to left- and right-moving modes of the boundary CFT – is a hint of holomorphic factorization of the boundary theory.

At any rate, regardless of whether they give the whole story, it does seem well-motivated to look for holomorphically factorized CFT's with central charges multiples of 24 that are dual to three-dimensional pure gravity at special values of the cosmological constant. That will be our main focus in the rest of this paper.

---

[10] The left-moving partition function would have to be $\Phi/\Delta^{1/4}$, where $\Delta = \eta(q)^{24}$ is the discriminant, η being the Dedekind eta function, and Φ is a modular form of weight 3. The power of Δ was determined to get the right ground state energy; modular invariance implies that the modular weight of Φ must equal that of $\Delta^{1/4}$. As there is no modular form of weight 3, such a theory does not exist. Even at $(c_L, c_R) = (12, 12)$, it is not possible to have holomorphic factorization up to a phase. To get modular invariance and the right ground state energy, the left-moving partition function would have to be $E_6/\Delta^{1/2}$, where E_6 is the Eisenstein series of weight 6. However, the coefficients in the q-expansion of this function are not positive.

2.4. Interpretation

A few further words of interpretation seem called for.

We do *not* claim that three-dimensional gravity is equivalent, nonperturbatively, to Chern-Simons gauge theory. Some objections to this idea were described in section 1.1. We know that Chern-Simons gauge theory is useful for perturbation theory, as was explained in that section, and we hope that it is useful for understanding some nonperturbative questions. We used the gauge theory approach to get some hints about the right values of the cosmological constant (or equivalently of the central charge) simply because it was the only tool available. We certainly do not claim to have a solid argument that the values of (c_L, c_R) suggested by $SO(2,1) \times SO(2,1)$ gauge theory are the only relevant ones.

Implicit in the gauge theory approach to quantization of the dimensionless parameter ℓ/G is an assumption that at least some of the non-geometrical states that can be described in gauge theory make sense. Indeed, when understood in classical geometry with the metric assumed to be smooth and nondegenerate, the Einstein-Hilbert action (1.1) is well-defined as a real-valued function. The topological problems that cause it to be multivalued when interpreted in gauge theory as a Chern-Simons function, and lead to quantization of ℓ/G, depend on allowing certain configurations that are natural in gauge theory, but singular in geometry because the vierbein is not invertible.

Furthermore, holomorphic factorization most likely is possible only if the path integral includes a sum over some non-geometrical configurations. In quantum gravity, we at least expect to sum over all topologies of a three-manifold W, perhaps with some fixed asymptotic behavior. The choice of topology should be expected to affect both the left- and right-movers of the boundary CFT. To achieve holomorphic factorization, there must presumably be some sort of separate topological sum for left-movers and right-movers. As this does not occur in classical geometry, it must depend on some sort of non-geometric contributions to the path integral – though these contributions may be exponentially small in many circumstances.

The Gravitational Chern-Simons Action Reconsidered

Our discussion of the quantization of the gravitational Chern-Simons coupling (2.1)

$$\Delta_0 I = \frac{k'}{4\pi} \int_W \operatorname{tr}\left(\omega \wedge d\omega + \frac{2}{3}\omega \wedge \omega \wedge \omega\right) \tag{2.21}$$

has been based entirely on gauge theory. We now want to describe the similar but slightly different answer that would come from classical differential geometry. As always, the differences reflect the fact that the gauge theory analysis allows some non-geometrical configurations.

We first briefly restate the gauge theory analysis. ω is a connection on an $SO(2,1)$ or (in Euclidean signature) $SO(3)$ bundle over a three-manifold W. As usual, to define $\Delta_0 I$ more precisely, we pick an oriented four-manifold M of boundary W with an extension of ω over W. Then we define

$$I_M = \frac{k'}{4\pi}\int_M \mathrm{tr}\, F\wedge F. \tag{2.22}$$

If M is replaced by some other four-manifold M', and $X = M - M'$ is a four-manifold without boundary obtained by gluing together M and M', then

$$I_M - I_{M'} = \frac{k'}{4\pi}\int_X \mathrm{tr}\, F\wedge F = 2\pi k'\int_X p_1(F), \tag{2.23}$$

where $p_1(F) = (1/8\pi^2)\mathrm{tr}\, F\wedge F$ is the first Pontryagin form. In general, $\int_X p_1(F)$ can be any integer, so the condition that the indeterminacy in I_M is an integer multiple of 2π means simply that k' is an integer.

This is the right answer if the right thing to do is to simply think of ω as an $SO(3)$ or $SO(2,1)$ gauge field, ignoring its classical relation to gravity. However, in classical gravity, one can get a better answer. In classical gravity, ω is a connection on the tangent bundle TW of W. Now replace TW by $TW\oplus\epsilon$, where ϵ is a trivial real line bundle. Then ω can be regarded as a connection on $TW\oplus\epsilon$ in an obvious way, and $TW\oplus\epsilon$ extends over M as the tangent bundle of M. With this choice, (2.22) becomes

$$I_M = \frac{k'}{4\pi}\int_M \mathrm{tr}\, R\wedge R, \tag{2.24}$$

where R is the curvature form of M, and (2.23) becomes

$$I_M - I_{M'} = 2\pi k'\int_X p_1(R). \tag{2.25}$$

The effect of this is that instead of the first Pontryagin number of a general bundle over X, as in (2.23), we have here the first Pontryagin number $p_1(TX)$ of the tangent bundle of X. This number is divisible by 3, because of the signature theorem, which says that for a four-manifold X, $p_1(TX)/3$ is an integer, the signature of X. Hence, in the gravitational interpretation, the condition on k' is

$$k' \in \frac{1}{3}\mathbb{Z}. \tag{2.26}$$

There is also a variant of this. If W is a spin manifold and we are willing to define the gravitational Chern-Simons coupling (2.21) in a way that depends on the spin structure of W (this does not seem natural in ordinary gravity, but it may be natural in supergravity, which we come to in section 3.2), the condition on k' can be further relaxed. In this case, we can select M so that the chosen spin structure on W extends over M. If M' is another choice with the same property, then $X = M - M'$ is a spin manifold. But (as follows from the Atiyah-Singer index theorem for the Dirac equation) the signature of a four-dimensional spin manifold is divisible by 16. So in this situation $p_1(TX)$ is a multiple of 48, and the result for k' under these assumptions is

$$k' \in \frac{1}{48}\mathbb{Z}. \tag{2.27}$$

The Physical Hilbert Space

Now we shall discuss the meaning for gravity of the physical Hilbert space of Chern-Simons gauge theory.

In three-dimensional Chern-Simons gauge theory, one can fix a Riemann surface C and construct a Hilbert space $\mathcal{H}_C$ of physical states obtained by quantizing the given theory on C. This Hilbert space depends on the Chern-Simons couplings, so when we want to be more precise, we will call it $\mathcal{H}_C(k_L, k_R)$. In [6], it was proposed that the physical Hilbert space of three-dimensional gravity on a Riemann surface C should be obtained in essentially this way, using $SO(2,1) \times SO(2,1)$ gauge theory (or something similar, depending on whether the cosmological constant is positive, negative, or zero). Some serious objections to the claim that pure gravity and Chern-Simons gauge theory are equivalent in three dimensions were noted in section 1.1. Yet remarkable progress has made made [8,11] in understanding the quantization of $SO(2,1)$ gauge theory, and even more remarkably, in relating this quantization to Liouville theory. It therefore seems likely that the Hilbert space obtained by quantizing Chern-Simons gauge theory of $SO(2,1) \times SO(2,1)$ means something for three-dimensional gravity even if the proposal in [6] was premature. The rest of this subsection will be devoted to an attempt (not used in the rest of the paper) to reconcile the different points of view. See [39] for some useful background.

We may start by asking what we mean by the physical Hilbert space $\mathcal{H}_C$ obtained in quantum gravity by quantizing on a closed manifold C. What type of question is this space supposed to answer? Quantization on, for example, an asymptotically flat spacetime leads to a Hilbert space that can be interpreted in a relatively straightforward way, but the physical meaning of a Hilbert space obtained by quantizing on a compact spatial manifold (if such a Hilbert space can be defined at all) is not clear.

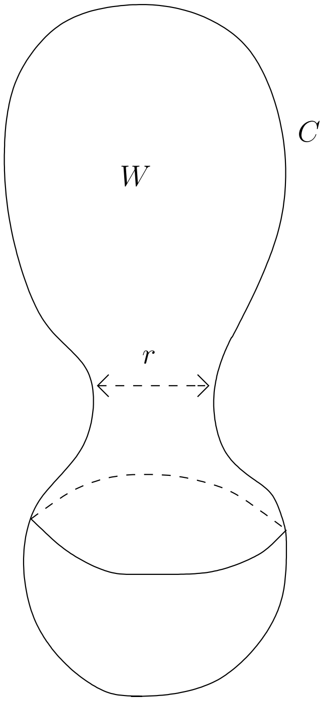

Fig. 1:

The Hartle-Hawking wavefunction Ψ is computed by integrating over three-manifolds W with a given boundary C. The dotted line labeled r denotes a path in W connecting two points in C. It is possible to vary W so that the length of this path goes to zero with no change in the geometry of C. In this limit, W becomes singular even though C is smooth. This gives a "source term" in the Wheeler-de Witt equation, because of which the Hartle-Hawking wavefunction does not obey this equation.

One line of thought that is relatively close to working is to consider the Hartle-Hawking wavefunction [40] and claim that it is a vector in $\mathcal{H}_C$. (The obvious idea that quantum mechanical probabilities would be calculated in terms of inner products of vectors in a Hilbert space $\mathcal{H}_C$ of physical states is afflicted with similar but more serious problems.) The Hartle-Hawking wavefunction is a functional of metrics on C. For every metric h on C, we define $\Psi(h)$ as the result of performing a path integral over three-manifolds W whose boundary is C and whose metric g coincides with h on the boundary. Formally, one can try to argue that $\Psi(h)$ obeys the Wheeler-de Witt equation and thus is a vector in a Hilbert space $\mathcal{H}_C$ of solutions of this equation. Moreover, one can formally match the Wheeler-de Witt equations of gravity with the conditions for a physical state in Chern-Simons gauge theory. Though many steps in these arguments work nicely, one runs into trouble because a Riemann surface can be immersed, rather than embedded, in a three-manifold, and hence it is possible for W to degenerate without C degenerating (fig. 1). As a result, the Hartle-Hawking wavefunction does not obey the Wheeler-de Witt equation and is not a vector in $\mathcal{H}_C$.

In the case of negative cosmological constant, the boundary CFT gives a sort of cure for the problem with the Hartle-Hawking wavefunction. Instead of thinking of C as an ordinary boundary of W, we think of it as a conformal boundary at infinity. The partition function $\widehat{\Psi}(h)$ of the boundary CFT is defined by performing the path integral over all choices of W with C as conformal boundary. This is well-behaved, because, with C at conformal infinity, it is definitely embedded rather than immersed. Moreover, $\widehat{\Psi}(h)$ is a sort of limiting value of the Hartle-Hawking wavefunction. Indeed, let ϕ be a positive function on C. Then $\widehat{\Psi}(h)$ is essentially[11] the limiting value of $\Psi(e^\phi h)$ as $\phi \to \infty$.

This suggests that we should be able to think of $\widehat{\Psi}(h)$ as a vector in the Hilbert space $\mathcal{H}_C$ associated with three-dimensional gravity and a two-manifold C. This viewpoint can be explained more fully. The phase space of $SO(2,1) \times SO(2,1)$ Chern-Simons theory on C is the space of $SO(2,1) \times SO(2,1)$ flat connections on C. The space of $SO(2,1)$ flat connections on C has several topological components (labeled by the first Chern class, which comes in because $SO(2,1)$ is contractible to $SO(2) \cong U(1)$). One of these components, the only one that can be simply interpreted in terms of classical gravity with negative cosmological constant,[12] is isomorphic to Teichmuller space $\mathcal{T}$. Thus, this component of the classical phase space $\mathcal{M}$ is a product of two copies of $\mathcal{T}$, parametrized by a pair of points $\tau, \tau' \in \mathcal{T}$. One can quantize $\mathcal{M}$ (or at least this component of it) naively by using the standard holomorphic structure of $\mathcal{T}$. If we do this, the wavefunction of a physical state is a "function" of τ and τ' that is holomorphic in τ and antiholomorphic in τ'. (Antiholomorphy in one variable reflects the relative minus sign in the Chern-Simons action (2.15); we assume that k_L and k_R are positive.) Actually, a physical state wavefunction $\Psi(\tau, \overline{\tau}')$ is not quite a function of τ and $\overline{\tau}'$ in the usual sense, but is a form, of weights determined by k_L and k_R. So it takes values in a Hilbert space $\mathcal{H}_C(k_L, k_R)$ that depends on the Chern-Simons couplings. Such a wavefunction $\Psi(\tau, \overline{\tau}')$ is determined by its restriction to the diagonal subspace $\tau = \tau'$. Moreover, if we want to make a relation to gravity, it is natural to require that Ψ should be invariant under the diagonal action of the mapping class group on τ and τ'; this condition is compatible with restricting to $\tau = \tau'$.

---

[11] One needs some renormalization in this limit; the necessary renormalization reflects the conformal anomaly. Because of this anomaly, $\widehat{\Psi}(h)$ is not quite a function only of the conformal structure of C but a function of the metric that transforms with a certain weight under conformal rescalings. As a result, the precise choice of ϕ matters, but only in a rather simple way.

[12] In the approach to quantization developed in [8,11], this is the only component considered.

Similarly, the partition function of a CFT on the Riemann surface C is a not necessarily holomorphic "function" (actually a form of appropriate weights) $\Psi(\tau, \overline{\tau})$. Being real analytic, Ψ can be analytically continued to a function $\Psi(\tau, \overline{\tau}')$ with τ' at least slightly away from τ. It does not seem to be a standard fact[13] that Ψ analytically continues to a holomorphic function on $\mathcal{T} \times \mathcal{T}$ (with invariance only under one diagonal copy of the mapping class group). However, this is true in genus 1, since the partition function can be defined as $\operatorname{Tr} q^{L_0} \overline{q}'^{\overline{L}_0}$, where we can take q and q' to be independent complex variables of modulus less than 1. It seems very plausible that the statement is actually true for all values of the genus, since one can move on Teichmuller space by "cutting" on a circle and inserting $q^{L_0} \overline{q}'^{\overline{L}_0}$. If so, the partition function of the CFT can always be interpreted as a vector[14] in the Chern-Simons Hilbert space $\mathcal{H}_C(k_L, k_R)$.

If we are given a theory of three-dimensional gravity, possibly coupled to other fields, the partition function of the dual CFT is a wavefunction $\Psi(\tau, \overline{\tau}')$ which, according to the conjecture just stated, is a vector in $\mathcal{H}_C(k_L, k_R)$. Any gravitational theory of the same central charges leads to another vector in the same space.

From this point of view, it seems that we should not claim, as was done in [6], that $\mathcal{H}_C(k_L, k_R)$ is a space of physical states that are physically meaningful in pure three-dimensional gravity. Rather, a particular bulk gravitational theory, such as pure gravity, gives rise to a particular dual CFT whose partition function gives a definite vector in $\mathcal{H}_C(k_L, k_R)$. Another gravitational theory, perhaps with matter fields, whose dual CFT has the same values of the central charges, will lead to a dual partition function that is another vector in the same space. Thus, $\mathcal{H}_C(k_L, k_R)$ is in a sense a universal target for gravitational theories – with arbitrary matter fields – of given central charges.

We have formulated this for a particular Riemann surface C, but in either the gravitational theory or the dual CFT, C can vary and there is a nice behavior when C degenerates. So it is more natural to think of this as a structure that is defined for all Riemann surfaces. In conformal theory, this perspective is described in [41].

---

[13] However, G. Segal has obtained results in this direction.

[14] It may be necessary here to extend $\mathcal{H}_C(k_L, k_R)$ to a space of forms on $\mathcal{T} \times \mathcal{T}$ that are invariant under the action of the mapping class group but not necessarily square-integrable.

2.5. Analog For Supergravity

Here we will discuss the extension of some of these ideas to three-dimensional supergravity.

We consider primarily minimal supergravity, corresponding to the case that the boundary CFT has $\mathcal{N} = 1$ supersymmetry for left-movers or right-movers or perhaps both. Thus, for, say, the left-movers, the Virasoro algebra is replace by an $\mathcal{N} = 1$ super-Virasoro algebra. The symmetry algebra generated by $L_{\pm 1}$ and L_0 is extended (in the Neveu-Schwarz sector) to a superalgebra that also includes the fermionic generators $\mathcal{G}_{\pm 1/2}$. This is the Lie superalgebra of the supergroup $OSp(1|2)$, whose bosonic part is $Sp(2,\mathbb{R})$, or equivalently $SL(2,\mathbb{R})$. In particular, since the operators $\mathcal{G}_{\pm 1/2}$ transform in the two-dimensional representation of $SL(2,\mathbb{R})$, the relevant group is definitely $SL(2,\mathbb{R})$ (or possibly a covering of it), not its quotient $SO(2,1)$.

For definiteness, consider a two-dimensional CFT with $(0,1)$ supersymmetry, that is, with $\mathcal{N} = 1$ supersymmetry for right-movers and none for left-movers. Then left-movers have an ordinary Virasoro symmetry and right-movers have an $\mathcal{N} = 1$ super-Virasoro symmetry. Such a theory can be dual to a three-dimensional supergravity theory, which classically can be described by a Chern-Simons gauge theory in which the gauge supergroup is $SO(2,1) \times OSp(1|2)$, or possibly a cover thereof. For brevity, we will here assume that the gauge group is precisely $SO(2,1) \times OSp(1|2)$. The action is the obvious analog of (2.15):

$$\begin{aligned} I =& k_L I_L + k_R I_R \\ =& \frac{k_L}{4\pi}\int \mathrm{tr}\left(A_L \wedge dA_L + \frac{2}{3} A_L \wedge A_L \wedge A_L\right) - \frac{k_R}{4\pi}\int \mathrm{str}\left(A_R \wedge dA_R + \frac{2}{3} A_R \wedge A_R \wedge A_R\right). \end{aligned} \tag{2.28}$$

Here A_L is an $SO(2,1)$ gauge field, A_R is an $OSp(1|2)$ gauge field, and str is the supertrace in the adjoint representation of $OSp(1|2)$.

We want to generalize the analysis of section 2.1 to determine the allowed values of k_L and k_R. There is actually almost nothing to do. A_L is simply an $SO(2,1)$ gauge field, so k_L must be an integer. As for A_R, we can for topological purposes replace the supergroup $OSp(1|2)$ by its bosonic reduction $SL(2,\mathbb{R})$, since the fermionic directions are infinitesimal and carry no topology. So we can borrow the result of (2.8):

$$\begin{aligned} k_L &\in \mathbb{Z} \\ k_R &\in \frac{1}{4}\mathbb{Z}. \end{aligned} \tag{2.29}$$

We still have $(c_L, c_R) = (24k_L, 24k_R)$, since the Brown-Henneaux computation of the central charge depends only on the bosonic part of the action. So c_L must be a multiple of 24, as before, but now it seems that c_R should be a multiple of 6.

This is not the result that one might hope for, because holomorphic factorization in $\mathcal{N} = 1$ superconformal field theories requires that c_R should be a multiple of 12, not 6. So half of the seemingly allowed values of c_R are difficult to interpret in the spirit of this paper. Replacing $SO(2,1) \times OSp(1|2)$ by a covering group would only make things worse, as in the bosonic case.

There are many conceivable ways to interpret this result, including the possibility that our assumptions have been too optimistic. However, one additional possibility seems worthy of mention here. Part of the structure of a superconformal field theory is that there are Ramond-sector vertex operators. They introduce a "twist" in the supercurrent, which has a monodromy of -1 around a point at which a Ramond vertex operator is inserted. Let us assume that the superconformal dual of three-dimensional supergravity should be a theory in which Ramond vertex operators make sense. What is the gravitational dual of an insertion of such a vertex operator?

As in fig. 2, points in the conformal boundary of spacetime at which a Ramond vertex operator is inserted must be connected in the bulk by lines – such as the line labeled L in the figure – around which the fermionic fields of $OSp(1|2)$ (that is, the gravitinos) have a monodromy -1. It is plausible to interpret these lines, which we will call Ramond lines, as world-lines of Ramond-sector black holes. A spacetime history containing a black hole trajectory is of course more complicated than a spacetime with a simple line drawn in it. But for our present purposes, which are purely topological, the difference may not be important. There can also be Neveu-Schwarz sector black holes (and black holes in purely bosonic gravity), but we are about to discuss an effect which seems special to Ramond-sector black holes.

So now we have a new problem. We want to define

$$I_R = \frac{1}{4\pi} \int_W \mathrm{str} \left(A_R \wedge dA_R + \frac{2}{3} A_R \wedge A_R \wedge A_R \right) \tag{2.30}$$

in the presence of a Ramond world-line L on W. In the absence of the Ramond line, we know that I_R in $OSp(1|2)$ gauge theory is defined modulo $4 \cdot 2\pi$, which is why as stated in (2.29), k_R can be a multiple of $1/4$. What happens in the presence of the Ramond line?

Rather than solving a new topological problem, we can take the following shortcut. Let W' be a new three-manifold obtained by taking a double cover of W branched over the

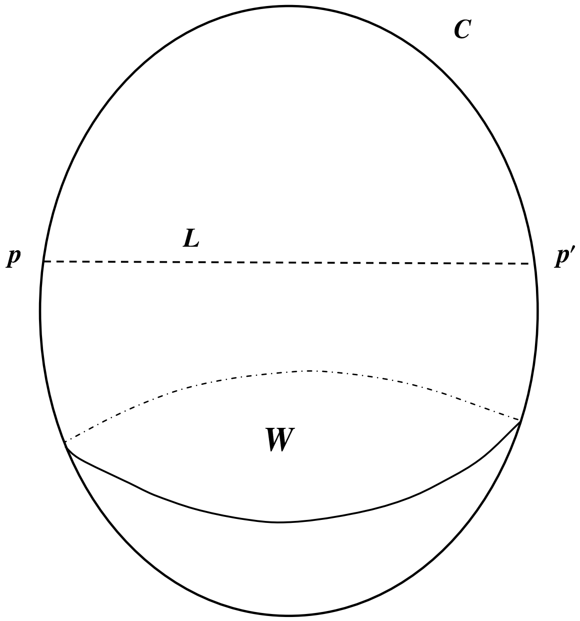

Fig. 2:

C is a Riemann surface with a pair of insertions of Ramond-sector vertex operators at points labeled p and p'. They are connected by a line L that runs in a three-manifold W whose boundary is C. Supergravity on W contributes to conformal field theory on C. The fermion fields of $OSp(1|2)$ receive a minus sign in monodromy around L.

line L. We let $I_R(W)$ be the action (2.30) and $I_R(W')$ be the corresponding action for the gauge field A_R pulled back to W'. When pulled back to W', the singularity of A_R along the Ramond line disappears, so $I_R(W')$ is defined modulo $4 \cdot 2\pi$. There is no better way to define $I_R(W)$ in the presence of a Ramond line than to say that $I_R(W) = I_R(W')/2$. So $I_R(W)$ is defined modulo $2 \cdot 2\pi$.

This means that k_R should be a multiple of 1/2, not 1/4. So in other words, if including Ramond lines is the right thing to do, we get

$$\begin{aligned} k_L &\in \mathbb{Z} \\ k_R &\in \frac{1}{2}\mathbb{Z}, \end{aligned} \tag{2.31}$$

and hence c_L and c_R are multiples of 24 and 12, respectively.

Unfortunately, the above "derivation" is little more than a scenario to try to justify the answer that we hoped for. However, a good pragmatic reason to focus on the case that c_R is a multiple of 12 is that there are interesting candidate superconformal field theories (SCFT's) in that case, as we discuss in section 3. There are no obvious interesting candidates at $c_R = 6, 18$, etc.

In the supersymmetric case it is convenient to express the Chern-Simons coupling k as $k = k^*/2$, where we will focus on the case that k^* is an integer. In terms of k^*, the central charge is $c = 12k^*$.

Some Generalizations

We conclude this section by briefly mentioning some simple generalizations.

First of all, $(1,1)$ supersymmetry in two dimensions, with $\mathcal{N} = 1$ super-Virasoro symmetry for both left-movers and right-movers, is dual to three-dimensional supergravity theories related to $OSp(1|2) \times OSp(1|2)$ Chern-Simons gauge theory. If one wants the left- or right-movers to have more than $\mathcal{N} = 1$ supersymmetry, one simply replaces $OSp(1|2)$ by an appropriate supergroup with more fermionic generators. For example, $OSp(2|2)$ is related to $\mathcal{N} = 2$ supersymmetry, $PSU(2|2)$ is related to what is usually called $\mathcal{N} = 4$ supersymmetry (with the "small" $\mathcal{N} = 4$ superconformal algebra), and $OSp(r|2)$ with $r > 2$ is related to theories with "large" $\mathcal{N} = k$ superconformal algebras. (The most widely studied case of these algebras is $r = 4$; for example, see [42].)

It is also possible to consider other extended chiral algebras, apart from superconformal algebras. For example, one can start in three dimensions with an $SL(3, \mathbb{R})$ Chern-Simons gauge theory, which plausibly may be related to some sort of three-dimensional W_3 gravity theory in much the same (not fully understood) way that $SL(2, \mathbb{R})$ Chern-Simons theory is related to ordinary three-dimensional gravity. A dual CFT would very likely then have a W_3 chiral algebra. An analogous statement plausibly holds for many extended chiral algebras.

3. Partition Functions

In this section, we will determine what we propose to be the exact spectrum of physical states of three-dimensional gravity or supergravity with negative cosmological constant, in a spacetime asymptotic at infinity to Anti de Sitter space. Equivalently, we will determine the genus one partition function of the dual CFT.

In all cases, we work at the values of ℓ/G at which holomorphic factorization is possible. These values were related to gauge theory in section 2. We assume holomorphic factorization, and mainly consider only the holomorphic sector of the theory. The full partition function is the product of the function we determine and a similar antiholomorphic function. These partition functions have been studied before [31,32], with different motivation.

3.1. The Bosonic Case

We begin with the bosonic case. What are the physical states of pure gravity in a spacetime asymptotic at infinity to AdS_3?

Since there are no gravitational waves in the theory, the only state that is obvious at first sight is the vacuum, corresponding in the classical limit to Anti de Sitter space. In a conformal field theory with central charge $c = 24k$, the ground state energy is $L_0 = -c/24 = -k$. The contribution of the ground state $|\Omega\rangle$ to the partition function $Z(q) = \operatorname{Tr} q^{L_0}$ is therefore q^{-k}.

Of course, there is more to the theory than just the ground state. According to Brown and Henneaux [21], a proper treatment of the behavior at infinity leads to the construction of a Virasoro algebra that acts on the physical Hilbert space. The Virasoro generators L_n, $n \geq -1$ annihilate $|\Omega\rangle$, but by acting with $L_{-2}, L_{-3}, \ldots$, we can make new states of the general form $\prod_{n=2}^{\infty} L_{-n}^{s_n}|\Omega\rangle$, with energy $-k+\sum_n ns_n$. (We assume that all but finitely many of the s_n vanish.) If these are the only states to consider, then the partition function would be

$$Z_0(q) = q^{-k}\prod_{n=2}^{\infty}\frac{1}{1-q^n}. \tag{3.1}$$

This cannot be the complete answer, because the function $Z_0(q)$ is not modular-invariant. There must be additional states such that $Z_0(q)$ is completed to a modular-invariant function.

Additional states are expected, because the theory also has BTZ black holes. The main reason for writing the present paper, after all, is to understand the role of the BTZ black holes in the quantum theory. We will assume that black holes account for the difference between the naive partition function $Z_0(q)$ and the exact one $Z(q)$. To use this assumption to determine $Z(q)$, we need to know something about the black holes.

The classical BTZ black hole is characterized by its mass M and angular momentum J. In terms of the Virasoro generators,

$$\begin{aligned} M =& \frac{1}{\ell}(L_0 + \overline{L}_0) \\ J =& (L_0 - \overline{L}_0), \end{aligned} \tag{3.2}$$

so $L_0 = (\ell M + J)/2$, $\overline{L}_0 = (\ell M - J)/2$. The classical BTZ black hole obeys $M\ell \geq |J|$, or $L_0, \overline{L}_0 \geq 0$. The BTZ black hole is usually studied in the absence of the gravitational Chern-Simons coupling, that is for $k_L = k_R = k$. Its entropy is $S = \pi(\ell/2G)^{1/2}\left(\sqrt{M\ell - J} + \sqrt{M\ell + J}\right)$. (This entropy was first expressed in terms of two-dimensional conformal field theory in [13].) With $\ell/G = 16k$ as in (2.19), this is equivalent to $S = 4\pi\sqrt{k}\left(\sqrt{L_0} + \sqrt{\overline{L}_0}\right)$. For the holomorphic sector, the entropy is therefore

$$S_L = 4\pi\sqrt{k_L L_0}, \tag{3.3}$$

and similarly for the antiholomorphic sector.

There is no classical BTZ black hole with $L_0 < 0$, and the entropy of such a black hole is zero if $L_0 = 0$. We will take this as a suggestion that quantum states corresponding to black holes exist only if $L_0 > 0$, that is $L_0 \geq 1$. This means that the exact partition function $Z(q)$ should differ from the function $Z_0(q)$ in (3.1) by terms of order q:

$$Z(q) = q^{-k}\prod_{n=2}^{\infty}\frac{1}{1-q^n} + \mathcal{O}(q). \tag{3.4}$$

Admittedly, we are here trying to squeeze more information from the classical result than is justified. But it turns out that a modular-invariant partition function of this form exists and is unique. This result (which is due to Höhn [31]) follows from the fact that the moduli space $\mathcal{M}_1$ of Riemann surfaces of genus 1 is itself a Riemann surface of genus 0, in fact parametrized by the j-function. If E_4 and E_6 are the usual Eisenstein series of weights 4 and 6, then $j = 1728E_4^3/(E_4^3 - E_6^2)$. Its expansion in powers of q is

$$j(q) = q^{-1} + 744 + 196884q + 21493760q^2 + 864299970q^3 + 20245856256q^4 + \dots. \tag{3.5}$$

Actually, it is more convenient to use the function

$$J(q) = j(q) - 744 = q^{-1} + 196884q + 21493760q^2 + \dots, \tag{3.6}$$

which likewise parametrizes the moduli space.

The J-function has a pole at $q = 0$ and no other poles. The statement that J parametrizes the moduli space means precisely that any modular-invariant function can be written as a function of J. The partition function $Z(q)$ has a pole at $q = 0$, that is at $J = \infty$. This pole is of order k, and the partition function has no other poles. Any holomorphic function of J that has no singularity except at $J = \infty$ is a polynomial in J.

In the present case, as the pole in $Z(q)$ at $q=0$ is of order k, Z must be a polynomial in J of degree k. Thus

$$Z(q)=\sum_{r=0}^{k} f_r J^r, \tag{3.7}$$

with some coefficients f_r. These $k+1$ coefficients can be adjusted in a unique fashion to ensure that $Z(q)$ takes the form (3.4), or in other words to ensure that the terms in $Z(q)$ of order q^{-n}, $n=0,\dots,k$, coincide with the naive function $Z_0(q)$.

When we do this, we get a function that we will call $Z_k(q)$, $k=1,2,3,\dots$. This function is our candidate for the generating function that counts the quantum states of three-dimensional gravity in a spacetime asymptotic to AdS_3. For example, for $k=1$ we have simply $Z_1(q)=J(q)$, and the next few examples are

$$\begin{aligned}
Z_2(q) =& J(q)^2-393767\\
=& q^{-2}+1+42987520q+40491909396q^2+\dots\\
Z_3(q) =& J(q)^3-590651J(q)-64481279\\
=& q^{-3}+q^{-1}+1+2593096794q+12756091394048q^2+\dots\\
Z_4(q) =& J(q)^4-787535J(q)^2-8597555039J(q)-644481279\\
=& q^{-4}+q^{-2}+q^{-1}+2+81026609428q+1604671292452452276q^2+\dots.
\end{aligned} \tag{3.8}$$

Following [31], we refer to a holomorphic CFT with $c=24k$ and partition function $Z_k(q)$ as an extremal CFT. According to our proposals, the dual of three-dimensional gravity should be an extremal CFT.

As was already noted in the introduction, Frenkel, Lepowsky, and Meurman constructed [24,25] an extremal CFT with $k=1$, that is, a holomorphic CFT with $c=24$ and partition function $J(q)=Z_1(q)$. They also conjectured its uniqueness. If that conjecture as well as the ideas in the present paper are correct, then the FLM theory must be the dual to quantum gravity for $k=1$. Unfortunately, as also noted in the introduction, for $k>1$, extremal CFT's are not known, though their possible existence has been discussed in the literature [31-33] for reasons not related to three-dimensional gravity. Our reasoning in this paper suggests that such theories should exist and be unique for each k.

The main point of the FLM construction was that their theory has as a group of symmetries the Fischer-Griess monster group $\mathbb{M}$, the largest of the sporadic finite groups. Arguably, the FLM theory is the most natural known structure with $\mathbb{M}$ symmetry. The coefficients in the q-expansion of the J-function are integers for number-theoretic reasons, but the FLM construction gave a new perspective on why they are positive; this is a property of the partition function of any CFT. It also gave a new perspective on why these coefficients are so large; this follows from $\mathbb{M}$ symmetry, since $\mathbb{M}$ does not have small representations.

Indeed, the original clue to the FLM construction was the observation by J. McKay that the first non-trivial coefficient 196884 of the function $J(q)$ is nearly equal to the smallest dimension 196883 of a non-trivial representation of $\mathbb{M}$. (This observation was later greatly generalized [43,44].) The FLM interpretation is that 196884 is the number of operators of dimension 2 in their theory. One of these operators is the stress tensor, while the other 196883 are primary fields transforming in the smallest non-trivial representation of $\mathbb{M}$.

In our interpretation, the 196883 primaries are operators that (when combined with suitable anti-holomorphic factors) create black holes. It is illuminating to compare the number 196883 to the Bekenstein-Hawking formula. An exact quantum degeneracy of 196883 corresponds to an entropy of $\ln 196883 \cong 12.19$. By contrast, the Bekenstein-Hawking entropy at $k = 1$ and $L_0 = 1$ is $4\pi \cong 12.57$. We should not expect perfect agreement, because the Bekenstein-Hawking formula is derived in a semiclassical approximation which is valid for large k.

Agreement improves rapidly if one increases k. For example, at $k = 4$, and again taking $L_0 = 1$, the exact quantum degeneracy of primary states is 81026609426, according to eqn. (3.8). (Two of the states at this level are descendants.) This corresponds to an entropy $\ln 81026609426 \cong 25.12$, compared to the Bekenstein-Hawking entropy $8\pi \cong 25.13$. Shortly we will compute the entropy in the large k limit.

Our interpretation is that a primary state $|\Lambda\rangle$ represents a black hole, while a descendant $\prod_{n=1}^{\infty} L_{-n}^{s_n}|\Lambda\rangle$ describes a black hole embellished by boundary excitations. These boundary excitations are the closest we can come in $2+1$ dimensions to the gravitational waves that a black hole can interact with in a larger number of dimensions. If this interpretation is correct, then for an exact count of black hole states, we should count primaries only. However, as the above examples illustrate, in practice this issue has only a very slight effect on the black hole degeneracies. The boundary excitations contribute to the entropy an amount that is independent of k and thus negligible in the regime where we compare to the Bekenstein-Hawking entropy, and also, numerically, negligible even for small k. The separation between the black hole and the boundary excitations is best-motivated for large k.

Alternative Formula

Now we will present an alternative formula for the partition functions $Z_k(q)$. This formula avoids the large coefficients involved in writing the Z_k as a polynomial in J, and will make some properties of the Z_k more manifest.

Let $q = \exp(2\pi i\tau)$ with τ in the upper half plane. If p is a prime number, then the Hecke operators acting on functions $F(\tau)$ are defined essentially by

$$T'_pF(\tau) = F(p\tau) + \sum_{b=0}^{p-1} F((\tau+b)/p). \tag{3.9}$$

(What we call T'_p is p times the Hecke operator T_p as usually defined. See [45] for an introduction to Hecke operators and [29,30] for their use in the present subject.) More generally, for any positive integer t, we define

$$T'_tF(\tau) = \sum_{d|t}\sum_{b=0}^{d-1} F((t\tau+bd)/d^2). \tag{3.10}$$

For $t = 0$, we define $T'_0F(\tau) = 1$. If $F(\tau)$ is modular-invariant, then so is $T'_tF(\tau)$. The definition of Hecke operators generalizes naturally to modular forms, but we will not need this.

An immediate consequence of the definition is that, for any $F(\tau)$ that is invariant under $\tau \to \tau + 1$, and so has a Laurent expansion in powers of $q = \exp(2\pi i\tau)$, the coefficients in the q-expansion of $T'_nF(\tau)$ are linear combinations with positive integer coefficients of the q-expansion coefficients of $F(\tau)$. The FLM construction shows that the q-expansion coefficients of the J-function are non-negative integers and the coefficients of positive powers of q are dimensions of non-trivial (reducible) monster representations. Hence the same is true of T'_nJ.

An important special case of how the Hecke operators act on q-expansion coefficients is that if $F(\tau) = q^{-1} + \mathcal{O}(q)$, then

$$T'_nF(\tau) = q^{-n} + \mathcal{O}(q). \tag{3.11}$$

Now we can give an alternative description of the partition functions $Z_k(\tau)$. We recall that these functions are uniquely determined by being modular-invariant and agreeing up to order q with the function $Z_0 = q^{-k}\prod_{n=2}^{\infty}(1-q^n)^{-1}$. To find a function with these properties, we simply expand

$$Z_0 = \sum_{r=-k}^{\infty} a_rq^r, \tag{3.12}$$

and then we let

$$Z_k(\tau) = \sum_{r=0}^{k} a_{-r} T'_r J(\tau). \tag{3.13}$$

For example,

$$Z_2(\tau) = (T'_2 + T'_0)J(\tau) = J(2\tau) + J(\tau/2) + J((\tau+1)/2) + 1. \tag{3.14}$$

This representation makes it clear that, just like the $T'_r J$, the functions Z_k share some properties with the J-function: the q-expansion coefficients are non-negative, and the coefficients of positive powers of q are dimensions of non-trivial monster representations.

This makes it tempting to speculate that the CFT's dual to three-dimensional gravity have $\mathbb{M}$ symmetry for all k. If so, the $\mathbb{M}$ symmetry is invisible in classical General Relativity and acts on the microstates of black holes. (However, the analogous conjecture for supergravity, which would involve the Conway group, appears to be untrue, as we will see in section 3.3.)

As an illustration of the usefulness of the expression for the partition function in terms of Hecke operators, we will use it to compare with the Bekenstein-Hawking entropy. We consider the semiclassical limit $k, L_0 \to \infty$, with $r = L_0/k$ positive and fixed. We take $r = p/q$ to be a rational number and assume that k is divisible by q, so that L_0 is an integer n. If we write

$$J(q) = \sum_{m=-1}^{\infty} c_m q^m, \tag{3.15}$$

then a formula of Petersson and Rademacher gives the asymptotic behavior

$$\ln c_m \sim 4\pi\sqrt{m} - \frac{3}{4}\ln m - \frac{1}{2}\ln 2 + \dots. \tag{3.16}$$

Let

$$Z_k(\tau) = \sum_{n=-k}^{\infty} b_{k,n} q^n. \tag{3.17}$$

We want to determine the behavior of $b_{k,n}$ for large k and n with $r = n/k$ fixed. To evaluate the partition function using the formula (3.13), let us first look at the contribution from $r = k$, that is $T'_k J(\tau)$. In evaluating $T'_k J$ from the definition (3.10), the dominant term (for large k and n) is the term with $d = k$. This contribution to $b_{k,n}$ is $b^0_{k,n} \sim k c_{kn}$, and hence, using the Petersson-Rademacher formula,

$$\ln b^0_{k,n} \sim 4\pi\sqrt{kn} + \frac{1}{4}\ln k - \frac{3}{4}\ln n - \frac{1}{2}\ln 2 + \dots. \tag{3.18}$$

The first term is the Bekenstein-Hawking entropy (3.3). The additional terms in (3.18), as well as the remaining contributions in (3.13) with $r < k$ that we have omitted in deriving (3.18), do not modify the Bekenstein-Hawking formula in the limit of large k, fixed n/k, but give interesting subleading corrections that will be studied elsewhere [46].

Another method to get similar results (expressing black hole degeneracies in terms of coefficients of the singular part of the partition function) is the Farey tail expansion [34]. See also [47].

The FLM Construction

Consider a holomorphic CFT with $c = 24$. If the number of primary fields of dimension 1 is s, then the expansion of the partition function near $q = 0$ begins $Z(q) = q^{-1} + s + \mathcal{O}(q)$, and modular invariance implies that the genus 1 partition function is precisely $Z(q) = J(q) + s = q^{-1} + s + 196884q + \ldots$. Of the 196884 fields of dimension 2, one is a descendant of the identity and s are descendants of dimension 1 primaries. Hence there are $196883 - s$ primary fields of dimension 2, too few to furnish a non-trivial representation of the monster group unless $s = 0$.

For this reason, Frenkel, Lepowsky, and Meurman [24] aimed to construct a holomorphic CFT of $c = 24$ with no primary fields of dimension 1, hoping that it would have monster symmetry. Their construction was made as follows. The Leech lattice is an even, unimodular lattice of rank 24 with no vector of length squared less than 4. One can construct a holomorphic theory of $c = 24$ by compactifying 24 chiral bosons X_i, $i = 1, \ldots, 24$ using any even unimodular lattice. If one uses the Leech lattice, then because it contains no vector of length squared less then 4, a primary field of the form $\exp(ip \cdot X)$ has dimension at least 2, as desired. However, this lattice theory has 24 primary fields ∂X_i of dimension 1. Aiming to eliminate those fields, FLM considered an orbifold[15] by the $\mathbb{Z}_2$ symmetry $X_i \to -X_i$ which eliminates the dimension 1 primaries. As it turns out, this particular orbifold preserves modular invariance, does not add dimension 1 primaries in twisted sectors, and gives the hoped-for theory with monster symmetry.

FLM conjectured that the model they constructed is the unique holomorphic CFT with partition function J. If this conjecture is correct, it implies that many other constructions give the same theory. There are [49] many orbifolds of the Leech lattice theory that give holomorphic CFT's with no primary of dimension 1. According to the FLM uniqueness conjecture, all of these theories are isomorphic to their monster theory. Moreover, the Leech lattice theory itself can be obtained as an orbifold theory starting from another even unimodular lattice of rank 24, so other lattices can be used as starting points as well.

---

[15] Their work preceded the general study of orbifolds in string theory [48], though some related stringy constructions, such as the Ramond and Neveu-Schwarz sectors of string theory, were already known.

Aiming to imitate the FLM construction for $k = 2$, one might start with an even unimodular rank 48 lattice with no vector of length squared less than 6. Three such lattices are known; two are described in [50] and a third has been constructed more recently [51]. (There is no reason to believe that these are the only three rank 48 lattices with this property; there may be a vast number of them.) In the theory of 48 free chiral bosons X_i compactified using such a lattice, a primary field $\exp(ip \cdot X)$ has dimension at least 3, but there are dimension 1 primaries ∂X_i and dimension 2 primaries $\partial X_i \partial X_j - \frac{1}{48}\delta_{ij}\partial X \cdot \partial X$. A simple $\mathbb{Z}_2$ orbifold eliminates the dimension 1 primaries, as in the FLM case, but not the dimension 2 primaries. One may attempt to find a more complicated orbifolding construction to remove the unwanted primaries. Though all three lattices have interesting discrete symmetry groups, it appears that there is no anomaly-free subgroup that removes all dimension 2 primaries.[16] Many other orbifolds can be considered, such as the symmetric product of k copies of the $k = 1$ monster theory, but it appears difficult to remove all primaries of low dimension.

Optimistically speaking, this situation might be compared to current algebra of a simply-laced compact Lie group G. At level 1, one has the Frenkel-Kac-Segal construction of current algebra of G via free bosons. At higher integer level, the theory still exists, but generically has no equally straightforward realization in terms of free fields. Perhaps the situation is somewhat similar for extremal CFT's.

Further Remarks

We have emphasized here the partition function, because it is what we can determine for general k. However, if one can actually describe the relevant CFT – as conjecturally we can at $k = 1$ via the FLM construction – this gives much more than a partition function. In this case, by computing matrix elements of primary fields, we get a detailed description of the black hole quantum mechanics.

Above 2+1 dimensions, a black hole can form out of radiation and ordinary matter. In pure gravity in 2+1 dimensions, the only thing that a black hole can form from is, roughly speaking, smaller black holes. To be more precise, let Φ_i, $i = 1, \ldots, w$ be primary fields of dimension not much greater than k that individually could, in acting on the vacuum, create black holes of fairly small mass. A product of such fields acting on the vacuum at prescribed points

---

[16] I am grateful for assistance from G. Nebe in investigating this question.

$$\prod_{i=1}^{w} \Phi_i(z_i)|\Psi\rangle \tag{3.19}$$

may create a black hole of large mass, that is, a primary state of large energy or a descendant of such a state. Evaluating such matrix elements is the closest analog we can find, in the present model, to describing the formation of a large mass black hole from matter. Unfortunately, at the moment, we can perform such computations only for $k = 1$, since for other values of k we do not know the CFT. Ideally, one would like to describe the CFT for all k and investigate the semiclassical limit of large k.

If our hypotheses are correct, the following may be the most significant difference between three-dimensional pure gravity and a more realistic theory of black holes in $3 + 1$ dimensions. In the present model, as the holomorphic fields are all conserved currents, and the energy levels are integers, the dynamics is integrable and periodic on a short time scale. This is certainly not expected for black holes in general. An embedding of three-dimensional gravity in a larger system, such as a string theory, would be expected to give a non-integrable deformation of the model.

A Conundrum

We have here considered the holomorphic sector of a CFT, but the CFT dual of three-dimensional gravity has both holomorphic and antiholomorphic degrees of freedom. Let us therefore discuss a puzzle (stressed by J. Maldacena) that arises when one combines the holomorphic and antiholomorphic degrees of freedom. We let $|\Omega\rangle$, $|\widetilde{\Omega}\rangle$ be the ground states in the holomorphic and antiholomorphic sectors, and let $|\Phi\rangle$ and $|\widetilde{\Phi}\rangle$ denote primary states other than the ground state. The state $|\Omega\rangle \otimes |\widetilde{\Omega}\rangle$ and its descendants correspond, according to our picture, to Anti de Sitter space and its boundary excitations. A state $|\Phi\rangle \otimes |\widetilde{\Phi}\rangle$, or a descendant thereof, corresponds to a BTZ black hole, perhaps with boundary excitations. But what do we make of states $|\Omega\rangle \otimes |\widetilde{\Phi}\rangle$ or $|\Phi\rangle \otimes |\widetilde{\Omega}\rangle$, and their descendants? Such states are trying to be Anti de Sitter space for holomorphic variables and black holes for antiholomorphic variables, or vice-versa.

In classical three-dimensional gravity, there is no satisfactory solution that has this interpretation. We can, however, see what is involved in trying to make one. First of all, three-dimensional Anti de Sitter space AdS$_3$ is simply the universal cover of the $SL(2, \mathbb{R})$ group manifold, with the symmetry $SL(2, \mathbb{R}) \times SL(2, \mathbb{R})$ (or rather a cover thereof) coming from the left and right action of $SL(2, \mathbb{R})$ on itself. The conformal boundary of the universal cover of AdS$_3$ is a cylinder $\mathbb{R} \times S^1$. We can parametrize it by $-\infty < \tau < \infty$, $0 \leq \sigma \leq 2\pi$, with conformal structure described by the metric $ds^2 = d\tau^2 - d\sigma^2$. The BTZ black hole is the quotient of (a cover of) $SL(2, \mathbb{R})$ by a subgroup $\mathbb{Z} \subset SL(2, \mathbb{R}) \times SL(2, \mathbb{R})$ that is not simply a subgroup of one factor or the other. This quotient has conformal boundary that is again a cylinder, conformally equivalent to the boundary of Anti de Sitter space itself. That is why the BTZ black hole can be regarded as an excitation of Anti de Sitter space.

To describe a state $|\Omega\rangle \otimes |\Phi\rangle$ (or its parity conjugate) at the classical level, we want a solution of Einstein's equations that is invariant under precisely one of the two factors of the $SL(2, \mathbb{R}) \times SL(2, \mathbb{R})$ symmetry. This will reflect the fact that $|\Omega\rangle$ is $SL(2, \mathbb{R})$-invariant and $|\Phi\rangle$ is not. A space with just one of the $SL(2, \mathbb{R})$ symmetries is AdS$_3/\mathbb{Z}$, where $\mathbb{Z}$ is a subgroup of one $SL(2, \mathbb{R})$ factor. The quotient AdS$_3/\mathbb{Z}$ is a perfectly good solution of Einstein's equations in bulk, but its asymptotic behavior at infinity does not quite agree with that of AdS$_3$. The boundary at infinity is a cylinder, but the compact direction in the cylinder is lightlike rather than spacelike. For our approach to three-dimensional gravity in the present paper to be correct, something like this quotient AdS$_3/\mathbb{Z}$ has to make sense at the quantum level, perhaps because of a small quantum correction that makes the compact direction in the cylinder effectively spacelike. Note that the metric $ds_\epsilon^2 = d\tau^2 - \epsilon d\sigma^2$ induces on the cylinder a conformal structure that is independent of ϵ up to isomorphism as long as $\epsilon > 0$.

What we have described is an analog for black holes of a statement made in section 2.4: to ensure holomorphic factorization, the sum over topologies probably must be extended to include configurations that are difficult to interpret classically. In the present case, the analog of the sum over topologies is the sum over states with or without the presence of a black hole.

3.2. The Supersymmetric Case

Now we consider the analog for supergravity. The analysis is a little more complicated and in some ways the results are less satisfactory.

A rather similar problem has been treated by Höhn [31]. He considered not a superconformal field theory, but a more general holomorphic theory with bosonic operators of integral dimension and fermionic operators of half-integral dimension. In that case, the partition function can have a pole at the Ramond cusp, and is given by a Laurent series in $j_\theta = K - 24$ rather than a polynomial.

We continue to assume holomorphic factorization, and we assume that the holomorphic part of the boundary CFT is an $\mathcal{N} = 1$ superconformal field theory (SCFT). This means (in whatever not well understood sense gravity is related to gauge theory) that the gauge group of the bulk theory has a factor $OSp(1|2)$. From a classical point of view, the $OSp(1|2)$ bundle over a three-manifold W endows W with a spin structure. In the AdS/CFT correspondence, W has for conformal boundary a Riemann surface C, and the spin structure on W determines one on C. One is instructed in the AdS/CFT correspondence to specify C, including its spin structure, and sum over all choices of W. (Depending on the theory, the antiholomorphic degrees of freedom may themselves be supersymmetric and endowed with a choice of spin structure.) We will assume that it is physically appropriate to specify the spin structure on C rather than summing over it (just as one specifies the complex structure of C), though at the end of section 3.3, we discuss what happens if one sums over spin structures.

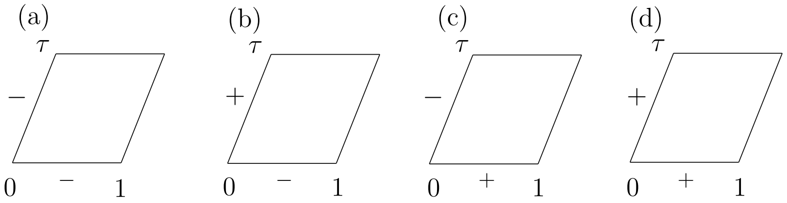

Fig. 3:

We represent a genus 1 Riemann surface C as the quotient of the complex plane by the lattice generated by complex numbers 1 and τ, where τ lies in the upper half plane $\mathcal{H}$. There are four possible spin structures, classified by whether the fermions are periodic or antiperiodic around the "horizontal" and "vertical" cycles. This is indicated by labeling the horizontal and vertical directions with a + sign for periodicity or a − sign for antiperiodicity.

We focus on the case that C has genus 1, in which case there are four possible spin structures (fig. 3). The path integrals for these four spin structures can be interpreted in terms of traces in two Hilbert spaces, known as the Neveu-Schwarz (NS) and Ramond (R) Hilbert spaces $\mathcal{H}_{\mathrm{NS}}$ and $\mathcal{H}_{\mathrm{R}}$, respectively.

Traces in $\mathcal{H}_{\mathrm{NS}}$ are constructed using the spin structures, shown in (a) and (b) in the figure, in which fermions are antiperiodic in the horizontal direction. If additionally the fermions are antiperiodic in the vertical direction, as in (a), then the path integral computes

$$F(\tau) = \mathrm{Tr}_{\mathcal{H}_{\mathrm{NS}}}\, q^{L_0}, \tag{3.20}$$

where $q = \exp(2\pi i\tau)$. We call this the NS partition function. If they are periodic in the vertical direction, as in (b), the path integral computes instead

$$G(\tau) = \mathrm{Tr}_{\mathcal{H}_{\mathrm{NS}}}(-1)^F q^{L_0}, \tag{3.21}$$

where $(-1)^F$ is the operator that is $+1$ on bosonic states, including the ground state of the NS sector, and -1 on fermionic states.

Traces in $\mathcal{H}_{\mathrm{R}}$ are computed using spin structures, shown in (c) and (d) in the figure, in which fermions are periodic in the horizontal direction. If the fermions are antiperiodic in the vertical direction, the path integral computes an ordinary trace

$$H(\tau) = \mathrm{Tr}_{\mathcal{H}_{\mathrm{R}}}\, q^{L_0}. \tag{3.22}$$

If fermions are periodic in both directions, the path integral gives

$$\chi = \mathrm{Tr}_{\mathcal{H}_{\mathrm{R}}}\, (-1)^F q^{L_0} = \mathrm{Tr}\, (-1)^F. \tag{3.23}$$

Both $H(\tau)$ and χ are severely constrained by the fact that in the R sector, one of the superconformal generators, which we will $\mathcal{G}_0$, commutes with L_0 and obeys $\mathcal{G}_0^2 = L_0$. This implies first of all that $L_0 \geq 0$ in the R sector, so $H(\tau)$ has no pole at $q = 0$. Further, the action of $\mathcal{G}_0$ implies that states of $L_0 > 0$ are paired between bosons and fermions. They cancel out of χ and make equal contributions to $H(\tau)$. It follows that χ is simply an integer, the trace of the operator $(-1)^F$ in the subspace with $L_0 = 0$ (or alternatively the index of the operator $\mathcal{G}_0$ mapping from bosonic states to fermionic ones). Moreover, if we expand $H(\tau)$ in powers of q

$$H(\tau) = \sum_{n=0}^{\infty} h_n q^n, \tag{3.24}$$

then all coefficients h_n are even except possibly h_0. In this expansion, only integral powers of q appear, since all fields obey integral boundary conditions in the R sector.

In the NS sector, the ground state energy is $-c/24$. In the holomorphically factorized case that we focus on, $c = 12k^*$ for an integer k^*, so the ground state energy is $-k^*/2$.

Since fermions in the NS sector are antiperiodic in the spatial direction, NS excitations may have either integer or half-integer energy above the ground state. The partition function therefore takes the general form

$$F(\tau) = q^{-k^*/2}(1 + aq^{1/2} + bq + cq^{3/2} + \ldots) = \sum_{m\in\mathbb{Z}/2,\, m\geq -k^*/2} f_m q^m. \tag{3.25}$$

In this expansion, the states in which $m + k/2$ is an integer are bosons, while the states in which $m + k/2$ is half-integral are fermions. That is so because, in the NS sector, bosonic fields are periodic and have integral excitation energies, while fermionic fields are half-integral and have half-integral excitation energies. $G(\tau)$ can therefore very explicitly be expressed in terms of the same coefficients:

$$G(\tau) = \sum_{m\in\mathbb{Z}/2,\, m\geq -k^*/2} (-1)^{2m+k^*} f_m q^m. \tag{3.26}$$

We have simply included a factor that is $+1$ on bosons and -1 on fermions. A more succinct way to say the same thing is that

$$G(\tau) = (-1)^{k^*} F(\tau + 1). \tag{3.27}$$

Thus, G is simply determined in terms of F. The same is true for H. Consider the modular transformation $\tau \to -1/\tau$, which has the effect of exchanging the horizontal and vertical directions in fig. 3 (with a reversal of orientation for one). This exchanges spin structures (b) and (c), as a result of which

$$H(\tau) = G(-1/\tau). \tag{3.28}$$

We can combine (3.27) and (3.28) to get

$$H(\tau) = (-1)^{k^*} F(-1/\tau + 1). \tag{3.29}$$

An important special case of this is

$$\lim_{\tau\to i\infty} H(\tau) = (-1)^{k^*} F(1). \tag{3.30}$$

The limit on the left hand side exists, because H has no pole at $q = 0$. The limit is just the coefficient h_0 in (3.24):

$$h_0 = (-1)^{k^*} F(1). \tag{3.31}$$

h_0 is the number of Ramond states of zero energy.

According to the above formulas, everything (except an integer χ, the supersymmetric index) can be expressed in terms of F. So it is useful to understand the modular properties of F. F is not invariant under $\tau \to \tau + 1$, as we have already seen. But, since all energies take values in $\mathbb{Z}/2$, F is invariant under $\tau \to \tau + 2$. In addition, since the modular transformation $\tau \to -1/\tau$ maps spin structure (a) itself, F is invariant under $\tau \to -1/\tau$. The two transformations $\tau \to \tau + 2$ and $\tau \to -1/\tau$ generate a subgroup of $SL(2, \mathbb{Z})$ that consists of 2×2 integral unimodular matrices

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} \tag{3.32}$$

that are congruent mod 2 to one of

$$\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}. \tag{3.33}$$

These matrices of course act on τ in the usual fashion, $\tau \to (a\tau + b)/(c\tau + d)$. This group is sometimes called Γ_θ; it is conjugate to the group $\Gamma_0(2)$ characterized by requiring b to be even. (A third conjugate group is characterized by the condition that c should be even. Each of these three groups can be defined as the subgroup of $SL(2, \mathbb{Z})$ that leaves fixed one of the even spin structures, that is, one of the first three shown in fig. 3.)

The quotient of the upper half plane $\mathcal{H}$ by $SL(2, \mathbb{Z})$ is a curve of genus zero with one point missing. This can be seen by studying the fundamental domain (fig. 4(a)). The missing point is called the "cusp" at $\tau = i\infty$. It is because the quotient has genus zero that Riemann surfaces of genus 1 can be parametrized by a single holomorphic function, namely $J(\tau)$. As we have seen in section 3.1, this is useful because it means that the constraints of modular invariance are equivalent to the statement that the partition function is a function of J. Similarly, the quotient of the upper half plane $\mathcal{H}$ by Γ_θ is again a curve of genus zero, this time with two missing points or cusps, as explained in fig. 4(b). This means that there is a function $K(\tau)$ such that any Γ_θ-invariant function F can be expressed as a function of K.

The two cusps of $\mathcal{H}/\Gamma_\theta$ are at $\tau \to i\infty$ and $\tau = 1$, and correspond respectively to the NS sector and the R sector. For $\tau \to i\infty$, the NS partition function $F(\tau)$ has an expansion in terms of L_0 eigenvalues in the NS sector. Likewise, the Ramond partition function $H(\tau)$ can be expanded for $\tau \to i\infty$ in L_0 eigenvalues in the Ramond sector; but according to (3.29), the behavior of $H(\tau)$ for τ near $i\infty$ is the same as the behavior of $F(\tau)$ for τ near 1.

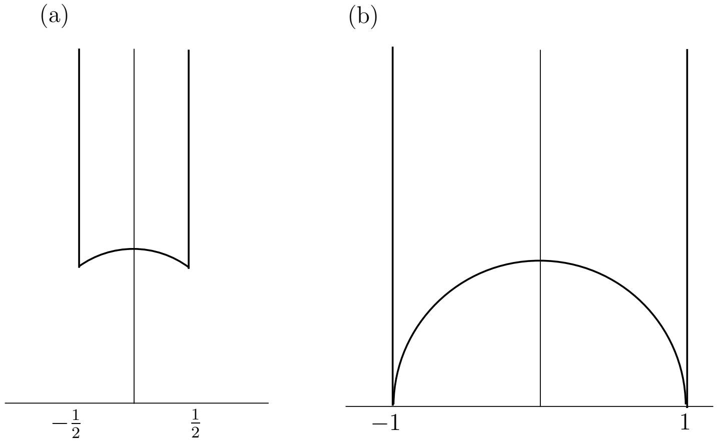

Fig. 4:

(a) A fundamental domain for the action of $SL(2,\mathbb{Z})$ on the upper half plane. By the action of $\tau \to \tau+1$, one can take $|\mathrm{Re}\,\tau| \leq 1/2$, and by the action of $\tau \to -1/\tau$, one can take $|\tau| \geq 1$. The $SL(2,\mathbb{Z})$ action identifies the left and right hand halves of the boundary of the fundamental domain, making what topologically is a Riemann surface of genus zero with one missing point at $\tau = i\infty$. This point is called the cusp. (b) The analogous fundamental domain for the action of Γ_θ. Here the symmetry $\tau \to \tau+2$ lets us reduce to $|\mathrm{Re}\,\tau| \leq 1$, and $\tau \to -1/\tau$ still lets us reduce to $|\tau| \geq 1$. The group action still identifies the left and right hand halves of the boundary of the fundamental domain, and the result is a Riemann surface of genus zero, now with two points omitted. The missing points are the Neveu-Schwarz cusp at $\tau = i\infty$ and the Ramond cusp at $\tau = \pm 1$ (those two points are equivalent under $\tau \to \tau+2$). The Ramond cusp is missing in the quotient of the upper half plane by Γ_θ because the points $\tau = \pm 1$ are not in the upper half plane, but on its boundary.

So in terms of the function F, the behavior at the two cusps is determined by the low-lying spectrum in the NS and Ramond sectors, respectively.

We therefore call these the NS and R cusps. The natural uniformizing parameter at the NS cusp is $q^{1/2} = \exp(i\pi\tau)$, where τ is the argument of the function F in (3.25). The right parameter is $\exp(i\pi\tau)$ since the symmetry is $\tau \to \tau+2$. At the R cusp, the natural parameter is $q = \exp(2\pi i\tau)$, where now τ is the argument of H.

To get a clear picture of the nature of a holomorphic function F on $\mathcal{H}/\Gamma_\theta$, it is necessary to describe the behavior near the cusps, or equivalently to describe what happens when one tries to extend F to a function on the compactification of $\mathcal{H}/\Gamma_\theta$ that is obtained by adding the cusps. This compactification is a space $\mathcal{Y} \cong \mathbb{CP}^1$.

We can explicitly describe a function K that parametrizes $\mathcal{H}/\Gamma_\theta$ and has a pole only at the NS cusp. This can be done in several ways. One formula is

$$K(\tau) = \frac{\Delta(\tau)^2}{\Delta(2\tau)\Delta(\tau/2)} - 24, \tag{3.34}$$

where $\Delta = q\prod_{n=1}^{24}(1-q^n)^{24}$ is the discriminant, a modular form of weight 24. In (3.34), we have subtracted the constant 24 so that the expansion of $K(\tau)$ in powers of $q^{1/2}$ has no constant term:

$$\begin{aligned} K(\tau) &= q^{-1/2} + 276q^{1/2} + 2048q + 11202q^{3/2} + 49152q^2 + 184024q^{5/2} + 614400q^3 \\ &\qquad + 1881471q^{7/2} + 5373952q^4 + 14478180q^{9/2} + \dots . \end{aligned} \tag{3.35}$$

This is analogous to the definition of the J-function without a constant term. Another formula for K is

$$K = \frac{q^{-1/2}}{2}\left(\prod_{n=1}^{\infty}(1+q^{n-1/2})^{24} + \prod_{n=1}^{\infty}(1-q^{n-1/2})^{24}\right) + 2048q\prod_{n=1}^{\infty}(1+q^n)^{24}. \tag{3.36}$$

The product formula in (3.34), since it converges for all $|q| < 1$, shows that K is nonsingular as a function on $\mathcal{H}$. As for the behavior at the cusps, either formula shows that K has a simple pole at the NS cusp, that is, it behaves for $q \to 0$ as $q^{-1/2}$. K is regular at the Ramond cusp; in fact

$$K(\tau = 1) = -24. \tag{3.37}$$

This statement is equivalent to the statement that $K + 24 = \Delta(\tau)^2/\Delta(2\tau)\Delta(\tau/2)$ vanishes at $\tau = 1$. Indeed, that function has a pole at the NS cusp, so it must have a zero somewhere. Its representation as a convergent infinite product shows that it is nonzero for $0 < |q| < 1$, so the zero is at the Ramond cusp. We give another explanation of (3.37) in section 3.3 in analyzing the $k^* = 1$ model. The fact that the holomorphic function K on $\mathcal{Y}$ has only one pole, which is of first order, gives another way to prove that $\mathcal{Y}$ is of genus zero.

Now let us consider the Neveu-Schwarz partition function F of a holomorphic SCFT. Any Γ_θ-invariant function F on $\mathcal{H}$ can be written as a function of K. The function F arising in a holomorphic SCFT is actually *polynomial* in K. Indeed, since the definition of F as $\mathrm{Tr}\, q^{L_0}$ is convergent for $0 < |q| < 1$, F is regular as a function on $\mathcal{H}$. So the only poles of F are at cusps, but the formula (3.31), which reflects the fact that the ground state energy in the Ramond sector is zero, says that F has no pole at the Ramond cusp.

So the only pole of F is at the Neveu-Schwarz cusp, that is at $K = \infty$. Consequently, in any holomorphic SCFT, the Neveu-Schwarz partition function F is a polynomial in K.

The degree of this polynomial is precisely k^*, since $F \sim q^{-k^*/2}$ for $q \to 0$. So

$$F = \sum_{r=0}^{k^*} f_r K^r. \tag{3.38}$$

Thus, F depends on $k^* + 1$ coefficients.

Now, for the case of an SCFT that is dual to three-dimensional supergravity, what would we expect F to be? To follow the same logic as in the bosonic case, we would argue that since the minimum energy of a BTZ black hole is $L_0 = 0$, and the entropy vanishes at $L_0 = 0$, primary states corresponding to black holes should be absent for $L_0 \leq 0$. Equivalently, primary fields other than the identity should be absent for dimension less than $(k^* + 1)/2$. Either statement would mean that up to terms of order $q^{1/2}$, F would coincide with the naive function

$$F_0(k^*) = q^{-k^*/2} \prod_{n=2}^{\infty} \frac{1 + q^{n-1/2}}{1 - q^n} \tag{3.39}$$

that counts superconformal descendants of the identity.

For each positive integer k^*, there is a uniquely determined function F_{k^*} that is a polynomial in K and coincides with $F_0(k^*)$ up to order $q^{1/2}$. This is a natural analog of the partition function Z_k that we defined for an extremal CFT without supersymmetry.

However, the same logic that makes us think that there should be no NS primaries of $L_0 \leq 0$ also would make us believe that there should be no Ramond primaries of $L_0 = 0$. (There are automatically no Ramond states of $L_0 < 0$, since $L_0 = \mathcal{G}_0^2$.) In either the NS or Ramond sector, the classical black hole entropy vanishes for $L_0 \leq 0$.

The number of Ramond primaries of $L_0 = 0$ in a theory with Neveu-Schwarz partition function F_{k^*} is, according to (3.31), $h_0 = (-1)^{k^*} F_{k^*}(1)$. Let us call this number β_{k^*}. β_{k^*} is uniquely determined for each k^*. A practical way to determine it, using (3.37), is to write

$$\beta_{k^*} = (-1)^{k^*} F_{k^*}(1) = (-1)^{k^*} \sum_{r=0}^{k^*} f_r K(1)^r = (-1)^{k^*} \sum_{r=0}^{k^*} f_r (-24)^r. \tag{3.40}$$

So one first evaluates the coefficients f_r in (3.38) to ensure that there are no NS primary states with $L_0 \leq 0$, and then one evaluates the sum in (3.40).

The first ten values of β_{k^*} are given in Table 1. The first observation is that β_{k^*} never vanishes in this range. Consequently, it is impossible to assume that there are no primary operators other than the identity of dimension less than $(k^*+1)/2$. If we assume that there are no such primaries in the NS sector, then there are primaries of dimension $k^*/2$ in the Ramond sector.

k^*	β_{k^*}
1	24
2	24
3	95
4	1
5	143
6	1
7	262
8	-213
9	453
10	-261

Table 1. Values of the index β_{k^*} for $k^* = 1, \ldots, 10$.

The good news is that the numbers in the table are rather small compared to black hole multiplicities that arise in the classically allowed region $L_0 > 0$. So an optimistic view is to interpret the numbers in the table as quantum corrections. For example, at $k^* = 9$, where β takes the relatively large value 453, the multiplicity of the lowest mass classically allowed black hole, namely $L_0 = 1/2$ in the NS sector, turns out to be 135149371 if the partition function F_9 can be trusted. (As usual, we count only primaries, although this involves only a small correction.) The lowest classically allowed black hole in the Ramond sector, at $L_0 = 1$, has multiplicity 381161020987.

However, it may not seem logical to assume that there are no NS primaries at dimension $k^*/2$ and allow Ramond primaries of that dimension. Moreover, it really does not make sense to do this, since some values of β in the table are negative.

So we retreat from claiming that there are no NS primary fields of dimension less than $(k^*+1)/2$, and instead we consider the hypothesis that there are no such primaries of dimension less than $k^*/2$. In this case, we are free to add an integer s to F_{k^*}. If we do so, the number of NS primaries of dimension $k^*/2$ becomes $f_0 = s$, and the number h_0 of Ramond primaries of that dimension changes by $(-1)^{k^*}s$. The combination

$$\beta_{k^*} = h_0 - (-1)^{k^*} f_0 \tag{3.41}$$

is unchanged, and so is still given by the numbers in the table.

Unfortunately, then, we have no way to determine the numbers f_0 and h_0 separately, only the "index" β. We also have little insight about the more conventional index χ defined in (3.23). Both of these quantities characterize the primary states of $L_0 = 0$.

As in the bosonic case, one can construct useful formulas for the functions F_{k^*} in terms of Hecke operators acting on F_1. However, we will omit this.

Optimistic Conjecture

We define an extremal SCFT to be one with no primary fields other than the identity of dimension less than $k^*/2$. Equivalently, the NS partition function is equal up to an additive integer to the function F_{k^*} that was defined above.

Generalizing what we have said about the bosonic case, the most optimistic conjecture we can propose is that an extremal SCFT exists and is unique for every positive integer k^*, and is dual to three-dimensional supergravity. The best evidence we can offer is that extremal SCFT's in this sense do exist for $k^* = 1, 2$ and there are results about uniqueness [31,35] at least for $k^* = 1$.

In addition, as we will see, the functions F_{k^*} with $k^* = 3, 4$ have interesting properties suggestive of the existence of actual theories.

These matters are discussed in section 3.3. In addition, in the appendix, we describe the functions F_{k^*} for $5 \leq k^* \leq 10$.

3.3. Extremal SCFT's With Small k^*

k^*=1

The first construction of an extremal SCFT was made by FLM at $k^* = 1$, that is $c = 12$. They considered eight free bosons X_i compactified using the E_8 root lattice, combined with eight free fermions ψ_i to achieve superconformal symmetry. This theory has NS primary fields of dimension 1/2, namely the ψ_i. To eliminate these fields, they considered a $\mathbb{Z}_2$ orbifold, dividing by the operation that acts as -1 on all X_i and ψ_i.

They conjectured that this construction gave the unique SCFT that has $c = 12$ and no NS primary of dimension 1/2.

While the construction is simple, it has the drawback of not making manifest the global symmetry of the model. This was remedied much more recently by Duncan [35], who described the same model in another way. In this construction, one begins with 24 free fermions λ_i, $i = 1, \ldots, 24$, forming again a system with $c = 12$. In quantization, one can require the λ_i to be either antiperiodic or periodic around the spatial direction, giving what we will call NS_0 and R_0 sectors. (We reserve the name NS and R for another construction that will appear shortly.)

With 24 fermions, the ground state energy in the NS_0 sector is $-1/2$, while in the R_0 sector, the ground state energy is $+1$. The minimum dimension of a spin field is the difference between these two energies, or 3/2.

The model has an $O(24)$ symmetry that rotates the fields λ_i. The ground state in the R_0 sector is highly degenerate, because of zero modes of the fields λ_i. It consists of $2^{12} = 4096$ states, transforming in the spinor representation of $O(24)$ (or rather its double cover).

The spin fields of lowest dimension are therefore 4096 fields W_α of dimension 3/2 transforming as spinors. Dimension 3/2 is the correct dimension for a supercurrent, but a generic linear combination $W = \sum_\alpha \epsilon^\alpha W_\alpha$, with c-number coefficients ϵ^α, does not generate a superconformal algebra. Schematically, and without worrying about the precise coefficients, the operator product $W \cdot W$ gives

$$W(x)W(0) \sim \frac{\overline{\epsilon}\epsilon}{x^3} + \frac{\overline{\epsilon}\epsilon\, T}{x} + \frac{\overline{\epsilon}\Gamma^{ij}\epsilon\, \lambda_i\lambda_j}{x^2} + \frac{\overline{\epsilon}\Gamma^{ijkl}\epsilon\, \lambda_i\lambda_j\lambda_k\lambda_l}{x} + \text{regular}. \tag{3.42}$$

(Here T is the stress tensor and Γ_i are the gamma matrices of $O(24)$.) The condition for W to generate a superconformal algebra is that the last two terms should be absent. This is equivalent to

$$\overline{\epsilon}\Gamma^{ij}\epsilon = \overline{\epsilon}\Gamma^{ijkl}\epsilon = 0. \tag{3.43}$$

It is shown in [35] that a spinor ϵ obeying these conditions exists and, if normalized to have $\overline{\epsilon}\epsilon = 1$, is unique up to an $O(24)$ transformation. Another important fact is that any such ϵ has one definite $SO(24)$ chirality or the other.

Any choice of a solution of (3.43) turns the theory into an $\mathcal{N} = 1$ superconformal field theory, with W as the supercurrent. However, as ϵ is not $O(24)$-invariant, the theory regarded as an $\mathcal{N} = 1$ SCFT does not have $O(24)$ symmetry. Rather, the choice of ϵ breaks

$O(24)$ symmetry to a group that is known as the Conway group Co_0. It is the symmetry group of the Leech lattice, and is a double cover of a sporadic finite group Co_1. Thus, as a superconformal field theory, this model has symmetry Co_0, not $O(24)$.

With this choice of superconformal algebra, we need to understand what are the Neveu-Schwarz and Ramond vertex operators. A Ramond vertex operator $\mathcal{O}$ has a square root singularity in the presence of the supercurrent W:

$$W(x)\mathcal{O}(x') \sim \frac{\mathcal{O}'}{(x-x')^{n-1/2}} \tag{3.44}$$

for some integer n and some operator $\mathcal{O}'$. With W understood as a spin operator with respect to the original fermions λ, those fermions have precisely this property. So they are Ramond fields. This enables us to analyze all of the states in the original NS_0 sector. The ground state corresponds to the identity operator, whose OPE with W of course has no branch cut, so it is an NS rather than Ramond operator. The operators in the NS_0 sector that have no branch cut with W are those that are products of an even number of λ's and their derivatives. The partition function that counts the corresponding states is

$$\frac{q^{-1/2}}{2}\left(\prod_{n=1}^{\infty}(1+q^{n-1/2})^{24}+\prod_{n=1}^{\infty}(1-q^{n-1/2})^{24}\right). \tag{3.45}$$

We recognize this as part of the formula (3.36) for the function K. In the R_0 sector, of the 4096 ground states, half have one chirality or fermion number and half have the other. Any excitation at all can be combined with a ground state of properly chosen chirality to get an operator that either does or does not have a branch cut with W, as desired. So for each L_0 eigenvalue in the R_0 sector, precisely half the states contribute to the NS sector and half to the R sector. The contribution of R_0 states to the NS sector is therefore

$$2048q\prod_{n=1}^{\infty}(1+q^n)^{24}. \tag{3.46}$$

Adding up (3.45) and (3.46), we see that the total partition function F_1 of the NS sector in this model is precisely what we have called K:

$$F_1 = K = \frac{q^{-1/2}}{2}\left(\prod_{n=1}^{\infty}(1+q^{n-1/2})^{24}+\prod_{n=1}^{\infty}(1-q^{n-1/2})^{24}\right)+2048q\prod_{n=1}^{\infty}(1+q^n)^{24}. \tag{3.47}$$

We can similarly compute the Ramond partition function H_1 of this model. The contribution of the NS_0 sector is obtained from (3.45) by changing a sign so as to project onto states of odd fermion number, rather than even fermion number. And the contribution of the R_0 sector is the same as (3.46). So

$$\begin{aligned} H_1 &= \frac{q^{-1/2}}{2}\left(\prod_{n=1}^{\infty}(1+q^{n-1/2})^{24}-\prod_{n=1}^{\infty}(1-q^{n-1/2})^{24}\right)+2048q\prod_{n=1}^{\infty}(1+q^n)^{24} \\ &= 24+4096q+98304q^2+1228800q^3+10747904q^4+\dots. \end{aligned} \tag{3.48}$$

Except for states of $L_0=0$, the global supercharge $\mathcal{G}_0$ of the Ramond sector exchanges the part of the Ramond sector coming from NS_0 with the part coming from R_0. This implies that we can alternatively write

$$H_1 = 24+4096q\prod_{n=1}^{\infty}(1+q^n)^{24}, \tag{3.49}$$

where we have removed the NS_0 contribution except for the ground states, and doubled the R_0 contribution. The equivalence of these formulas is not very obvious.

A consequence of the above formulas is that h_0, the number of Ramond states of $L_0=0$, is equal to 24. This gives another explanation for (3.37). Another consequence of (3.49) and (3.47) is that for $L_0>0$, the coefficients h_n in the q-expansion of H_1 are precisely twice the corresponding coefficients f_n in the expansion of F_1:

$$h_n = 2f_n. \tag{3.50}$$

(Here h_n is defined for integer n, while f_n is defined for integer or half-integer n, so this formula involves all coefficients h_n but only half of the f_n.) This is highly exceptional for SCFT's and reflects the particular way that this one was constructed. The relation (3.50) is equivalent to

$$0 = F_1(\tau)+F_1(\tau+1)-H_1(\tau) = F_1(\tau)-G_1(\tau+1)-H_1(\tau). \tag{3.51}$$

Although disguised in our way of presenting it, this is a standard relation in string theory. In the FLM construction of the model via 8 free bosons and 8 free fermions, (3.51) amounts to the statement of Gliozzi, Olive, and Scherk [52] that the Ramond-Neveu-Schwarz model has equal partition function in the Ramond and Neveu-Schwarz sectors, because of spacetime supersymmetry.

The factor of 2 in (3.50) is consistent with asymptotic equality between the numbers of NS and Ramond black holes because it only involves half of the coefficients of F_1. H_1 has only half as many coefficients as F_1, but they are twice as big.

As we have explained, the NS partition function F_{k^*} of an extremal SCFT with any k^* is a polynomial in K or equivalently in F_1,

$$F_{k^*} = f(F_1), \tag{3.52}$$

for some polynomial f. From (3.29), it follows that the Ramond partition function H_{k^*} of an extremal SCFT can be obtained from H_1 using the same polynomial:

$$H_{k^*} = (-1)^{k^*} f(-H_1). \tag{3.53}$$

A Model With $k^* = 2$

What in our language is an extremal SCFT of $k^* = 2$ was constructed [26] by Dixon, Ginsparg, and Harvey (DGH), relatively soon after the work of FLM, by twisting the FLM monster construction in a somewhat similar fashion. Note that an extremal SCFT of $k^* = 2$ has $c = 24$, like the FLM monster theory.

We recall that the starting point of the FLM construction is 24 free bosons X_i that are compactified via the Leech lattice. Then one performs a $\mathbb{Z}_2$ orbifold, dividing by the symmetry $X_i \to -X_i$. To construct an orbifold, one first constructs untwisted and twisted sectors (by quantizing fields $X_i(\sigma)$ that are assumed to be periodic or antiperiodic functions of σ) and then one projects both sectors onto their $\mathbb{Z}_2$-invariant subspaces.

DGH observed that the ground state energy in the untwisted sector is -1, while the ground state energy in the twisted sector is $+1/2$. So a twist operator of lowest energy has dimension $3/2$, the right dimension for a supercurrent. They went on to show that it is possible to pick a twist operator $\mathcal{S}$ that generates a superconformal algebra.

In the FLM construction, the field $\mathcal{S}$ is not present, since it is odd rather than even under $\mathbb{Z}_2$, and is projected out when one forms the orbifold theory. However, DGH showed that it is possible to obtain an $\mathcal{N} = 1$ SCFT by modifying the usual orbifold projection. They defined the NS sector to consist of fields that do not have a cut in their OPE with $\mathcal{S}$, while the Ramond sector consists of fields that do have such a cut. Concretely, the NS sector consists of the $\mathbb{Z}_2$-even part of the untwisted sector of the orbifold plus the part of the twisted sector that transforms under $\mathbb{Z}_2$ as does $\mathcal{S}$ (so that $\mathcal{S}$, in particular, is an NS field), while the Ramond sector consists of the $\mathbb{Z}_2$-odd part of the untwisted sector plus the $\mathbb{Z}_2$-even part of the twisted sector.

From this information, one can of course compute the NS and Ramond partition functions F_2 and H_2. From our point of view, of course, F_2 is a polynomial in $F_1 = K$, chosen so that $F_2 = q^{-1} + \mathcal{O}(q^{1/2})$. This gives $F_2 = K^2 - 552$, and similarly, in view of (3.53), $H_2 = H_1^2 - 552$. From this, we get

$$\begin{aligned} F_2 &= q^{-1} + 4096q^{1/2} + 98580q + 1228800q^{3/2} + 10745856q^2 + 74244096q^{5/2} + 432155586q^3 + \dots \\ H_2 &= 24 + 196608q + 21495808q^2 + 864288768q^3 + \dots . \end{aligned} \tag{3.54}$$

The number of states of $L_0 = 0$ is 24 in the Ramond sector and 0 in the NS sector.

The global symmetry of the DGH model is closely related to the symmetry group Co_0 of the Leech lattice (it is an extension of this by a finite abelian group that involves the momenta of the Leech lattice). Since the $k^* = 1$ model also has Co_0 symmetry, one might optimistically conjecture that this group is relevant to supergravity at all k^*. However, results below about $k^* = 3$ indicate that this is not the case.

Partition Function With $k^* = 3$

Unfortunately, this is the last case for which a suitable SCFT is known, but we can of course determine the appropriate NS and Ramond partition functions for all k^*, at least modulo an additive integer. We consider $k^* = 3, 4$ here because they turn out to have unusual properties, and relegate the further cases $k^* = 5, 6, \dots, 10$ to an appendix.

For $k^* = 3$, we have

$$F_3 = K^3 - 828K - 6143. \tag{3.55}$$

This leads to

$$\begin{aligned} F_3 &= q^{-3/2} + 1 + 33606q^{1/2} + 1843200q + 43434816q^{3/2} + 648216576q^2 \\ &\quad + 7171304841q^{5/2} + 63903727616q^3 + \dots \\ H_3 &= 95 + 3686400q + 1296433152q^2 + 127807455232q^3 + \dots . \end{aligned} \tag{3.56}$$

Here one finds an identity just like (3.50): the expansion coefficients h_n of H_3 are related for $n > 0$ to analogous coefficients f_n of F_3 by

$$h_n = 2f_n. \tag{3.57}$$

This expresses the fact that

$$F_1^3(\tau) + F_1^3(\tau + 1) = H_1^3(\tau) - 1536, \tag{3.58}$$

along with the similar linear relation (3.51).

It seems that the identity $h_n = 2f_n$, $n > 0$, does not hold for any values of k^* except 1 and 3. In general, the differences $h_n - 2f_n$ are relatively small, reflecting the fact that asymptotically an NS or Ramond black hole has the same entropy, but they are not zero. The fact that these degeneracies are actually equal for $k^* = 3$ may be a clue to the construction of this model.

One important point about the $k^* = 3$ model is that it seems very unlikely to have Co_0 or Co_1 symmetry. Indeed the leading coefficient 95 of H_3 is not in any economical way the dimension of a representation of Co_0. (The dimensions of the first few irreducible representations of this group are 1, 24, 276, 299, and 1771; for Co_1, one must omit the number 24 from this list.) Adding an integer n to F_3 and therefore subtracting n from H_3, does not help; we cannot pick n so that n and $95 - n$ are both dimensions of Co_0 representations in an economical fashion. So it appears that, despite the tempting evidence from the cases $k^* = 1, 2$, the group Co_0 is probably not a general symmetry of three-dimensional supergravity.

Monster Symmetry For $k^* = 4$?

However, in the next case, $k^* = 4$, there may well be a much larger discrete symmetry group, namely the monster group $\mathbb{M}$.

For $k^* = 4$, we have

$$F_4 = K^4 - 1104K^2 - 8191K + 107545. \tag{3.59}$$

This leads to the NS and Ramond partition functions

$$\begin{aligned} F_4 &= q^{-2} + q^{-1/2} + 1 + 196884q^{1/2} + 21493760q + 864299970q^{3/2} + 20246053140q^2 \\ &\quad + 333202640600q^{5/2} + 4252023300096q^3 + 44656994071935q^{7/2} + 401490908149760q^4 + \dots \\ H_4 &= 1 + 42987520q + 40491712512q^2 + 8504046600192q^3 + 802981773312000q^4 + \dots . \end{aligned} \tag{3.60}$$

The first non-trivial coefficient in F_4 is the famous number $196884 = 196883 + 1$ whose appearance in the J function gave the original hint of a connection between $\mathbb{M}$ and modular functions and ultimately conformal field theory. Moreover, the leading coefficient in H_4 is 1, which is compatible with any assumption about an automorphism group, since it is the dimension of an irreducible representation, namely the trivial one. The contrasts with what we found for $k^* = 3$, where the leading coefficient, namely 95, makes it difficult to postulate a large discrete symmetry.

To explore further the hypothesis of $\mathbb{M}$ symmetry, we attempt to express the coefficients in F_4 and H_4 in terms of dimensions of representations of $\mathbb{M}$. The dimensions $d_1, d_2, \ldots, d_{12}$ of the first 12 monster representations, which we call R_i, $i = 1, \ldots, 12$, are given in the table.

d_1	1
d_2	196883
d_3	21296876
d_4	842609326
d_5	18538750076
d_6	19360062527
d_7	293553734298
d_8	3879214937598
d_9	36173193327999
d_{10}	125510727015275
d_{11}	190292345709543
d_{12}	222879856734249

Table 2. Presented here from [53] are the dimensions d_i of the i^{th} irreducible representation of the monster group $\mathbb{M}$, for $i = 1, \ldots, 12$. We denote as R_i the representation of dimension d_i.

A little experimentation soon shows that the nontrivial coefficients in the NS partition function F_4 can be nicely written in terms of the d_i. The first 8 nontrivial coefficients $f_{1/2}, f_1, \ldots, f_4$ are

$$\begin{aligned}
196884 &= d_1 + d_2 \\
21493760 &= d_1 + d_2 + d_3 \\
864299970 &= 2d_1 + 2d_2 + d_3 + d_4 \\
20246053140 &= 3d_1 + 4d_2 + 2d_3 + d_4 + d_6 \\
333202640600 &= 4d_1 + 5d_2 + 3d_3 + 2d_4 + d_5 + d_6 + d_7 \\
4252023300096 &= 5d_1 + 7d_2 + 4d_3 + 4d_4 + 2d_5 + 2d_6 + d_7 + d_8 \\
44656994071935 &= 7d_1 + 11d_2 + 7d_3 + 6d_4 + 3d_5 + 4d_6 + 2d_7 + 2d_8 + d_9 \\
401490908149760 &= 10d_1 + 16d_2 + 12d_3 + 9d_4 + 5d_5 + 7d_6 + 4d_7 + 4d_8 + d_9 + d_{10} + d_{12}.
\end{aligned} \tag{3.61}$$

The coefficients on the right hand side are rather small given the numbers involved, and as we will explain shortly, they do not grow much faster than is required by superconformal symmetry. The first three numbers here equal the first three non-trivial coefficients of the J function, but afterwards the two series diverge.

The coefficients h_n in the q-expansion of H_4 can similarly be expressed in terms of dimensions of monster representations. In doing so, however, the following is a useful shortcut and also possibly a clue to constructing the model. First of all, in contrast to the case of $k^* = 1, 3$, it is not true that $h_n - 2f_n = 0$ for $k^* = 4$ and all $n > 0$. But some of these differences vanish, and they are all relatively small. As we have already expressed the f_n for small n in terms of monster dimensions in (3.61), it suffices now to find similar expressions for $h_n - 2f_n$. Actually, as the h_n are all even for $n > 0$, we prefer to divide by 2, and we find

$$\begin{aligned}
\frac{h_1}{2} - f_1 &= 0 \\
\frac{h_2}{2} - f_2 &= -f_{1/2} \\
\frac{h_3}{2} - f_3 &= 0 \\
\frac{h_4}{2} - f_4 &= -f_1 \\
\frac{h_5}{2} - f_5 &= 0.
\end{aligned} \tag{3.62}$$

When this is combined with (3.61), we see that the $h_i/2$, $i \leq 5$ are linear combinations of the d_i with small positive integer coefficients. So the initial coefficients of the Ramond partition function are compatible with $\mathbb{M}$ symmetry, and in addition many of the differences $h_n/2 - f_n$ vanish.

T. Gannon has given a simple explanation of these results by showing that one can express F_4 and H_4 in terms of the J-function via $F_4(\tau) = J(2\tau) + J(\tau/2) + 1$, $H_4(\tau) = J(\tau/2) + J((\tau+1)/2) + 1$. Hence F_4 and H_4 inherit a relation to the monster from J. The fact that the formulas have such a direct explanation may lessen the case for a new SCFT with monster symmetry.

Given that the above formulas exist, they are not quite unique, because there are some linear relations[17] among the d_i with small coefficients:

$$\begin{aligned} d_1 + d_4 + d_5 &= d_3 + d_6 \\ d_3 + d_8 + d_{12} &= d_2 + d_7 + d_9 + d_{11}. \end{aligned} \tag{3.63}$$

We have made some choices to ensure that the above formulas are compatible with superconformal symmetry, in the following sense. The first formula in (3.61) indicates that at $L_0 = 1/2$, the NS sector has 196883 primary states $|\rho_i\rangle$ transforming in the representation R_2. It follows that at $L_0 = 1$, there are descendants $\mathcal{G}_{-1/2}|\rho_i\rangle$ transforming in the same representation. This continues at higher levels; the number of copies of R_2 appearing as descendants of the primary states $|\rho_i\rangle$ at $L_0 = s/2$ is $1, 1, 1, 2, 3, 4, 5, 7$ for $s = 1, 2, \ldots, 8$. If we count only primary states, we find, assuming that (3.61) is the right decomposition, that primary states in the representation R_2 occur at $L_0 = 1/2, 3/2, 2, 7/2, 4$, each time with multiplicity 1. Similar remarks apply to other representations. A special case is that, for the range of L_0 considered in (3.61), most of the states that transform in the trivial representation R_1 are actually descendants of the identity. If (3.61) is the right decomposition, then the first primary field that is $\mathbb{M}$-invariant is at $L_0 = 5/2$. If we were to rewrite (3.61) in terms of primary states only, the coefficients would be even smaller (but still nonnegative), strengthening the case for monster symmetry.

In this particular example, we cannot add an integer to F_4 without spoiling the hypothesis of monster symmetry. If there were an NS primary with $L_0 = 2$, it would have a descendant at $L_0 = 5/2$, and the number of primaries at $L_0 = 5/2$ would be less than 196883.

In the appendix, we present somewhat similar though less extensive evidence for baby monster symmetry at $k^* = 6$.

Sum Over Spin Structures

---

[17] These relations can be explained as follows. The symmetric part of $R_2 \otimes R_2$ decomposes as $\mathrm{Sym}^2 R_2 \cong R_1 \oplus R_2 \oplus R_4 \oplus R_5$, and the antisymmetric part decomposes as $\wedge^2 R_2 \cong R_3 \oplus R_6$. On the other hand, $\dim(\mathrm{Sym}^2 R_2) - \dim(\wedge^2 R_2) = \dim R_2 = d_2$. Taken together, these facts imply the first relation in (3.63), and the second follows similarly by considering the decomposition of $R_3 \otimes R_3$.

Given an SCFT with c an integer multiple[18] of 24, by summing over spin structures, one can make an ordinary bosonic CFT. The sum over spin structures projects both the NS and Ramond sectors onto bosonic states of integer dimension, as is appropriate for a bosonic CFT.

For c to be a multiple of 24, k^* must be even. It was already shown by DGH that the sum over spin structures, applied to their model which in our language is $k^* = 2$, gives the FLM model at $k = 1$. A natural question (raised by J. Duncan) is what this operation does at higher even values of k^*.

The sum over spin structures removes fermionic operators such as the supercurrent $\mathcal{S}$, of dimension 3/2. However, it leaves operators such as $\mathcal{S}\partial\mathcal{S}$ that are even in $\mathcal{S}$. This operator has dimension 4, and is a Virasoro primary (though, of course, it is a descendant in the $\mathcal{N} = 1$ super-Virasoro algebra). A bosonic extremal CFT of $k \geq 4$ should not have a primary of dimension 4. Hence, the "sum over spin structures" operation applied to an extremal SCFT of $k^* \geq 8$ does not give an extremal CFT. However, it does give an extremal CFT if applied to a theory of $k^* = 4$ or 6.

Hence, if extremal SCFT's exist with $k^* = 4, 6$, they can be used to generate extremal CFT's of $k = 2, 3$. It is interesting that $k^* = 4, 6$ are precisely the values at which extremal SCFT's may have monster or baby monster symmetry. (The baby monster group is the centralizer of an involution in the monster, and hence it is conceivable for an SCFT at $k^* = 6$ to have baby monster symmetry while the CFT at $k = 3$ has monster symmetry. The framework for this is described in [26].)

Part of what we have said can be understood in another way. Supergravity and gravity are different in the semiclassical limit, and one cannot be obtained from the other by merely summing over spin structures. So whatever is the SCFT dual of supergravity (even if our assumptions are too optimistic and it is not extremal), the sum over spin structures applied to this SCFT cannot give, for arbitrarily large k^*, the CFT that is dual to gravity.

---

[18] If c is an odd multiple of 12, the sum over spin structures is modular-invariant but projects out the NS ground state and does not give a CFT in the usual sense. This is actually important in superstring theory, where, with $c = 12$ in the light-cone treatment, the NS ground state is a "tachyon" and is removed in the sum over spin structures.

4. $k = 2$ Partition Function On A Hyperelliptic Riemann Surface

The most important question raised by this paper is certainly whether appropriate CFT's and SCFT's exist, beyond the few examples that are known.

In this section, we will perform a small computation that aims to give a hint that this is the case, at least for the bosonic theory with $k = 2$ and hence $c = 48$. We will show that the partition function of such a theory on a hyperelliptic Riemann surface of any genus can be determined in a unique and consistent way. This includes, for example, any Riemann surface of genus 2. The fact that we get a unique and consistent result in this situation gives some encouragement for believing that the $k = 2$ model does exist and is unique.

In this paper, we merely demonstrate the consistency of an algorithm for determining the partition function. Hopefully it will be possible in future work to get explicit formulas, at least for genus 2. Our method also works for $k = 1$, though here the ability in principle to determine the partition function comes as no surprise, since the model has been constructed explicitly [24] and in fact the genus 2 partition function has been computed [54] by a quite different method.

Perhaps it would help orient the reader to compare what we will do to another possible approach to determining the partition function. Genus 2 partition functions were determined in [54] for a variety of holomorphic CFT's with $c = 24$. The basic method was to express the partition function in terms of a Siegel modular form, which depends on only finitely many coefficients, and determine the coefficients by considering the behavior when the Riemann surface C degenerates. There are two types of degeneration (C can break up into two genus 1 curves joined at a point, or can reduce to a single genus 1 curve with two points glued together). The partition function can be determined from the behavior at just one degeneration, and there is a problem of consistency to show that one gets the same result either way. One could attempt to demonstrate the consistency by studying the appropriate Siegel modular forms, but we prefer to prove consistency by establishing the associativity of a certain operator product algebra. One advantage is that this method can be used to determine the partition function on a hyperelliptic Riemann surface of any genus. On the other hand, if one could overcome the technicalities in genus 2 (see [55] for one approach), one could possibly compute the genus 2 partition function of an extremal CFT for all k.

4.1. Twist Fields

A hyperelliptic Riemann surface C is a double cover of the complex plane, for example a double cover of the complex x-plane, which we will call C_0, described by an equation

$$y^2 = \prod_{i=1}^{2g+2} (x - e_i). \tag{4.1}$$

The $2:1$ cover $C \to C_0$ is branched at the points $e_1, \ldots, e_{2g+2}$. C is smooth if the e_i are distinct, and has genus g if the number of branch points is precisely $2g+2$.

Our approach to determining the partition function on such a Riemann surface is based on an old idea [56-59]. The partition function of a conformal field theory $\mathcal{W}$ on the hyperelliptic Riemann surface C can be determined by computing, in a doubled theory, the correlation function of $2g+2$ copies of a "twist field" $\mathcal{E}$, inserted at the points $e_1, \ldots, e_{2g-2}$ in C_0.

Consider any CFT $\mathcal{W}$ of central charge c. Away from branch points, the theory $\mathcal{W}$ on the double cover C looks locally like the theory $\mathcal{W} \times \mathcal{W}$ on C_0. Here we have one copy of $\mathcal{W}$ for each of the two branches of $C \to C_0$.

In going around a branch point, the two copies of $\mathcal{W}$ are exchanged. So a more complete description is to say that the theory on C_0 is $\mathrm{Sym}^2\mathcal{W}$, the symmetric product of two copies of $\mathcal{W}$. The symmetric product theory is an orbifold of the product theory $\mathcal{W} \times \mathcal{W}$ in which one divides by the $\mathbb{Z}_2$ symmetry that exchanges the two branches.

Let us describe what kind of operators the symmetric product theory has. First, there are "untwisted" operators. These are simply operators of the theory $\mathcal{W} \times \mathcal{W}$ that are invariant under the exchange of the two factors. For example, let T^+ and T^- be the stress tensors of the two factors. Any local operator constructed as a polynomial in T^+ and T^- and their derivatives and invariant under the exchange $T^+ \leftrightarrow T^-$ gives an operator in the symmetric product theory. Operators of this particular type generate a chiral algebra that we will call $\mathrm{Sym}^2\mathcal{V}$, where $\mathcal{V}$ denotes the chiral algebra generated by a single stress tensor.

In addition, there are "twisted sector" operators. These operators correspond (in the operator/state correspondence of CFT) to states obtained by quantizing the theory $\mathcal{W} \times \mathcal{W}$ on a circle S^1, in such a way that the two copies of $\mathcal{W}$ are exchanged in monodromy around the circle. These states are the states of a *single* copy of $\mathcal{W}$ on a circle of twice the circumference. The energies of the states in the twisted sector of the $\mathrm{Sym}^2\mathcal{W}$ theory are therefore precisely one-half the energies of the original $\mathcal{W}$ theory (in conformal field theory, doubling the circumference of the circle divides the Hamiltonian by two).

Operators related to states in the twisted sector are called twist fields. The dimension of a twist field is the same as the difference in energy between the corresponding twisted sector state and the untwisted ground state. The ground state energy in the untwisted sector is $-2 \cdot c/24$ (where the 2 comes from the two copies of $\mathcal{W}$) and the ground state energy in the twisted sector is $-(1/2) \cdot c/24$ (where the factor of 1/2 was explained in the last paragraph). The difference is $d_{\mathcal{E}} = (c/24)(-1/2 - (-2)) = (3/2)c/24$, and this is the dimension of the twist field $\mathcal{E}$ of lowest energy. For our application, we are interested in the case that $c/24$ is an integer k, and hence $d_{\mathcal{E}} = 3k/2$.

Now we can explain how the partition function of the theory $\mathcal{W}$ on the hyperelliptic Riemann surface C defined in eqn. (4.1) can be interpreted as a genus zero correlation function in the theory $\mathrm{Sym}^2\mathcal{W}$. From the standpoint of the $\mathrm{Sym}^2\mathcal{W}$ theory on the x-plane, the role of the branch points is just to exchange the two copies of $\mathcal{W}$, via a twist field. On the double cover, there is no operator insertion at the branch points except the identity; the identity operator at a branch point corresponds in the downstairs description to the ground state in the twisted sector and hence to the twist operator $\mathcal{E}$ of lowest dimension. So the partition function on the double cover can be expressed in terms of the correlation function $\left\langle \mathcal{E}(e_1)\mathcal{E}(e_2)\ldots\mathcal{E}(e_{2g+2})\right\rangle$ on the x-plane. (The precise statement involves the conformal anomaly; this is deferred to section 4.5.)

To compute this correlation function, we need to understand the chiral algebra that is obtained by extending the symmetric product $\mathrm{Sym}^2\mathcal{V}$ of two Virasoro algebras by the field $\mathcal{E}$. For this, we need to know what primary fields (of $\mathrm{Sym}^2\mathcal{V}$) appear in the operator product $\mathcal{E} \cdot \mathcal{E}$. To calculate the product $\mathcal{E} \cdot \mathcal{E}$, we need to look at the behavior when a pair of branch points approach each other. This situation is described locally by an equation

$$y^2 = (x - e)(x - e'), \tag{4.2}$$

and we are interested in the behavior for $e \to e'$. In that limit, the equation becomes $y^2 = (x - e)^2$, and the surface breaks up into two branches $C_\pm : y = \pm(x - e)$. Each branch is a copy of the complex plane. We can express the product $\mathcal{E}(e) \cdot \mathcal{E}(e')$ for $e \to e'$ as a sum of operators of the form $\mathcal{U}_+ \otimes \mathcal{U}_-$, where $\mathcal{U}_\pm$ is an operator in the original CFT $\mathcal{W}$ on the branch $C_\pm$. Moreover, the $\mathcal{U}_\pm$ are descendants of some Virasoro primary fields $\mathcal{O}_\pm$.

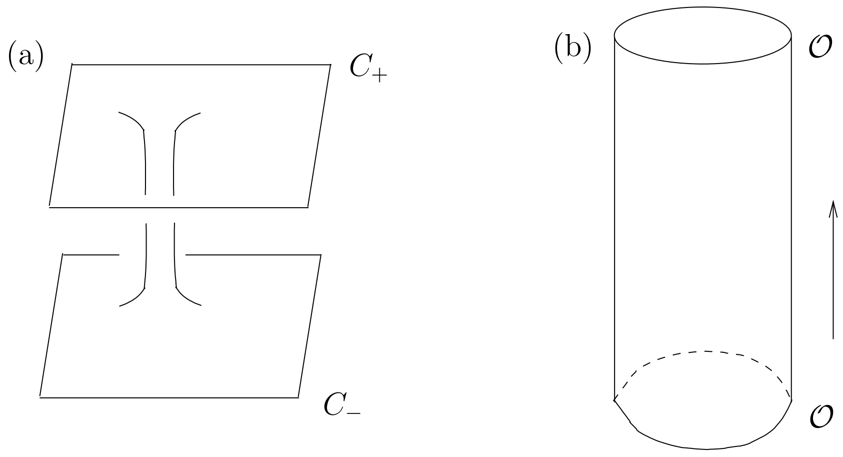

Fig. 5:

(a) The equation $y^2 = (x-e)(x-e')$ describes two branches connected by a tube. The tube collapses to a point as $e \to e'$. (b) Topologically, the tube is equivalent to a cylinder. Propagation along the tube multiplies any energy eigenstate by a c-number factor. If a primary field $\mathcal{O}$ flows in from the past, the same field flows out in the future. Alternatively, if we think of all fields as flowing out, then the two fields emerging at the two ends of the cylinder are conjugate.

The decomposition of $\mathcal{E}(e)\cdot\mathcal{E}(e')$ as a sum of descendants of operators $\mathcal{O}_+\otimes\mathcal{O}_-$ can be made in such a way that the operator $\mathcal{O}_+$ is conjugate to $\mathcal{O}_-$, meaning that the two-point function $\langle\mathcal{O}_+\mathcal{O}_-\rangle$ (in the original theory $\mathcal{W}$) is nonzero in genus zero. To see this, go back to the smooth double cover with $e \neq e'$. For e near e', the two branches are smoothly connected by a tube (fig. 5a). The surface thus has the topology of a cylinder (fig. 5b). Propagation along this cylinder is the "identity operator" on primary fields. So if a given primary state flows in at the bottom, it or flows out at the top. When we write $\mathcal{E}(e)\cdot\mathcal{E}(e')$ as a sum of descendants of operators $\mathcal{O}_+\otimes\mathcal{O}_-$, the convention is that both $\mathcal{O}_+$ and $\mathcal{O}_-$ are outgoing, so they are conjugate, rather than being equal. At any rate, the important conclusion for us is that $\mathcal{O}_+$ and $\mathcal{O}_-$ have the same dimension.

According to our interpretation of three-dimensional gravity, it is described by a conformal field theory with $c = 24k$ and no primary field other than the identity of dimension less than $k+1$. Hence, a primary operator $\mathcal{O}_+\otimes\mathcal{O}_-$ of the symmetric product theory, where $\mathcal{O}_+$ and $\mathcal{O}_-$ have the same dimension, is either the identity operator or has dimension at least $2(k+1)$.

To understand the chiral algebra or superalgebra[19] generated by $\mathcal{E}$ together with $\mathrm{Sym}^2\mathcal{V}$, we need to know all primary fields that appear with singular coefficients in the operator product $\mathcal{E}(e)\cdot\mathcal{E}(e')$. Since $\mathcal{E}$ has dimension $3k/2$, an operator that will contribute a singularity must have dimension less than $3k$ and hence at most $3k-1$. On the other hand, we have just seen that all operators appearing in the OPE are either descendants of the identity or have dimension at least $2(k+1)$.

For $k=1$ or 2, we have $3k-1<2(k+1)$. This leads to a drastic simplification, which is the reason that we will restrict ourselves here to $k=1,2$: singularities in the product $\mathcal{E}(e)\cdot\mathcal{E}(e')$ come only from the identity operator and its $\mathrm{Sym}^2\mathcal{V}$ descendants. Therefore, to understand correlation functions of $\mathcal{E}$, we need only understand the chiral algebra that is obtained by adding to $\mathrm{Sym}^2\mathcal{V}$ the primary field $\mathcal{E}$ of dimension $3k/2$ with the OPE schematically

$$\mathcal{E}\cdot\mathcal{E}\sim 1+\text{descendants}. \tag{4.3}$$

This is a chiral algebra that can be described in closed form and explicitly proved to obey the Jacobi identity. The only $\mathrm{Sym}^2\mathcal{V}$ primaries are 1 and $\mathcal{E}$. The only genus zero three point functions of primaries are $\langle 1\cdot 1\cdot 1\rangle$, which is trivial, and $\langle 1\cdot\mathcal{E}\cdot\mathcal{E}\rangle$, which is almost trivial in the sense that it reduces to a two-point function. To understand correlation functions of descendants, it suffices to understand the module for $\mathrm{Sym}^2\mathcal{V}$ consisting of $\mathcal{E}$ and its descendants. One way to construct this module explicitly is to observe that on the double cover of the x-plane, $\mathcal{E}$ simply corresponds to the identity operator and $\mathrm{Sym}^2\mathcal{V}$ to the ordinary Virasoro algebra; so this module for $\mathrm{Sym}^2\mathcal{V}$ can be deduced from the identity module for $\mathcal{V}$.

To get beyond the three-point function, the key step is to show that the chiral algebra obtained by adding $\mathcal{E}$ to $\mathrm{Sym}^2\mathcal{V}$ is consistent, that is, that the Jacobi identity is obeyed. If so, this chiral algebra determines all genus zero correlation functions of $\mathcal{E}$, and hence determines the partition function of our CFT on a general hyperelliptic Riemann surface.

In such a problem of trying to extend a known chiral algebra $\mathrm{Sym}^2\mathcal{V}$ by additional primary fields $\mathcal{E}$ (of integer or half-integer dimension, in which case one will get an extended chiral algebra or a superalgebra), the Jacobi identity is equivalent [60] to the statement that there exists a four-point function of the additional primary fields that has the appropriate singularities determined by the operator product expansion in all channels. (Such a function automatically has the right symmetries.) In the case at hand, since the only primary field that we are trying to add is $\mathcal{E}$, the only non-trivial primary four-point function that we have to consider is $\langle \mathcal{E}(e_1)\mathcal{E}(e_2)\mathcal{E}(e_3)\mathcal{E}(e_4)\rangle$. In section 4.3, we explicitly construct this four-point function and show that it behaves correctly in all channels.

---

[19] As $\mathcal{E}$ has dimension $3k/2$, it is a fermionic operator if k is odd.

In the following sense, this result is not at all surprising. The four-point function $\langle \mathcal{E}(e_1)\mathcal{E}(e_2)\mathcal{E}(e_3)\mathcal{E}(e_4)\rangle$ is essentially the partition function of the underlying CFT on the hyperelliptic Riemann surface $y^2 = (x-e_1)(x-e_2)(x-e_3)(x-e_4)$. That surface has genus 1, and we already know from section 3 that for every k there is a unique, natural genus 1 partition function with the properties we want. In section 4.4, we show explicitly, for $k = 1, 2$, that the four-point function $\langle \mathcal{E}(e_1)\mathcal{E}(e_2)\mathcal{E}(e_3)\mathcal{E}(e_4)\rangle$ determined from the OPE's agrees with the genus 1 partition function as described in section 3.

4.2. The $\mathcal{E} \cdot \mathcal{E}$ Operator Product

As a first step in that direction, we will calculate the details of the $\mathcal{E} \cdot \mathcal{E}$ operator product. For this, we start with a double cover C of the x-plane branched at e and $e' = -e$, and so described by an equation $y^2 = x^2 - e^2$. If $u = x + y$, $v = x - y$, then the equation is $uv = e^2$. The two branches C_+ and C_- correspond respectively to $u \to \infty$, $v \to 0$ and $u \to 0$, $v \to \infty$.

The path integral over C gives a quantum state Ψ in the theory $\mathcal{W} \times \mathcal{W}$, that is, one copy of $\mathcal{W}$ for each branch. This state is invariant under exchange of the two branches by the symmetry $y \to -y$, so it is really a state in the symmetric product theory $\mathrm{Sym}^2\mathcal{W}$. We are really only interested in the part of Ψ proportional to the vacuum state and its descendants. As we have seen, this part suffices to describe the desired chiral algebra if $k \leq 2$.

We will determine Ψ by using the fact that certain elements in the product $\mathcal{V}\times\mathcal{V}$ of two Virasoro algebras annihilate Ψ. This is so because there are globally-defined holomorphic vector fields on C, of the form $V_n = 2^{-n}u^{n+1}d/du = -2^{-n}(e^2/v)^n v d/dv$. Let $\mathcal{S}$ be a contour on the surface C that wraps once around the "hole." If T is the stress tensor, the contour integral $\int_{\mathcal{S}} V_n T$ can be regarded, for any n, as an operator acting on the state Ψ. This operator is invariant under deformation of the contour. It can be deformed (fig. 6) to a contour $\mathcal{S}_+$ in the upper branch C_+ or a contour $\mathcal{S}_-$ in the lower branch C_-. So we have for all n

$$\left(\int_{\mathcal{S}_+} V_n T - \int_{\mathcal{S}_-} V_n T\right)\Psi = 0. \tag{4.4}$$

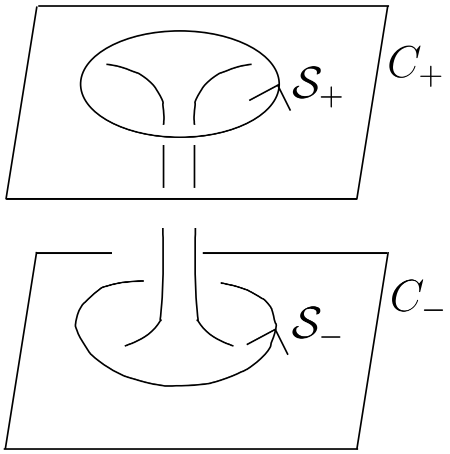

Fig. 6:

A contour $\mathcal{S}$ that wraps once around the hole can be deformed to the contour $\mathcal{S}_+$ in the upper branch or to the contour $\mathcal{S}_-$ in the lower branch.

We want to express the two contour integrals that appear here in terms of Virasoro generators on the two branches. To do this, we simply express V_n as a vector field on the branch C_+ or C_-, either of which we identify with the x-plane. For example, on the branch C_+, we write explicitly $y = \sqrt{1 - e^2/x^2} = 1 - e^2/2x^2 - e^4/8x^4 + \mathcal{O}(e^6)$. We have carried the expansion far enough to determine (for $k \leq 2$) all singular terms in the product $\mathcal{E}(e) \cdot \mathcal{E}(-e)$. So

$$V_n = x^{n+1}\left(1 - (n+2)\frac{e^2}{4x^2} + \frac{e^4}{x^4}\left(\frac{n^2+n-4}{32}\right) + \mathcal{O}(e^6)\right)\frac{d}{dx}. \tag{4.5}$$

This means, if we ignore the conformal anomaly for the moment, that $\int_{\mathcal{S}_+} V_n T$ corresponds, on the branch C_+, to the operator

$$Q_n^+ = L_n^+ - \frac{n+2}{4}e^2 L_{n-2}^+ + \left(\frac{n^2+n-4}{32}\right)e^4 L_{n-4}^+ + \mathcal{O}(e^6). \tag{4.6}$$

As a check, one can verify that $[Q_n^+, Q_m^+] = (n-m)Q_{n+m}^+$. Similarly, $\int_{\mathcal{S}_-} V_n T$ corresponds on the branch C_- to the operator

$$Q_n^- = \left(\frac{e^2}{4}\right)^n \left(L_{-n}^- - e^2\left(\frac{-n+2}{4}\right)L_{-n-2}^- + e^4\left(\frac{n^2-n-4}{32}\right)L_{-n-4}^- + \mathcal{O}(e^6)\right). \tag{4.7}$$

The state Ψ is determined for each value of e (up to multiplication by a complex scalar) by the condition that $\widehat{Q}_n\Psi = 0$, where $\widehat{Q}_n = Q_n^+ - Q_n^-$. However, because of the Virasoro anomaly some c-number terms must be added to the above formulas, reflecting the conformal anomaly in the mapping from u to x. There is no such c-number contribution to $\widehat{Q}_0$, since it cancels between the two branches. The c-numbers in $\widehat{Q}_n$ for other n can be conveniently determined by requiring that $[\widehat{Q}_n, \widehat{Q}_m] = (n-m)\widehat{Q}_{n+m}$. For our purposes, the only formulas we need are

$$\begin{aligned}
\widehat{Q}_0 &= \left(L_0^+ - \frac{e^2}{2}L_{-2}^+ - \frac{e^4}{8}L_{-4}^-\right) - \left(L_0^+ - \frac{e^2}{2}L_{-2}^- - \frac{e^4}{8}L_{-4}^-\right) + \dots \\
\widehat{Q}_1 &= \left(L_1^+ - \frac{3e^2}{4}L_{-1}^+ - \frac{e^4}{16}L_{-3}^+\right) - \frac{e^2}{4}\left(L_{-1}^- - \frac{e^2}{4}L_{-3}^-\right) + \dots \\
\widehat{Q}_2 &= L_2^+ - e^2L_0^+ - 3ke^2 + \frac{e^4}{16}L_{-2}^+ - \frac{e^4}{16}L_{-2}^- + \dots .
\end{aligned} \tag{4.8}$$

Terms of order e^6 have been omitted. The constant in $\widehat{Q}_2$ was obtained from $[\widehat{Q}_0, \widehat{Q}_2] = -2\widehat{Q}_2$.

By requiring that $\widehat{Q}_m\Psi = 0$ for $m = 0, 1, 2$, and that Ψ converges to the Fock vacuum $|\Omega\rangle$ for $e \to 0$, we now find Ψ to be

$$\begin{aligned}
\Psi(e) = \Bigg(1 &+ \frac{e^2}{4}(L_{-2}^+ + L_{-2}^-) + \frac{e^4}{32}(L_{-4}^+ + L_{-4}^-) \\
&+ \frac{e^4}{32}(L_{-2}^+ + L_{-2}^-)^2 + \frac{e^4}{192k}L_{-2}^+L_{-2}^- + \dots\Bigg)|\Omega\rangle.
\end{aligned} \tag{4.9}$$

We can immediately use this formula to determine the singular part of the $\mathcal{E}\cdot\mathcal{E}$ OPE. We normalize $\mathcal{E}$ so that the most singular term is $\mathcal{E}(x/2)\mathcal{E}(-x/2) \sim 1/x^{3k}$. Then, setting $e = x/2$, we get

$$\begin{aligned}
\mathcal{E}(x/2)\mathcal{E}(-x/2) \sim \frac{1}{x^{3k}}\Bigg(1 &+ \frac{x^2}{16}T + \frac{x^4}{2^{10}}\partial^2T \\
&+ \frac{x^4}{2^9}T\star T + \frac{x^4}{3k\cdot 2^{10}}T^+T^-\Bigg) + \mathcal{O}(x^{-3k+6}).
\end{aligned} \tag{4.10}$$

All we have done is to write, on the right hand side, the operator that corresponds to the state $\Psi(e)/x^{3k}$, for $e = x/2$. (The factor of $1/x^{3k}$ must be supplied by hand, since in defining $\Psi(e)$, we just normalized it so that the coefficient of the Fock vacuum is 1.) Also, T^+ and T^- are the stress tensors on the branches C_+ and C_-, respectively. $T = T^+ + T^-$ is the diagonal or total stress tensor, and similarly $L_n = L_n^+ + L_n^-$. In addition, we use the fact that in the correspondence between operators and states, the states $L_{-2}^{\pm}|\Omega\rangle$ correspond to the operators $T^{\pm}$, while $L_{-4}^{\pm}|\Omega\rangle$ correspond to $\frac{1}{2}\partial^2T^{\pm}$. Finally, we have written $T\star T$ for the operator corresponding to the state $L_{-2}^2|\Omega\rangle$. $T\star T(0)$ can be obtained as the term of order x^0 in the operator product $T(x)\cdot T(0)$.

4.3. Determining The Four-Point Function

Our goal is to use the explicit formula (4.10) to show that the chiral algebra obtained by adjoining $\mathcal{E}$ to $\mathrm{Sym}^2\mathcal{V}$ obeys the Jacobi identity. The Jacobi identity is equivalent to the existence of a four-point function for primary fields with the right symmetry properties and the right OPE singularities in all channels. It is enough to consider primary fields with respect to the $\mathrm{Sym}^2\mathcal{V}$ algebra, which we already know to exist. The only non-trivial case is the four-point function of $\mathcal{E}$.

For $k = 1$, the singular part of the $\mathcal{E} \cdot \mathcal{E}$ operator product only involves the diagonal stress tensor $T = T^+ + T^-$. This is a substantial simplification; the extended chiral superalgebra obtained by incorporating $\mathcal{E}$ can be viewed an extension of an ordinary Virasoro algebra $\mathcal{V}$, rather than a symmetric product $\mathrm{Sym}^2\mathcal{V}$. In fact, this algebra is a familiar one, an $\mathcal{N} = 1$ super Virasoro algebra:

$$\mathcal{E}(x/2)\mathcal{E}(-x/2) \sim \frac{1}{x^3}\left(1 + \frac{x^2}{16}T\right) + \mathcal{O}(x). \tag{4.11}$$

The stress tensor T has $c = 48$ (as it is the diagonal stress tensor in the symmetric product of two copies of a $c = 24$ theory). A superconformal field theory with this central charge can be constructed from 32 chiral multiplets consisting of bosonic and fermionic fields ϕ_i and ψ_i, where $\langle\phi_i(x)\phi_j(0)\rangle = -\delta_{ij}\ln(x)$, and $\langle\psi_i(x)\psi_j(0)\rangle = \delta_{ij}/x$, for $i, j = 1, \ldots, 32$. In terms of these fields, we can take

$$\mathcal{E} = \frac{i}{4\sqrt{2}}\sum_{k=1}^{32}\psi_k\partial\phi_k. \tag{4.12}$$

With this free field realization, all correlation functions of $\mathcal{E}$ can be explicitly computed. For example, the four-point function is

$$\begin{aligned}\big\langle\mathcal{E}(e_1)\mathcal{E}(e_2)\mathcal{E}(e_3)\mathcal{E}(e_4)\big\rangle = \prod_{i=1}^{4}(de_i)^{3/2}\Bigg(&\left(\frac{1}{(e_1 - e_2)^3(e_3 - e_4)^3} + \text{cyclic}\right)\\ &+\frac{3}{32}\frac{1}{\prod_{i<j}(e_i - e_j)}\Bigg),\end{aligned} \tag{4.13}$$

where additional terms obtained by cyclic permutations of e_2, e_3, e_4 are to be added in the first term on the right. We will eventually compare this formula to the known genus 1 partition function of the monster theory of $k = 1$.

In (4.13), we included a factor of $(de)^{3/2}$ for each operator $\mathcal{E}(e)$ to reflect the fact that $\mathcal{E}$ has dimension 3/2. Thus the correlation "function" $\langle\mathcal{E}(e_1)\mathcal{E}(e_2)\mathcal{E}(e_3)\mathcal{E}(e_4)\rangle$ is most naturally understood as a 3/2-differential in each variable. This factor is often omitted in writing such formulas, and we will do so as an abbreviation except when the factor is important.

For $k = 2$, the singular part of $\mathcal{E}\cdot\mathcal{E}$ cannot be expressed in terms of the diagonal stress tensor T only, and there is no way to avoid using $\mathrm{Sym}^2\mathcal{V}$. Correspondingly, the chiral algebra for $k = 2$ seems to be unfamiliar, and it is considerably harder to get the analog of (4.13) for $k = 2$. Since we do not have an explicit realization of the algebra analogous to (4.12), we cannot compute the four-point function directly, and instead we will determine it by requiring the appropriate OPE singularities.

The function $\langle\mathcal{E}(e_1)\mathcal{E}(e_2)\mathcal{E}(e_3)\mathcal{E}(e_4)\rangle$, with $e_1,\dots,e_4\in C_0\cong\mathbb{CP}^1$, must be symmetric in all arguments and must have the appropriate OPE singularities in all channels. In addition, it is highly constrained by invariance under the action of $SL(2,\mathbb{C})$ on C_0. The most general "function," actually a cubic differential in each variable, that is symmetric, $SL(2,\mathbb{C})$-invariant, and consistent with at least the leading OPE singularity, is

$$\begin{aligned}\langle\mathcal{E}(e_1)\mathcal{E}(e_2)\mathcal{E}(e_3)\mathcal{E}(e_4)\rangle = &\prod_{i=1}^{4}(de_i)^3\Bigg(\left(\frac{1}{(e_1-e_2)^6(e_3-e_4)^6}+\text{cyclic}\right)\\ &+A\left(\frac{1}{(e_1-e_2)^4(e_3-e_4)^4}\prod_{i=1,2,\,j=3,4}\frac{1}{e_i-e_j}+\text{cyclic}\right)\\ &+B\frac{1}{\prod_{i<j}(e_i-e_j)^2}.\Bigg).\end{aligned} \tag{4.14}$$

Cyclic permutations of e_2, e_3, e_4 are to be added as shown, and the coefficients A and B must be determined to ensure that the OPE singularities are correct.

After a detailed calculation, one finds that the right values are

$$A=\frac{3}{16},\ B=\frac{12k+1}{2^{16}} \tag{4.15}$$

where of course $k = 2$. To get these formulas, one may for instance set $e_1 = -e_2 = e$, and use (4.10) to determine the singular behavior for $e \to 0$. In this way, one expresses the singular behavior of the four-point function in terms of three-point functions $\langle\mathcal{X}(0)\mathcal{E}(e_3)\mathcal{E}(e_4)\rangle$, where $\mathcal{X}$ is one of the descendants of the identity that appear in (4.10).

The coefficient A appears in the coefficient of $1/e^4$ for $e \to 0$, and in determining it, the only important choices of $\mathcal{X}$ are 1 and T. The three-point functions that we need are

$$\begin{aligned} \bigl\langle 1 \cdot \mathcal{E}(z)\mathcal{E}(w)\bigr\rangle &= \frac{1}{(z-w)^6} \\ \bigl\langle T(x)\mathcal{E}(z)\mathcal{E}(w)\bigr\rangle &= \frac{3}{(z-x)^2(w-x)^2(z-w)^4}. \end{aligned} \tag{4.16}$$

The first is immediate from the way we have normalized $\mathcal{E}$. The second, since the three fields involved are quasi-primary fields (they transform as primaries under $SL(2,\mathbb{C})$) is determined by $SL(2,\mathbb{C})$ invariance up to a constant multiple. The constant can be determined using the $T \cdot \mathcal{E}$ OPE (which reflects the fact that $\mathcal{E}$ is a primary of dimension $3 = 3k/2$) or the $\mathcal{E} \cdot \mathcal{E}$ OPE.

To determine B, we need three more three-point functions, namely

$$\begin{aligned} \bigl\langle \partial^2 T(0)\mathcal{E}(z)\mathcal{E}(w)\bigr\rangle &= \left(\frac{1}{z^2} + \frac{1}{w^2}\right)\frac{18}{z^2 w^2 (z-w)^4} + \frac{24}{z^3 w^3 (z-w)^4} \\ \bigl\langle T \star T(0)\mathcal{E}(z)\mathcal{E}(w)\bigr\rangle &= \left(\frac{5}{z^2} + \frac{5}{w^2} - \frac{4}{zw}\right)\frac{3}{z^2 w^2 (z-w)^4} \\ \bigl\langle T^+T^-(0)\mathcal{E}(z)\mathcal{E}(w)\bigr\rangle &= \left(\frac{9k^2}{16} + \frac{3k}{64}\right)\frac{1}{z^4 w^4 (z-w)^2}. \end{aligned} \tag{4.17}$$

The first of these results is obtained simply by differentiating the second formula in (4.16).

To get the second, we use the fact that

$$T \star T(0) = \mathrm{Res}_{x=0} \frac{dx\, T(x)}{x} T(0). \tag{4.18}$$

Now consider the expression

$$\Bigl\langle \frac{dx\, T(x)}{x} T(0)\mathcal{E}(z)\mathcal{E}(w)\Bigr\rangle. \tag{4.19}$$

We view this as a differential form on the complex x-plane, with z and w kept fixed. As such, it has poles precisely at $x = 0, z, w$. The residue at $x = 0$ is the desired three-point function $\bigl\langle T \star T(0)\mathcal{E}(z)\mathcal{E}(w)\bigr\rangle$. The residues at at $x = z, w$ can be computed in terms of the correlator $\bigl\langle T(0)\mathcal{E}(z)\mathcal{E}(w)\bigr\rangle$ by using the fact that $\mathcal{E}$ is a primary of dimension 3, which determines the singular behavior of the product $T \cdot \mathcal{E}$. The sum of the residues must vanish, and this gives our result.

Finally, to get the last formula in (4.17), we note first that since the operators T^+T^- and $\mathcal{E}$ are quasiprimary fields of dimension 4 and 3, we have

$$\left\langle T^+T^-(x)\mathcal{E}(z)\mathcal{E}(w)\right\rangle = \frac{\theta}{(x-z)^4(x-w)^4(z-w)^2}, \tag{4.20}$$

for some constant θ. We have

$$\lim_{w\to\infty}\frac{\left\langle T^+T^-(x)\mathcal{E}(0)\mathcal{E}(w)\right\rangle}{\left\langle\mathcal{E}(0)\mathcal{E}(w)\right\rangle} = \frac{\theta}{x^4}. \tag{4.21}$$

This is supposed to be computed in the theory $\mathrm{Sym}^2\mathcal{W}$ on the x-plane, with insertions of $\mathcal{E}$ at $0, w$. This is equivalent to a computation in the theory $\mathcal{W}$ on a double cover of the x-plane branched at $0, w$. In the limit $w \to \infty$, the double cover is described by the equation $y^2 = x$, and it is convenient to transfer the computation to the y-plane.

We will now write the stress tensor explicitly as T_{xx} or T_{yy} depending on which local parameter is used in defining it. Allowing for the conformal anomaly, the relation between the stress tensor T_{xx} on the x-plane and the corresponding stress tensor T_{yy} on the y-plane is

$$\left(\frac{\partial y}{\partial x}\right)^2 T_{yy} = T_{xx} - \frac{c}{12}\{y,x\}, \tag{4.22}$$

where $\{y,x\}$ denotes the Schwarzian derivative of these two functions. With $y^2 = x$, we get $\{y,x\} = 3/8x^2$. In the case of interest, $c = 24k$ so

$$T_{xx} = \frac{1}{4x}T_{yy} + \frac{3k}{4x^2}. \tag{4.23}$$

This formula enables us to express T^+ in terms of $T_{yy}|_{y=\sqrt{x}}$ and T^- in terms of $T_{yy}|_{y=-\sqrt{x}}$. The limit in (4.21) becomes

$$\left\langle \left(\frac{1}{4x}T_{yy}|_{y=\sqrt{x}} + \frac{3k}{4x^2}\right)\left(\frac{1}{4x}T_{yy}|_{y=-\sqrt{x}} + \frac{3k}{4x^2}\right)\right\rangle. \tag{4.24}$$

(The idea is that passing to the y-plane eliminates the twist operators $\mathcal{E}$ from the formalism, and replaces $T^\pm(x)$ by a stress tensor evaluated at $y = \pm\sqrt{x}$.) Using the fact that in conformal field theory on the y-plane, $\langle T_{yy}\rangle = 0$ and $\left\langle T_{yy}(y_1)T_{yy}(y_2)\right\rangle = c/2(y_1 - y_2)^4$ with $c = 24k$, the correlation function in (4.24) can be evaluated to give θ/x^4 with $\theta = 9k^2/16 + 3k/64$. This gives the last formula in (4.17).

With the aid of the three-point functions in (4.16) and (4.17) and the operator product formula (4.10), one can verify that the candidate four-point function (4.14) has the right singularities precisely if the coefficients A and B are as claimed in (4.15).

Our derivation has in fact been somewhat redundant, since the formulas for three-point functions can largely be deduced from the formula for the $\mathcal{E}\cdot\mathcal{E}$ operator product, and vice-versa.

4.4. The Genus One Partition Function Revisited

We will now explicitly use our formulas for the four-point function of the twist field $\mathcal{E}$ to recover the partition functions of a $k = 1$ or $k = 2$ extremal CFT on a Riemann surface of genus 1.

First we must describe the necessary formalism more precisely. The partition function $Z_C(e_1, e_2, \ldots, e_{2g+2})$ of any conformal field theory $\mathcal{W}$ on the hyperelliptic Riemann surface C defined by

$$y^2 = \prod_{i=1}^{2g+2} (x - e_i) \tag{4.25}$$

can indeed be expressed in terms of the genus zero twist field correlation function

$$\big\langle \mathcal{E}(e_1)\mathcal{E}(e_2)\ldots\mathcal{E}(e_{2g+2})\big\rangle. \tag{4.26}$$

However, to do so requires an important detail that we have not yet described.

There are at first sight several strange features in relating Z_C to the twist field correlation function:

(1) The dimension of the twist field $\mathcal{E}$ seems to be wrong. The Riemann surface C degenerates as $e_i \to e_j$ for any i and j. As the complex structure of C is invariant under the exchange $e_i \leftrightarrow e_j$, a natural local parameter near the degeneration locus on the moduli space is actually $w = (e_i - e_j)^2$. (For example, this statement can be made precise using eqn. (4.30) below.) One expects Z_C to behave for $e_i \to e_j$ as w^{-k}, since the ground state energy is $-k$. However, as $\mathcal{E}$ has dimension $3k/2$, the behavior of the twist field correlation function as $e_i \to e_j$ is actually $(e_i - e_j)^{-3k} \sim w^{-3k/2}$.

(2) This brings in relief the fact that if k is odd, $\mathcal{E}$ actually has half-integral dimension and so is fermionic. For odd k, the twist field correlation function (4.26) actually changes sign under exchange of e_i and e_j, while Z_C is invariant under this exchange.

(3) The twist field correlation function is most naturally understood as a $3k/2$-differential in each variable. We have written the formulas (4.13) and (4.14) in such a way as to emphasize this. It may not be immediately clear what this means for the partition function Z_C.

The answer to all of these questions has to do with the proper treatment of the conformal anomaly in the holomorphic context. We postpone a full explanation to section

4.5 and for now we merely write down the precise relation between the genus 1 partition function and the twist field correlation function:

$$Z_C(e_1, e_2, \ldots, e_4) = 2^{8k}\Bigl(\prod_{1\le i<j\le 4}(e_i - e_j)^k\Bigr)\bigl\langle\mathcal{E}(e_1)\mathcal{E}(e_2)\ldots\mathcal{E}(e_4)\bigr\rangle. \tag{4.27}$$

The factor of 2^{8k} just reflects the way we have normalized $\mathcal{E}$. The factor of $\prod_{i<j}(e_i - e_j)^k$ resolves problems (1) and (2) above. In section 4.5, we will explain the meaning of that factor and its relation to problem (3) (as well as the generalization to higher genus). For now, we merely mention that in eqn. (4.27), the twist field correlation function should be understood as a function, without the factor of $\prod_i (de_i)^{3k/2}$.

Now we will use the general relation (4.27) along with our previous formulas for the twist field correlation functions to analyze the genus 1 partition function for $k = 1, 2$. We make an $SL(2,\mathbb{C})$ transformation to set $e_4 = \infty$ and to fix

$$e_1 + e_2 + e_3 = 0. \tag{4.28}$$

The genus 1 partition function at $k = 1$ is then, using (4.13),

$$Z_C(k=1) = \frac{2^8}{\prod_{i<j}(e_i - e_j)^2}\bigl((e_1 - e_3)^3(e_2 - e_3)^3 + \text{cyclic}\bigr) + 24. \tag{4.29}$$

We want to express this in terms of $q = \exp(2\pi i\tau)$, the usual parameter on the genus 1 moduli space, and to show explicitly that Z_C has the expected behavior near $q = 0$. The classical formulas are

$$\begin{aligned} e_1 - e_2 &= \theta_3^4(0,\tau) \\ e_3 - e_2 &= \theta_1^4(0,\tau) \\ e_1 - e_3 &= \theta_2^4(0,\tau), \end{aligned} \tag{4.30}$$

where

$$\begin{aligned} \theta_1(0,\tau) &= \sum_{n\in\mathbb{Z}} q^{(n+1/2)^2/2} \\ \theta_2(0,\tau) &= \sum_{n\in\mathbb{Z}} (-1)^n q^{n^2/2} \\ \theta_3(0,\tau) &= \sum_{n\in\mathbb{Z}} q^{n^2/2}. \end{aligned} \tag{4.31}$$

Expanding (4.29) near $q = 0$, one can readily verify the expected behavior $Z_C(k=1) = q^{-1} + \mathcal{O}(q)$. Since Z_C is manifestly modular-invariant, this implies that Z_C must equal

J. This can also be verified directly by comparing (4.29) to the classical formula for the j-function

$$j(q) = 2^5 \frac{\left((e_1-e_2)^2+(e_2-e_3)^2+(e_3-e_1)^2\right)^3}{\prod_{i<j}(e_i-e_j)^2} \tag{4.32}$$

and recalling that $J = j - 744$.

The case $k=2$ can be treated similarly. Our previous formula (4.14) for the twist field four-point function implies, via (4.27), a formula for $Z_C(k=2)$. If we take $e_4 \to \infty$ and $e_1+e_2+e_3=0$, this formula becomes

$$\begin{aligned} Z_C(k=2) = & 2^{16}\left(\frac{(e_1-e_3)^2(e_2-e_3)^2}{(e_1-e_2)^4}+\text{cyclic}\right) \\ & + 3\cdot 2^{12}\left(\frac{(e_1-e_3)(e_2-e_3)}{(e_1-e_2)^2}+\text{cyclic}\right)+(12k+1). \end{aligned} \tag{4.33}$$

One can expand this near $q=0$ and verify the expected behavior $Z_C(k=2) = q^{-2}+1+\mathcal{O}(q)$. Together with modular invariance, this implies that $Z_C(k=2) = J^2 - 393767$, as one can also verify directly using (4.32).

4.5. Role Of The Conformal Anomaly

Naively speaking, the partition "function" of a conformal field theory on a Riemann surface C depends only on the complex or conformal structure of C.

Actually, because of the conformal anomaly, things are more subtle. The usual way to describe the situation is to endow C with a metric h, and to think of the partition function as a function $Z(h)$ that transforms in a certain prescribed way (depending on the central charge) under conformal rescaling $h \to e^{\phi}h$ of the metric.

This description is natural in differential geometry. However, it has a few limitations. One is that it really only gives an adequate framework if the left and right central charges c_L and c_R are equal. A second limitation, more crucial for our purposes, is that it is not well-adapted to holomorphic factorization. In a holomorphic CFT, everything will be much simpler if we can incorporate the conformal anomaly in purely holomorphic terms.

An alternative approach is to think of the partition function not as a function but as a section of a suitable line bundle $\mathcal{R}$ over $\mathcal{M}$, the moduli space of complex Riemann surfaces. This approach is developed in detail in [61]. Holomorphic factorization is incorporated naturally in this approach by saying that in a holomorphic CFT, $\mathcal{R}$ is a holomorphic line bundle over $\mathcal{M}$.

More specifically, $\mathcal{R} \cong \mathcal{L}^{c/2}$, where c is the central charge and $\mathcal{L}$ is a fundamental line bundle over $\mathcal{M}$ that is known as the determinant line bundle. $\mathcal{L}$ is defined as follows. Let p be a point in $\mathcal{M}$ corresponding to a Riemann surface C. Then $\mathcal{L}_p$, the fiber of $\mathcal{L}$ at p, is the top exterior power of the vector space $H^0(C, K_C)$ of holomorphic differentials on C. So if C has genus g and $\omega_1, \ldots, \omega_g$ are holomorphic differentials on C, then the expression $\omega_1 \wedge \omega_2 \wedge \ldots \wedge \omega_g$ defines a vector in $\mathcal{L}_p$. In our problem, $c = 24k$, and the partition function is a section of $\mathcal{L}^{12k}$.

On a hyperelliptic Riemann surface

$$y^2 = \prod_{i=1}^{2g+2} (x - e_i), \tag{4.34}$$

we can make this completely explicit. A basis of the space of holomorphic differentials is given by

$$\frac{dx}{y}, \frac{x\,dx}{y}, \frac{x^2\,dx}{y}, \ldots, \frac{x^{g-1}\,dx}{y}. \tag{4.35}$$

A section of $\mathcal{L}^{12k}$ over the space of hyperelliptic equations is hence an expression of the form

$$\Theta = \left(\frac{dx}{y} \wedge \frac{x\,dx}{y} \wedge \frac{x^2\,dx}{y} \wedge \ldots \wedge \frac{x^{g-1}\,dx}{y} \right)^{12k} F(e_1, \ldots, e_{2g+2}). \tag{4.36}$$

To get a section of $\mathcal{L}^{12k}$ over the moduli space of hyperelliptic Riemann surfaces, Θ must be invariant under the action of $SL(2, \mathbb{C})$ on the space of hyperelliptic equations. This action takes the form

$$\begin{aligned} e_i &\to \frac{ae_i + b}{ce_i + d} \\ x &\to \frac{ax + b}{cx + d} \\ y &\to \frac{y}{(cx + d)^{g+1} \prod_{i=1}^{2g+2} (ce_i + d)^{1/2}}, \end{aligned} \tag{4.37}$$

and the condition for Θ to be invariant is that F transforms by

$$F(e_1, \ldots, e_{2g+2}) \to F(e_1, \ldots, e_{2g+2}) \prod_{i=1}^{2g+2} (ce_i + d)^{-6kg}. \tag{4.38}$$

The twist field correlation function, on the other hand, is of the form

$$\left\langle \mathcal{E}(e_1)\mathcal{E}(e_2) \ldots \mathcal{E}(e_{2g+2}) \right\rangle = \prod_{i=1}^{2g+2} (de_i)^{3k/2} G(e_1, \ldots, e_{2g+2}) \tag{4.39}$$

for some "function" G. $SL(2,\mathbb{C})$ invariance of the correlation function means that G transforms by

$$G(e_1,\dots,e_{2g+2}) \to G(e_1,\dots,e_{2g+2}) \prod_{i=1}^{2g+2}(ce_i+d)^{3k}. \tag{4.40}$$

Comparing (4.38) and (4.40), we see that the two transformation laws are consistent if the relation between F and G is

$$F(e_1,\dots,e_{2g+2}) = A_g\, G(e_1,\dots,e_{2g+2}) \prod_{1\le i<j\le 2g+2}(e_i-e_j)^{3k} \tag{4.41}$$

with some constant A_g. Moreover, this is the most general transformation between F and G that is holomorphic, invariant under permutations of the e_i, and an isomorphism as long as the e_i are all distinct. So it must be correct with some choice of the constant. (The relation between F and G is actually part of a general theory that is briefly indicated below.)

This is not the whole story. The partition function has another important property in genus 1: it can be regarded as an ordinary function, rather than a section of a line bundle. Indeed, the genus 1 partition function can be defined as a trace, $Z(q) = \mathrm{Tr}\, q^{L_0}$, and in this form it manifestly is equal to an ordinary function of q. Yet in the above presentation, the genus 1 partition function is a section of $\mathcal{L}^{12k}$. What reconciles the two points of view is that the line bundle $\mathcal{L}^{12}$ is trivial in genus 1. If we describe a genus 1 Riemann surface C by the hyperelliptic equation $y^2 = \prod_{i=1}^{4}(x-e_i)$, then as explained in [61], $\mathcal{L}^{12}$ is trivialized by the section

$$s = \left(\frac{dx}{y}\right)^{12} \prod_{1\le i<j\le 4}(e_i-e_j)^2. \tag{4.42}$$

The point of this formula is that s is holomorphic, $SL(2,\mathbb{C})$-invariant, invariant under permutations of the e_i, and nonzero as long as the e_i are all distinct (so that C is smooth). A power $\mathcal{L}^n$ of the line bundle $\mathcal{L}$ can be trivialized in this fashion precisely if n is an integer multiple of 12 (and this gives one way to understand the fact that holomorphic factorization is possible only if c is an integer multiple of 24). The genus 1 partition function Z understood as an ordinary function is obtained from the section Θ of $\mathcal{L}^{12k}$ by dividing by s^k. Thus

$$Z = \frac{F}{\prod_{1\le i<j\le 4}(e_i-e_j)^{2k}}. \tag{4.43}$$

Combining this with (4.41), we get the relation (4.27) between the genus 1 partition function, understood as a trace, and the correlation function of twist fields:

$$Z = A_1\Big(\prod_{1\le i<j\le 4}(e_i-e_j)\Big)\big\langle \mathcal{E}(e_1)\mathcal{E}(e_2)\mathcal{E}(e_3)\mathcal{E}(e_4)\big\rangle. \tag{4.44}$$

The numerical value of the constant A_1 depends on how the twist field $\mathcal{E}$ has been normalized.

What about $g>1$? What is the best formula depends on how one prefers to treat the conformal anomaly, and there seems to be in the physics literature no standard recipe for doing so in the holomorphic context. To make contact with the genus 2 formulas of Tuite [54], we may proceed as follows. A genus 2 Riemann surface is always a hyperelliptic curve, $y^2=\prod_{i=1}^6(x-e_i)$. In genus 2, we cannot trivialize the line bundle[20] $\mathcal{L}^{12}$, but we can trivialize $\mathcal{L}^{10}$ by an obvious analog of (4.42):

$$\widetilde{s}=\left(\frac{dx}{y}\wedge\frac{x\,dx}{y}\right)^{10}\prod_{1\le i<j\le 6}(e_i-e_j)^2. \tag{4.45}$$

Hence, instead of regarding the genus 2 partition function as a section Θ of $\mathcal{L}^{12k}$, we can regard it as a section $Z=\Theta/\widetilde{s}^k$ of $\mathcal{L}^{2k}$. If we do this, then the relation between Z and the twist field correlation function is the obvious analog of (4.44):

$$Z = A_2\Big(\prod_{1\le i<j\le 6}(e_i-e_j)\Big)\big\langle \mathcal{E}(e_1)\mathcal{E}(e_2)\dots\mathcal{E}(e_6)\big\rangle. \tag{4.46}$$

It can be shown that, in genus 2, a section of $\mathcal{L}^r$ is the same as a Siegel modular function of weight r. So the formula (4.46) is the one we should use if we wish to regard the genus 2 partition function at $c=24k$ as a Siegel modular function of weight $2k$, as was done in [54]. This probably gives the most intuitively appealing formulas in genus 2. For genus greater than 2, we leave the choice of the most useful formalism to the reader.

We conclude by briefly sketching the theoretical context for the formula (4.41). In doing so, we will not limit ourselves to the case of a hyperelliptic Riemann surface, but will consider an arbitrary base curve C_0 and a two-fold cover $C\to C_0$ branched at points $e_1,\dots,e_s$. Let K_i be the cotangent bundle to C_0 at the point e_i. Let $\mathcal{L}_{C_0}$ and $\mathcal{L}_C$ be the determinant lines of C_0 and C respectively. Then as has been shown by P. Deligne, using results in [62], there is a natural isomorphism $\mathcal{L}_C^8\cong\mathcal{L}_{C_0}^{16}\otimes_i K_{C_i}$. If C_0 is of genus zero, then $\mathcal{L}_{C_0}$ is naturally trivial, and the $3k/2$ power of this isomorphism is the map in (4.41). (The isomorphism has a natural square root, relevant if k is odd.)

---

[20] This fact is consistent with holomorphic factorization at $c=24k$, since the genus 2 partition function cannot be written as a trace and so need not be definable as an ordinary function.

Appendix A. More Extremal Partition Functions

F In section 3.3, we have already described the extremal superconformal partition functions F_{k^*} for $k^* \leq 4$. The purpose of this appendix is to briefly describe these functions, and the corresponding Ramond partition functions H_{k^*}, for $5 \leq k^* \leq 10$.

For $k^* = 5$, we have

$$\begin{aligned} F_5 &= K^5 - 1380K^3 - 10239K^2 + 324871K + 2579929 \\ &= q^{-5/2} + q^{-1} + q^{-1/2} + 1 + 924492q^{1/2} + 185710868q + 11953414737q^{3/2} \\ &\quad + 416513865728q^2 + 9727092442216q^{5/2} + \dots . \end{aligned} \tag{A.1}$$

The corresponding Ramond partition function is

$$H_5 = 143+371027968q+832984743936q^2+340658459983872q^3+56418463131631616q^4+\dots . \tag{A.2}$$

The coefficients in these series cannot be expressed as linear combinations of dimensions of monster representations with reasonably small coefficients. But strangely, at least one difference can be so represented; the difference between the coefficient of q in F_5 and half the corresponding coefficient in H_5 is $196884 = 1 + 196883$. (The coefficients in H_5, except the first one, are even because of supersymmetry, so it is natural to divide by 2.) Also, the first coefficient in H_5, namely 143, is the dimension of the smallest nontrivial representation of a sporadic finite group known as the Suzuki group. Unfortunately, the other coefficients are too large, and the representations of the Suzuki group too small, for it to be easy to get convincing evidence of whether the Suzuki group is a symmetry of supergravity at $k^* = 5$.

For $k^* = 6$, the partition functions are

$$\begin{aligned} F_6 &= K^6 - 1656K^4 - 12287K^3 + 618373K^2 + 6487237K - 12026567 \\ &= q^{-3} + q^{-3/2} + q^{-1} + q^{-1/2} + 1 + 3724378q^{1/2} + 1298410586q \\ &\quad + 127852130050q^{3/2} + 6378693040128q^2 + 204402839559265q^{5/2} + \dots \\ H_6 &= 1 + 2589372416q + 12754796707840q^2 \\ &\quad + 9529193701720064q^3 + 2622934801904828416q^4 + \dots . \end{aligned} \tag{A.3}$$

The fact that the leading coefficient in the Ramond sector is 1 suggests that the model may be invariant under a very large discrete symmetry group. The monster $\mathbb{M}$ does not work, since the first non-trivial NS coefficient 3724378 cannot be expressed nicely in terms of dimensions of monster representations. It turns out that another large sporadic group, the baby monster $\mathbb{B}$, is a better candidate. The dimensions $r_1, \ldots, r_{12}$ of the first 12 irreducible representations of $\mathbb{B}$ are listed in Table 3. In terms of those dimensions, we find that the first two non-trivial NS coefficients in the partition functions can be expressed as follows

$$\begin{aligned} 3724378 &= 7r_1 + 4r_2 + 3r_3 + 3r_4 \\ 1298410586 &= 14r_1 + 16r_2 + 7r_3 + 8r_4 + 4r_6 + 3r_7 + r_8 + 2r_9. \end{aligned} \tag{A.4}$$

These formulas are not unique, as the r_i obey linear relations with small coefficients, for example $r_1 + r_3 + r_5 + r_8 = r_2 + r_4 + r_9$. If we let h_1 denote the first non-trivial coefficient in H_6, then it turns out that $h_1/2 = f_1 - f_{1/2} = 1298410586 - 3724378$. So by subtracting the formulas in (A.4), $h_1/2$ can also be expressed as a positive linear combination of the r_i with fairly small coefficients. If is also true that $h_2/2 = f_2 - f_1 + f_{1/2}$, and so is consistent with $\mathbb{B}$ symmetry if f_2 can be suitably expressed in terms of the r_i.

These results are suggestive of baby monster symmetry at $k^* = 6$, though they are perhaps a little less striking than the evidence presented in section 3.3 for monster symmetry at $k^* = 4$, since the required coefficients are larger and the dimensions involved are smaller. Also, it is harder to continue this analysis beyond the first few coefficients, as many representations of $\mathbb{B}$ come in.

r_{11}	3214743741
r_{12}	4221380670

Table 3. Presented here from [53] are the dimensions r_i of the i^{th} irreducible representation of the baby monster group $\mathbb{B}$, for $i = 1, \ldots, 12$.

We present the remaining cases with little comment. For $k^* = 7$, we have

$$\begin{aligned} F_7 &= K^7 - 1932K^5 - 14335K^4 + 988051K^3 + 11525041K2 - 75824563K - 840705550 \\ &= q^{-7/2} + q^{-2} + q^{-3/2} + q^{-1} + q^{-1/2} + 2 + 13404883q^{1/2} \\ &\quad + 7740446996q + 1126452195714q^{3/2} + 78170641348884q^2 + \dots . \\ H_7 &= 262 + 15394525184q + 156260255891456q^2 + 2032039505847746 56q^3 + \dots . \end{aligned} \tag{A.5}$$

For $k^* = 8$, the analogous formulas are

$$\begin{aligned} F_8 &= K^8 - 2208K^6 - 16383K^5 + 1433905K^4 + 17693341K^3 - 213343055K^2 \\ &\quad - 3164679732K - 2780845557 \\ &= q^{-4} + q^{-5/2} + q^{-2} + q^{-3/2} + q^{-1} + 2q^{-1/2} + 3 + 44146598q^{1/2} \\ &\quad + 40700662036q + 8516908978515q^{3/2} + \dots \\ H_8 &= -213 + 80651894784q + 1605169778655232q^2 + 349692259738655129 6q^3 + \dots . \end{aligned} \tag{A.6}$$

This is the first case in which the leading coefficient in H is negative, so that it is necessary to add an integer to F and H.

For $k^* = 9$, we find

$$\begin{aligned} F_9 &= K^9 - 2484K^7 - 18431K^6 + 1955935K^5 + 24992137K^4 - 445606619K^3 \\ &\quad - 7443672266K^2 + 1774761946K + 223898812203 \\ &= q^{-9/2} + q^{-3} + q^{-5/2} + q^{-2} + q^{-3/2} + 2q^{-1} + 3q^{-1/2} + 3 + 135149374q^{1/2} \\ &\quad + 193216791918q + 56847816152503q^{3/2} + \dots \\ H_9 &= 453 + 381161021440q + 14282018665201664q^2 + 5051928839165624320 0q^3 + \dots \end{aligned} \tag{A.7}$$

Finally, for $k^* = 10$, we find

$$\begin{aligned} F_{10} &= K^{10} - 2760K^8 - 20479K^7 + 2554141K^6 + 33421429K^5 - 793639831K^4 \\ &\quad - 14145708496K^3 + 30831695165K^2 + 1166011724825K + 2482063616019 \\ &= q^{-5} + q^{-7/2} + q^{-3} + q^{-5/2} + q^{-2} + 2q^{-3/2} + 3q^{-1} + 3q^{-1/2} + 3 \\ &\quad + 389274233q^{1/2} + 842231630010q + 341925580784341q^{3/2} + \dots \\ H_{10} &= -261 + 1652836102144q + 112692628289650688q^2 + 63052056690161400 2176q^3 + \dots . \end{aligned} \tag{A.8}$$

This gives a second example in which the leading coefficient of H is negative, so that it is necessary to add an integer.

Abstract

AdS_2/CFT_1 correspondence predicts that the logarithm of a $\mathbb{Z}_N$ twisted index over states carrying a fixed set of charges grows as $1/N$ times the entropy of the black hole carrying the same set of charges. In this paper we verify this explicitly by calculating the microscopic $\mathbb{Z}_N$ twisted index for a class of states in the CHL models. This demonstrates that black holes carry more information about the microstates than just the total degeneracy.

1 Introduction and Summary

CHL models [1, 2] in four dimensions with $\mathcal{N} = 4$ supersymmetry have proved to be a rich arena for studying the physics of black holes [3–9]. On the one hand they have as much supersymmetry and hence as much control as the toroidally compactified heterotic string theory. On the other hand they have different effective actions beyond the supergravity approximation and hence make different predictions for the entropy of BPS black holes beyond the leading order result of [10, 11]. Thus they provide us with more data points at which we can compare the macroscopic and microscopic predictions for the black hole entropy. This comparison has been remarkably successful at the level of four derivative corrections to the effective action, reproducing complicated non-trivial functional dependence of the entropy on the charges on both sides.[1] Indeed, most of the results on black holes in heterotic string theory on T^6 [6, 16–24] have now been generalized to the case of CHL models.

In this paper we shall make use of the CHL model to explore another aspect of black holes. Based on AdS_2/CFT_1 correspondence [25, 26] it was argued in [27] that if a theory has a $\mathbb{Z}_N$ symmetry that cannot be regarded as part of a $U(1)$ gauge transformation, and if we pick a black hole carrying $U(1)$ charges which are invariant under this $\mathbb{Z}_N$ transformation, then the logarithm of the trace of the $\mathbb{Z}_N$ generator over the microstates of the black hole grows as $1/N$ times the entropy of the black hole.[2] This can be made more concrete for BPS black holes in supersymmetric string theories by working with protected helicity trace index. In the context of $\mathcal{N}=4$ supersymmetric string theories in four dimensions the relevant twisted index is the 6th helicity trace index [27,30,31]:

---

[1] We should add a note of caution that this comparison requires us to make assumption of certain non-renormalization results which have not been proven. In particular it assumes that at the level of four derivative terms the Gauss-Bonnet terms (or their supersymmetric completion given in [12–15]) in the action are sufficient to calculate the correction to the black hole entropy. The analysis in this paper does not require us to make any such assumption.

$$B_6^g(\vec{q}) = \frac{1}{6!}\, Tr_{\vec{q}} \left\{(-1)^{2h}(2h)^6\, g\right\} \,, \tag{1.1}$$

where the trace is taken over all states carrying a fixed set of charges $\vec{q}$, h is the third component of the angular momentum of the state in its rest frame, and g is the generator of a $\mathbb{Z}_N$ symmetry which leaves $\vec{q}$ invariant. This index receives contribution from 1/4 BPS states in this theory which describe large black holes with near horizon $AdS_2 \times S^2$ geometry. In this case the analysis of [27] applies and tells us that

$$|B_6^g(\vec{q})| \sim \exp[S_{BH}(\vec{q})/N]\,, \tag{1.2}$$

where $S_{BH}(\vec{q})$ is the entropy of an extremal black hole carrying charge $\vec{q}$. We shall not review the arguments of [27] here; but the central idea is that in computing the contribution to (1.2) from the horizon of the black hole the leading saddle point corresponding to the $AdS_2 \times S^2$ near horizon geometry does not contribute. However a $\mathbb{Z}_N$ orbifold of $AdS_2 \times S^2$ [26,32,33], whose asymptotic geometry coincides with that of the original near horizon geometry of the black hole, contributes and gives the answer $\exp[S_{BH}/N]$ in the semiclassical limit.

While (1.2) follows almost trivially from the AdS_2/CFT_1 correspondence, it is quite striking from the point of view of the microscopic theory. For large black holes the right hand side of (1.2) is much smaller than the untwisted helicity trace index carrying the same charges, since the latter is given by $\exp[S_{BH}(\vec{q})]$. What this tells us is that in a given charge sector the microstates of different g eigenvalues come in almost equal numbers so that the sum weighted by g is much smaller than the total number of states. This was explicitly verified in [27] by deriving the microscopic formula for this twisted index in toroidally compactified heterotic and type II string theories and then studying their asymptotic behaviour.[3]

---

[2] For a $\mathbb{Z}_N$ group that can be regarded as a subgroup of a spontaneously broken $U(1)$ gauge group, the possibility of hair modes containing information about the $\mathbb{Z}_N$ quantum numbers was explored in [28,29]. In contrast the $\mathbb{Z}_N$ groups we discuss here cannot be regarded as a subgroup of a spontaneously broken $U(1)$ symmetry. Also our goal here is quite different from the one of [28,29].

[3] Even though type II string theory on T^6 has $\mathcal{N}=8$ supersymmetry, only an $\mathcal{N}=4$ subgroup of this commutes with g. Thus effectively we can analyze it in the same way as in an $\mathcal{N}=4$ supersymmetric theory.

Given the unusual nature of this macroscopic prediction, it is important to test this in as many examples as possible. In this paper we shall verify this in the context of CHL models. The construction of the CHL models that we shall analyze proceeds as follows. We begin with type IIB string theory on $\mathcal{M} \times S^1 \times \widetilde{S}^1$ where $\mathcal{M}$ is either K3 or T^4 and go to a special subspace of the moduli space of $\mathcal{M}$ where the theory has a geometric $\mathbb{Z}_M \times \mathbb{Z}_N$ symmetry that commutes with 16 supersymmetry generators of the theory. An extensive list of possible symmetries of this type can be found in [34, 35]. Note also that a Z_{MN} group with M and N relatively prime can be considered as a $Z_M \times Z_N$ group for the purpose of our analysis. Let us denote by g_M and g_N the generators of $\mathbb{Z}_M$ and $\mathbb{Z}_N$ respectively. We now take an orbifold of this theory by a symmetry that involves $1/M$ unit of translation along the circle S^1 accompanied by the transformation g_M. This gives a theory with $\mathcal{N} = 4$ supersymmetry in four dimensions and the $\mathbb{Z}_N$ group generated by g_N is a symmetry of this theory. We now consider a g_N invariant charge vector $\vec{q}$ in this theory and define the index

$$d(\vec{q}) = -\frac{1}{6!}\, Tr_{\vec{q}} \left(e^{2\pi i h} (2h)^6 g_N \right) , \tag{1.3}$$

where the trace is taken over all states carrying the charge $\vec{q}$. Eq.(1.2) now translates to

$$|d(\vec{q})| \sim \exp[S_{BH}(\vec{q})/N] , \tag{1.4}$$

for large charges. Our goal will be to verify this by explicit computation of $d(\vec{q})$ in the microscopic theory.

Since the explicit counting of states involves technical details, we shall take this opportunity to summarize the results of our analysis. We use a convention in which the coordinate radius of the original circle S^1 before orbifolding is $2\pi M$ so that the orbifold action involves translation by 2π along S^1 accompanied by g_M. In this convention the minimum amount of momentum along S^1 is $1/M$. We focus on states carrying one unit of KK monopole charge associated with the circle $\widetilde{S}^1$, one unit of D5-brane charge wrapped on $\mathcal{M} \times S^1$, Q_1 units of D1-brane charge wrapped on S^1, left-moving momentum n/M along S^1 and J units of momentum along $\widetilde{S}^1$, and define

$$Q^2 = 2n/M, \qquad P^2 = 2Q_1, \qquad Q.P = J . \tag{1.5}$$

In this case our result of $d(\vec{q})$ is given by

$$d(\vec{q}) = \frac{1}{M}(-1)^{Q.P+1} \int_{\mathcal{C}} d\rho d\sigma dv e^{-\pi i (M\rho Q^2 + \sigma P^2/M + 2vQ.P)} \frac{1}{\widetilde{\Phi}(\rho, \sigma, v)} . \tag{1.6}$$

Here $\mathcal{C}$ is a three real dimensional subspace of the three complex dimensional space labelled by $(\rho=\rho_1+i\rho_2, \sigma=\sigma_1+i\sigma_2, v=v_1+iv_2)$ given by

$$\begin{aligned} &\rho_2 = M_1, \qquad \sigma_2 = M_2, \qquad v_2 = M_3, \\ &0 \le \rho_1 \le 1, \qquad 0 \le \sigma_1 \le M, \qquad 0 \le v_1 \le 1\,, \end{aligned} \tag{1.7}$$

M_1, M_2, M_3 being large but fixed positive numbers satisfying

$$M_1 M_2 > M_3^2\,. \tag{1.8}$$

The function $\widetilde{\Phi}(\rho,\sigma,v)$ is a modular form of a subgroup of $Sp(2,\ \mathbb{Z})$, given by

$$\begin{aligned} \widetilde{\Phi}(\rho,\sigma,v) &= e^{2\pi i(\widetilde{\alpha}\rho+\widetilde{\gamma}\sigma+\widetilde{\beta}v)} \prod_{b=0}^{1}\prod_{r=0}^{N-1}\prod_{r'=0}^{M-1} \prod_{\substack{k\in\mathbb{Z}+\frac{r'}{M}, l\in\mathbb{Z}, j\in 2\mathbb{Z}+b\\ k,l\ge 0, j<0\, for\, k=l=0}} \left[1-e^{2\pi i r/N}\, e^{2\pi i(k\sigma+l\rho+jv)}\right]^{a} \\ a &\equiv \sum_{s=0}^{N-1}\sum_{s'=0}^{M-1} e^{-2\pi i(s'l/M+rs/N)} c_b^{(0,s;r',s')}(4kl-j^2)\,, \end{aligned} \tag{1.9}$$

where the coefficients $c_b^{(r,s;r',s')}$ are defined via the equation:

$$\begin{aligned} &\sum_{b=0}^{1}\sum_{j\in 2\mathbb{Z}+b, n\in\mathbb{Z}/MN} c_b^{(r,s;r',s')}(4n-j^2)e^{2\pi i(n\tau+jz)} \\ &= \frac{1}{MN} Tr_{RR;g_M^{r'}g_N^{r}}\left(g_M^{s'}g_N^{s}(-1)^{J_L+J_R}e^{2\pi i(\tau L_0-\bar{\tau}\bar{L}_0)}e^{2\pi i J_L z}\right)\,. \end{aligned} \tag{1.10}$$

The trace is taken over all the $g_M^{r'}g_N^{r}$ twisted RR sector states in the (4,4) superconformal CFT$_2$ with target space $\mathcal{M}$. L_0 and $\bar{L}_0$ are the left and right-moving Virasoro generators and $J_L/2$ and $J_R/2$ are the generators of the $U(1)_L\times U(1)_R$ subgroup of the $SU(2)_L\times SU(2)_R$ R-symmetry group of this CFT$_2$. An algorithm for explicitly computing the right hand side of (1.10) has been outlined in appendix A. The coefficients $\widetilde{\alpha}$, $\widetilde{\beta}$, $\widetilde{\gamma}$ are given by

$$\begin{aligned} \widetilde{\alpha} &= \frac{1}{24M}Q_{0,0} - \frac{1}{2M}\sum_{s'=1}^{M-1} Q_{0,s'}\frac{e^{-2\pi i s'/M}}{(1-e^{-2\pi i s'/M})^2}\,, \\ \widetilde{\beta} &= 1 \\ \widetilde{\gamma} &= \frac{1}{24M}\,\chi(\mathcal{M}) = \frac{1}{24M}\,Q_{0,0}\,, \end{aligned} \tag{1.11}$$

where

$$Q_{r',s'} = MN\left(c_0^{(0,0;r',s')}(0) + 2c_1^{(0,0;r',s')}(-1)\right)\,. \tag{1.12}$$

Eqs. (1.10), (1.11) define all the quantities which appear in the definition of $\widetilde{\Phi}$. The only ambiguity that remains in computing the right hand side of (1.6) is the choice of the integration contour encoded in the choice of (M_1, M_2, M_3). As is well known by now, this ambiguity is related to the phenomenon of wall crossing [36–39]. Different choices of M_1, M_2 and M_3 give the value of $d(\vec{q})$ for different values of the asymptotic moduli. However the ambiguity in the value of $d(\vec{q})$ that it introduces is sufficiently small so as not to affect our analysis, and hence we shall ignore it in our subsequent discussion.

Given the result (1.6) for $d(\vec{q})$ we can find its behaviour for large Q^2, P^2 and $Q.P$ by standard method [3,6,16,17]. The result is that $d(\vec{q})$ behaves as

$$d(\vec{q}) \sim \exp\left[\pi\sqrt{Q^2P^2 - (Q.P)^2}/N\right] . \tag{1.13}$$

Since in this limit a black hole of charge $\vec{q}$ has entropy [10,11]

$$S_{BH}(\vec{q}) \simeq \pi\sqrt{Q^2P^2 - (Q.P)^2} , \tag{1.14}$$

we see that the microscopic result (1.13) is in perfect agreement with the macroscopic prediction (1.4).

Finally we would like to remark that even though we have presented our analysis for the index $Tr((-1)^{2h}(2h)^6 g_N)$, we can repeat the analysis with g_N replaced by $(g_N)^b$ for any integer b. In this case the role of N is played by the order of $(g_N)^b$, and in all the formulæ we simply have to replace g_N by $(g_N)^b$. This in turn allows us to compute the index $Tr((-1)^{2h}(2h)^6)$ for states carrying a definite g_N eigenvalue $e^{2\pi i a/N}$ using the combination

$$\frac{1}{N}\sum_{b=0}^{N-1} e^{-2\pi i a b/N}\, Tr((-1)^{2h}(2h)^6(g_N)^b) . \tag{1.15}$$

Thus our result can also be interpreted as the agreement between the macroscopic and the microscopic results for the helicity trace index over states carrying a definite g_N charge.

2 The counting

The counting of states of the D1-D5-KK monopole system proceeds as in [6–8,40]. We take the circle S^1 to be large compared to the size of $\mathcal{M}$ and regard the world-volume theory as a 1+1 dimensional field theory living on S^1. Denoting by $d(Q_1, n, J)$ the twisted index (1.3) of states carrying charge labeled by (Q_1, n, J) in the convention of §1, we define

$$Z(\rho, \sigma, v) = \sum_{Q_1, n, J} e^{2\pi i(Q_1\sigma/M + n\rho + vJ)}(-1)^J d(Q_1, n, J) . \tag{2.1}$$

Proving (1.6) is now equivalent to proving that $Z = -1/\widetilde{\Phi}$.

The twisted partition function Z is given by the product of three twisted partition functions, – that of the excitations living on the KK monopole, that of the dynamics describing the overall motion of the D1-D5 system in the background of the KK monopole and that of the motion of the D1-brane along the D5-brane. For each system we must keep the right-movers in their ground state and excite the left-movers in order to preserve supersymmetry.[4] Since the fermion zero modes associated with the broken supersymmetries are automatically removed while computing the helicity trace (which is B_6 in this case since the system breaks 12 of the 16 supersymmetries), we shall ignore their contribution during the rest of our analysis.

We begin by analyzing the partition function of the KK monopole. The massless bosonic modes on the world-volume of the KK monopole arise from the motion along the three transverse directions and the components of the p-form fields along the product of the harmonic $(p-2)$-forms of $\mathcal{M}$ and the harmonic 2-form of the Taub-NUT space. The massless fermions are the goldstinos associated with the supersymmetries broken by the Kaluza-Klein monopole. In general one can show that the left-moving bosons and fermions are in one to one correspondence with the even and odd degree harmonic forms on $\mathcal{M}$ [40]. Furthermore their (g_M, g_N) quantum numbers are also given by the (g_M, g_N) eigenvalues of the harmonic forms on $\mathcal{M}$. Since the harmonic (p,q) forms on $\mathcal{M}$ are in one to one correspondence with the RR sector ground states in the supersymmetric σ-model with target space $\mathcal{M}$ carrying $L_0 = \bar{L}_0 = 0$, $J_L = (p-1)$, $J_R = (q-1)$, it follows from (1.10) that the number of left-moving bosons minus the number of left-moving fermions on the KK monopole world-volume, carrying g_N quantum number $e^{2\pi i r/N}$ and g_M quantum number $e^{2\pi i k'/M}$, is given by [8, 40]

$$\begin{aligned}
&\frac{1}{MN}\sum_{s=0}^{N-1}\sum_{s'=0}^{M-1} e^{-2\pi i r s/N} e^{-2\pi i k' s'/M} Tr_{RR;I}\left[(-1)^{J_L+J_R}\, g_M^{s'} g_N^{s}\, \delta_{L_0,0}\, \delta_{\bar{L}_0,0}\right] \\
= \; &\sum_{s=0}^{N-1}\sum_{s'=0}^{M-1} e^{-2\pi i r s/N} e^{-2\pi i k' s'/M}\left(c_0^{(0,s;0,s')}(0) + 2c_1^{(0,s;0,s')}(-1)\right) . \qquad (2.2)
\end{aligned}$$

In arriving at (2.2) we have used the fact that $c_b^{(r,s;r',s')}(u) = 0$ for $u < -1$. Now consider a mode carrying g_M eigenvalue $e^{2\pi i k'/M}$ and left-moving momentum l/M along S^1. The requirement of invariance under the simultaneous action of g_M and 2π translation along S^1 gives us the requirement that $l = k'$ mod M. Furthermore the contribution to the twisted index from these states will be weighted by the g_N eigenvalue $e^{2\pi i r/N}$. Thus the net contribution to the partition function from these modes is given by

---

[4] Here and elsewhere left-moving modes will refer to modes carrying momentum along the negative S^1 direction. Thus left-moving momentum n will indicate momentum $-n$ along S^1.

$$Z_{KK} = e^{-2\pi i\widetilde{\alpha}\rho} \prod_{r=0}^{N-1} \prod_{l=1}^{\infty} \left(1 - e^{2\pi i r/N} e^{2\pi i l\rho}\right)^{-\sum_{s=0}^{N-1}\sum_{s'=0}^{M-1} e^{-2\pi i rs/N} e^{-2\pi i l s'/M} \left(c_0^{(0,s;0,s')}(0) + 2c_1^{(0,s;0,s')}(-1)\right)} . \tag{2.3}$$

Here the term $e^{-2\pi i\widetilde{\alpha}\rho}$ reflects the effect of the momentum carried by the ground state of the Kaluza-Klein monopole. The analysis of [8, 40] gives

$$\begin{aligned} \widetilde{\alpha} &= \frac{1}{24M} Q_{0,0} - \frac{1}{2M} \sum_{s'=1}^{M-1} Q_{0,s'} \frac{e^{-2\pi i s'/M}}{(1 - e^{-2\pi i s'/M})^2} , \\ & Q_{r',s'} \equiv MN \left(c_0^{(0,0;r',s')}(0) + 2c_1^{(0,0;r',s')}(-1)\right) . \end{aligned} \tag{2.4}$$

Next we turn to the dynamics of the overall motion of the D1-D5 system in the KK monopole background. The dynamics in the transverse direction is independent of whether we are working with $K3$ or T^4. Furthermore these modes do not carry any g_N or g_M quantum numbers; thus the contribution from these modes to the partition function is universal. The result is [8, 40]

$$\begin{aligned} & -e^{-2\pi i v} \left(1 - e^{-2\pi i v}\right)^{-2} \\ & \prod_{\substack{l \in M\mathbb{Z} \\ l>0}} \{(1 - e^{2\pi i l\rho})^4 (1 - e^{2\pi i l\rho + 2\pi i v})^{-2} (1 - e^{2\pi i l\rho - 2\pi i v})^{-2}\} . \end{aligned} \tag{2.5}$$

The first line represents the contribution from the zero mode dynamics that binds the D1-D5 system to the KK monopole [6, 41, 42], and the second line represents the contribution from the oscillators. The last two terms in the second line of (2.5) represent the contribution from the four left-moving bosonic modes representing transverse oscillation of the D1-D5 system whereas the first factor in the same line represents contribution from the left-moving fermionic modes.[5] In arriving at (2.5) one needs to use the fact that in the presence of the KK monopole background, the momentum along $\widetilde{S}^1$ appears as the angular momentum $2J_L$ for the D1-D5 system where J_L is the generator of the $U(1)_L \subset SU(2)_L$ subgroup of the rotation group in transverse space [43]. The v dependence of (2.5) then follows from the fact that the bosonic modes, transforming as a vector of the transverse rotation group $SU(2)_L \times SU(2)_R$, carry $J_L = \pm 1$ while the fermionic modes are neutral under $U(1)_L$ as a consequence of footnote 5.

---

[5] These left-moving bosonic and fermionic modes, as well as those which contribute to (2.7), are paired by the unbroken superysymmetry transformations on the D1-D5 world volume in flat space-time which commute with $\mathbb{Z}_M \times \mathbb{Z}_N$, are charged under the $SU(2)_L$ subgroup of the transverse rotation group, and act on the left-movers. Eventually when we place this system in the background of KK monopole this supersymmetry is broken since in the full system there is no supersymmetry acting on the left-movers. However this is still useful for determining the quantum numbers of the fermions from the known quantum numbers of the bosonic modes [8, 40].

For $\mathcal{M} = T^4$ we also have four additional bosonic modes arising from the Wilson lines on the D5-brane along T^4 and four additional fermionic modes. In order to find the contribution to the partition function from these modes we need to know the action of g_M and g_N on these modes. If z_1 and z_2 denote the complex coordinates on T^4 then in order to preserve supersymmetry both g_M and g_N must act as equal and opposite rotation of z_1 and z_2, possibly accompanied by shifts. We shall assume for definiteness that g_M and g_N induce respectively $2\pi/M$ and $2\pi/N$ rotations on these coordinates:

$$\begin{aligned} g_M &: \quad (dz_1, dz_2) \to \left(e^{2\pi i/M} dz_1, e^{-2\pi i/M} dz_2\right) , \\ g_N &: \quad (dz_1, dz_2) \to \left(e^{2\pi i/N} dz_1, e^{-2\pi i/N} dz_2\right) . \end{aligned} \tag{2.6}$$

(2.6) represents the action of g_M and g_N on the Wilson line variables. Furthermore the Wilson lines are neutral under the rotation group in the transverse space and hence carry $J_L = 0$. The result of footnote 5 now tells us that the additional fermionic modes on the D1D5 system, which arise for $\mathcal{M} = T^4$, transform in the same way under g_M and g_N, and carry $J_L = \pm 1$ uncorrelated with their (g_M, g_N) quantum numbers [8, 40]. Thus the contribution from these additional modes to the twisted partition function is given by

$$\begin{aligned} &\prod_{\substack{l \in M\mathbb{Z}+1 \\ l>0}} \left(1 - e^{2\pi i/N} e^{2\pi i l\rho}\right)^{-2} \prod_{\substack{l \in M\mathbb{Z}-1 \\ l>0}} \left(1 - e^{-2\pi i/N} e^{2\pi i l\rho}\right)^{-2} \prod_{\substack{l \in M\mathbb{Z}+1 \\ l>0}} \left(1 - e^{2\pi i/N} e^{2\pi i l\rho + 2\pi i v}\right) \\ &\prod_{\substack{l \in M\mathbb{Z}+1 \\ l>0}} \left(1 - e^{2\pi i/N} e^{2\pi i l\rho - 2\pi i v}\right) \prod_{\substack{l \in M\mathbb{Z}-1 \\ l>0}} \left(1 - e^{-2\pi i/N} e^{2\pi i l\rho + 2\pi i v}\right) \prod_{\substack{l \in M\mathbb{Z}-1 \\ l>0}} \left(1 - e^{-2\pi i/N} e^{2\pi i l\rho - 2\pi i v}\right) . \end{aligned} \tag{2.7}$$

The first two factors come from the bosonic modes and the last four factors arise from the fermionic modes whose contribution have not already been included in (2.5). The only new ingredient in this formula compared to that in [8, 40] is the insertion of the factors of $e^{\pm 2\pi i/N}$, – these arise from the insertion of g_N into the trace.

The product of (2.5) and (2.7) can be written in a compact form using the coefficients $c_1^{(0,s;0,s')}(-1)$. It follows from its definition, and the identification of the RR sector ground states in the SCFT with target space $\mathcal{M}$ carrying $(J_L, J_R) = (p-1, q-1)$ with the harmonic

(p,q) forms on $\mathcal{M}$, that $MNc_1^{(0,s;0,s')}(-1)$ represents trace over the $(0,q)$ forms on $\mathcal{M}$ weighted by $(-1)^q g_N^s g_M^{s'}$ [8, 40]. On $K3$ the only $(0,q)$ forms are $(0,0)$ forms and $(0,2)$ forms both of which are neutral under g_N and g_M, while on T^4 we also have a pair of $(0,1)$ forms dz_1 and dz_2 which we have chosen to carry (g_N, g_M) eigenvalues $(e^{\pm 2\pi i/N}, e^{\pm 2\pi i/M})$. This gives

$$\begin{aligned} c_1^{(0,s;0,s')}(-1) &= \frac{2}{MN} \quad \text{for } \mathcal{M} = K3\,, \\ &= \frac{1}{MN}\left(2 - e^{2\pi i s/N} e^{2\pi i s'/M} - e^{-2\pi i s/N} e^{-2\pi i s'/M}\right) \quad \text{for } \mathcal{M} = T^4\,. \end{aligned} \tag{2.8}$$

Using this we can express the total contribution to the partition function from the overall motion of the D1-D5 system in the Taub-NUT space, given by (2.5) for $\mathcal{M} = K3$ and the product of (2.5) and (2.7) for $\mathcal{M} = T^4$, as

$$\begin{aligned} Z_{CM} &= -e^{-2\pi i v} \prod_{l=1}^{\infty} \prod_{r=0}^{N-1} (1 - e^{2\pi i r/N}\, e^{2\pi i l\rho})^{2\sum_{s=0}^{N-1}\sum_{s'=0}^{M-1} e^{-2\pi i l s'/M} e^{-2\pi i r s/N} c_1^{(0,s;0,s')}(-1)} \\ & \prod_{l=1}^{\infty} \prod_{r=0}^{N-1} (1 - e^{2\pi i r/N}\, e^{2\pi i l\rho + 2\pi i v})^{-\sum_{s=0}^{N-1}\sum_{s'=0}^{M-1} e^{-2\pi i l s'/M} e^{-2\pi i r s/N} c_1^{(0,s;0,s')}(-1)} \\ & \prod_{l=0}^{\infty} \prod_{r=0}^{N-1} (1 - e^{2\pi i r/N}\, e^{2\pi i l\rho - 2\pi i v})^{-\sum_{s=0}^{N-1}\sum_{s'=0}^{M-1} e^{-2\pi i l s'/M} e^{-2\pi i r s/N} c_1^{(0,s;0,s')}(-1)}\,. \end{aligned} \tag{2.9}$$

Note that the $(1 - e^{-2\pi i v})^{-2}$ factor has been absorbed into the $l = 0$ term in the last term.

Finally let us turn to the contribution to the partition function from the motion of the D1-branes along the D5-branes. First we consider a single D1-brane wrapped w times along S^1, and count the number of states $n(w,j,l;r,k')$ of the system carrying left-moving momentum l/M along S^1, g_M eigenvalue $e^{2\pi i k'/M}$, g_N eigenvalue $e^{2\pi i r/N}$ and $\widetilde{S}^1$ momentum j. Since the boundary condition on various fields are twisted by g_M under 2π translation along S^1, the CFT on a D1-brane wrapped w times along S^1 satisfies boundary condition twisted by $(g_M)^w$. Furthermore since the effective length of the D1-brane is now $2\pi w$, a momentum l/M along S^1 will appear as lw/M units of momentum in the CFT living on the D1-brane. It now follows from (1.10) that [8, 40]

$$\begin{aligned} n(w,j,l;r,k') &= \sum_{s=0}^{N-1}\sum_{s'=0}^{M-1} e^{-2\pi i r s/N} e^{-2\pi i k' s'/M} c_b^{(0,s;r',s')}(4lw/M - j^2)\,, \\ & b = j \bmod 2, \quad r' = w \bmod M\,. \end{aligned} \tag{2.10}$$

The requirement that we only keep the modes which are invariant under the transformation g_M accompanied by 2π translation along S^1 forces the constraint $k' = l \bmod M$. It is now straightforward to evaluate the contribution to the g_N twisted partition function from multiple states of this type, carrying different (w,l,j) [44]:

$$Z_{D1D5} = e^{-2\pi i\widetilde{\gamma}\sigma} \prod_{r=0}^{N-1}\prod_{b=0}^{1} \prod_{\substack{w\in\mathbb{Z},l\in\mathbb{Z},j\in 2\mathbb{Z}+b\\ w>0,l\geq 0}} \left(1-e^{2\pi i r/N}e^{2\pi i(\sigma w/M+\rho l+vj)}\right)^{-n(w,j,l;r,l)} . \tag{2.11}$$

where

$$\widetilde{\gamma} = \begin{cases} 1/M \text{ for } \mathcal{M}=K3 \\ 0 \text{ for } \mathcal{M}=T^4 \end{cases} . \tag{2.12}$$

The $e^{-2\pi i\widetilde{\gamma}\sigma}$ in (2.11) accounts for the fact that the actual number of D1-branes required to produce a total D1-brane charge Q_1 in the background of a D5-brane is given by Q_1+1 for $\mathcal{M}=K3$ and Q_1 for $\mathcal{M}=T^4$. Multiplying (2.3), (2.9) and (2.11) we get the total partition function of the system:

$$Z(\rho,\sigma,v) = Z_{KK}\, Z_{CM}\, Z_{D1D5} = -1/\widetilde{\Phi}(\rho,\sigma,v)\,, \tag{2.13}$$

where

$$\begin{aligned} \widetilde{\Phi}(\rho,\sigma,v) &= e^{2\pi i(\widetilde{\alpha}\rho+\widetilde{\gamma}\sigma+\widetilde{\beta}v)} \prod_{b=0}^{1}\prod_{r=0}^{N-1}\prod_{r'=0}^{M-1} \prod_{\substack{k\in\mathbb{Z}+\frac{r'}{M},l\in\mathbb{Z},j\in 2\mathbb{Z}+b\\ k,l\geq 0,j<0\; for\; k=l=0}} \left[1-e^{2\pi i r/N}\, e^{2\pi i(k\sigma+l\rho+jv)}\right]^{a} \\ a &\equiv \sum_{s=0}^{N-1}\sum_{s'=0}^{M-1} e^{-2\pi i(s'l/M+rs/N)} c_b^{(0,s;r',s')}(4kl-j^2)\,, \end{aligned} \tag{2.14}$$

with $\widetilde{\alpha}$, $\widetilde{\beta}$, $\widetilde{\gamma}$ defined in (1.11). Note that the $k=0$ term in this product gives the result for $Z_{KK}Z_{CM}$.

3 Asymptotic Growth

We now study the growth of the index for large Q^2, P^2 and $Q.P$. This can be done by standard procedure described in [3, 6, 16, 17]. We deform the three dimensional contour of integration over (ρ,σ,v) to small imaginary values of (ρ,σ,v). During this deformation we pick up contribution from the residues at various poles, given by the zeroes of $\widetilde{\Phi}$, which give the leading contribution to the index, – the contribution from the final contour can be shown to be subleading compared to the contribution from the residues at the poles [40]. Thus we need to first determine the location of the zeroes of $\widetilde{\Phi}$. This has been done in appendix C where it is shown that $\widetilde{\Phi}$ has double zeroes on the subspaces:

$$n_2(\rho\sigma - v^2) - m_1\rho + n_1\sigma + m_2 + jv = 0\,, \tag{3.1}$$

for values of (m_1, n_1, m_2, n_2, j) satisfying

$$\begin{aligned} & m_1 n_1 + m_2 n_2 + \frac{j^2}{4} = \frac{1}{4}\,, \\ & m_1 \in M\,\mathbb{Z}, \quad m_2 \in \mathbb{Z}, \quad n_2 \in N\,\mathbb{Z}, \quad n_1 \in \mathbb{Z}, \quad j \in 2\,\mathbb{Z}+1\,. \end{aligned} \tag{3.2}$$

Now the analysis of [3,6,16,17] tells us that for large Q^2, P^2, $Q.P$ the contribution from the residue at the pole (3.1) of $1/\widetilde{\Phi}$ grows as

$$\exp\left(\pi\sqrt{Q^2P^2 - (Q.P)^2}/|n_2|\right) \qquad \text{for } |n_2| > 0\,. \tag{3.3}$$

On the other hand the poles at $n_2 = 0$ are responsible for wall crossing and their contribution grows much slower than (3.3) [36–39]. Thus the leading contribution comes from the pole at (3.1) for the minimum non-zero value of $|n_2|$. Eq.(3.2) shows that this is N. Thus the index grows as

$$\exp\left(\pi\sqrt{Q^2P^2 - (Q.P)^2}/N\right)\,. \tag{3.4}$$

Since for this charge the black hole entropy S_{BH} is given by $\pi\sqrt{Q^2P^2 - (Q.P)^2}$ [10,11], (3.4) is in precise agreement with the macroscopic prediction (1.2).

4 Conclusion

It is widely believed that since string theory provides us with a consistent quantum theory of gravity, black holes in string theory do not lead to a loss of information. If so, the black hole must represent an ensemble of microstates and the black hole entropy must have an interpretation as the logarithm of the degeneracy of microstates. Furthermore quantum string theory around a black hole background must contain all possible information about the microstates. It is therefore important to learn how we can extract information about the black hole microstates by studying quantum string theory around the black hole background.

The results of [27] and this paper provide a small step in this direction. In these papers we discuss how to extract information about one specific feature of the black hole microstates, namely distribution of the $\mathbb{Z}_N$ charges among the microstates. Quantum string theory around the near horizon background leads to a specific algorithm for extracting this information. Our analysis shows that in the limit of large charges the results of the macroscopic analysis are in exact agreement with the microscopic results in a wide class of models where the latter is computable. While using the rules of AdS_2/CFT_1 correspondence we can in principle compute the ensemble average of more general operators on the black hole side, in the absence of non-renormalization results it is not clear how we might compare this with the microscopic results.

Acknowledgment: I wish to thank Nabamita Banerjee, Atish Dabholkar, Joao Gomes and Sameer Murthy for useful discussions. This work was supported in part by the JC Bose fellowship of the Department of Science and Technology, India and by the Blaise Pascal Chair, France.

Note added: I have been informed by Suresh Govandarajan that the modular forms of subgroups of $Sp(2, \mathbb{Z})$ which appear here have also been constructed independently in [45,46].

A Explicit computation of $c_b^{(r,s;r',s')}$

In this appendix we shall describe the strategy for explicit computation of the right hand side of (1.10)

$$\begin{aligned} F^{(r,s;r',s')}(\tau, z) &\equiv \frac{1}{MN} Tr_{RR;g_M^{r'}g_N^r}\left(g_M^{s'}g_N^s(-1)^{J_L+J_R}e^{2\pi i(\tau L_0-\bar\tau\bar L_0)}e^{2\pi i J_L z}\right) \\ &= \sum_{b=0}^{1}\sum_{j\in 2\mathbb{Z}+b, n\in\mathbb{Z}/MN} c_b^{(r,s;r',s')}(4n-j^2)e^{2\pi i(n\tau+jz)}\,, \end{aligned} \tag{A.1}$$

and hence of $c_b^{(r,s;r',s')}$. First of all $F^{(0,0;0,0)}$ is simply $1/MN$ times the elliptic genus of $\mathcal{M}$ and is given by [47]

$$\begin{aligned} F^{(0,0;0,0)}(\tau, z) &= 0 \quad \text{for } \mathcal{M} = T^4 \\ &= \frac{8}{MN}\left[\frac{\vartheta_2(\tau,z)^2}{\vartheta_2(\tau,0)^2}+\frac{\vartheta_3(\tau,z)^2}{\vartheta_3(\tau,0)^2}+\frac{\vartheta_4(\tau,z)^2}{\vartheta_4(\tau,0)^2}\right] \quad \text{for } \mathcal{M} = K3\,, \end{aligned} \tag{A.2}$$

where ϑ_i are the Jacobi theta functions. For non-vanishing r and/or r' the contribution to the right hand side of (A.1), coming from twisted sectors localized at the fixed points of $g_M^{r'}g_N^r$, can be computed by taking the size of K3 to be large so that the geometry near the fixed points is nearly flat. In this case the σ model near the fixed point can be regarded as the orbifold of a free field theory, and the action of $g_N^r g_M^{r'}$ near the fixed point may be represented by a rotation by some angle $2\pi\theta$ in one plane and rotation by an opposite angle $-2\pi\theta$ in the orthogonal plane. The action of $g_M^{s'} g_N^s$ near such a fixed point can be of two types, – either it takes the fixed point to a different fixed point or it leaves the fixed point fixed. In the former case the contribution to the trace in (A.1) vanishes, whereas in the latter case the action of $g_M^{s'} g_N^s$ near the fixed point can be represented by a rotation by $2\pi\phi$ in one plane and a rotation by $-2\pi\phi$ in the orthogonal plane. This gives a contribution to (A.1) of the form

$$\begin{aligned}
& \frac{1}{MN} \prod_{n=1}^{\infty} \Big\{ \left(1 - q^{n+\theta-1} e^{2\pi i\phi}\right)^{-2} \left(1 - q^{n-\theta} e^{-2\pi i\phi}\right)^{-2} \left(1 - q^{n+\theta-1} e^{2\pi i\phi} e^{2\pi i z}\right) \\
& \qquad \left(1 - q^{n+\theta-1} e^{2\pi i\phi} e^{-2\pi i z}\right) \left(1 - q^{n-\theta} e^{-2\pi i\phi} e^{2\pi i z}\right) \left(1 - q^{n-\theta} e^{-2\pi i\phi} e^{-2\pi i z}\right) \\
= & \frac{1}{MN} \frac{\vartheta_1(\tau, z+\theta\tau+\phi)\vartheta_1(\tau, -z+\theta\tau+\phi)}{\vartheta_1(\tau, \theta\tau+\phi)^2}\,, \qquad (A.3)
\end{aligned}$$

where $q \equiv e^{2\pi i\tau}$. The full contribution to $F^{(r,s;r',s')}(\tau, z)$ is obtained by summing over the contribution from all the fixed points of $g_N^r g_M^{r'}$ which are also fixed by $g_M^{s'} g_N^s$. Finally $F^{(0,s;0,s')}$ can be computed using the modular transformation rules [47]

$$F^{(r,s;r',s')}\left(\frac{a\tau+b}{c\tau+d}, \frac{z}{c\tau+d}\right) = \exp\left[2\pi i \frac{cz^2}{c\tau+d}\right] F^{(cs+ar,ds+br;cs'+ar',ds'+br')}(\tau, z)\,. \qquad (A.4)$$

This gives a way to compute $F^{(r,s;r',s')}(\tau, z)$ using purely geometric data, namely the fixed points of the different elements of $\mathbb{Z}_M \times \mathbb{Z}_N$ and the action of the elements of $\mathbb{Z}_M \times \mathbb{Z}_N$ near the fixed points. Note that $F^{(r,s;r',s')}(\tau, z)$ constructed from (A.3), (A.4) is invariant under $z \to -z$. This is a consequence of the $SU(2)_L$ R-symmetry of the underlying conformal field theory that allows us to change the sign of J_L.

B Threshold Integral Representation of $\widetilde{\Phi}$

In this appendix we shall describe a threshold integral representation of $\widetilde{\Phi}$. For this we define

$$h_b^{(r,s;r',s')}(\tau) = \sum_{k \in \frac{1}{MN}\mathbb{Z} - \frac{b^2}{4}} c_b^{(r,s;r',s')}(4k) e^{2\pi i k\tau}, \qquad (B.1)$$

$$\Omega = \begin{pmatrix} \rho & v \\ v & \sigma \end{pmatrix}, \qquad (B.2)$$

and

$$\begin{aligned}
\frac{1}{2}p_R^2 &= \frac{1}{4\det Im\Omega} |-m_1\rho + m_2 + n_1\sigma + n_2(\sigma\rho - v^2) + jv|^2, \\
\frac{1}{2}p_L^2 &= \frac{1}{2}p_R^2 + m_1 n_1 + m_2 n_2 + \frac{1}{4}j^2\,. \qquad (B.3)
\end{aligned}$$

We now consider the 'threshold integral'

$$\widetilde{\mathcal{I}}(\rho,\sigma,v) = \sum_{r,s=0}^{N-1}\sum_{r',s'=0}^{M-1}\sum_{b=0}^{1}\widetilde{\mathcal{I}}_{r,s;r',s';b}\,, \tag{B.4}$$

where

$$\begin{aligned}\widetilde{\mathcal{I}}_{r,s;r',s';b} \;&=\; \int_{\mathcal{F}} \frac{d^2\tau}{\tau_2}\Big[\sum_{\substack{m_1\in\mathbb{Z},m_2\in\mathbb{Z}/N,n_2\in N\mathbb{Z}-r\\ n_1\in\mathbb{Z}+\frac{r'}{M},j\in 2\mathbb{Z}+b}} q^{p_L^2/2}\bar{q}^{p_R^2/2}e^{2\pi i m_1 s'/M}e^{-2\pi i m_2 s}h_b^{(r,s;r',s')}(\tau) \\ &\quad -\delta_{b,0}\delta_{r,0}\delta_{r',0}c_0^{(0,s;0,s')}(0)\Big]\,,\end{aligned} \tag{B.5}$$

with

$$q \equiv e^{2\pi i\tau}\,. \tag{B.6}$$

$\mathcal{F}$ denotes the fundamental region of $SL(2,\ \mathbb{Z})$ in the upper half plane. The subtraction terms proportional to $c_0^{(0,s;0,s')}(0)$ have been chosen so that the integrand vanishes faster than $1/\tau_2$ in the $\tau\to i\infty$ limit, rendering the integral finite.

Following the manipulations outlined in [4] following earlier work of [48–50] one can show that

$$\widetilde{\mathcal{I}}(\rho,\sigma,v) = -2\ln[(\det Im\ \Omega)^{\widetilde{k}}] - 2\ln\widetilde{\Phi}(\rho,\sigma,v) - 2\ln\check{\Phi}(\bar\rho,\bar\sigma,\bar v) + \text{constant} \tag{B.7}$$

where $\widetilde{\Phi}$ has been defined in (1.9) and[6]

$$\begin{aligned}\check{\Phi}(\bar\rho,\bar\sigma,\bar v) \;&=\; e^{-2\pi i(\widetilde{\alpha}\bar\rho+\widetilde{\gamma}\bar\sigma+\widetilde{\beta}\bar v)}\prod_{b=0}^{1}\prod_{r=0}^{N-1}\prod_{r'=0}^{M-1}\prod_{\substack{k\in\mathbb{Z}+\frac{r'}{M},l\in\mathbb{Z},j\in 2\mathbb{Z}+b\\ k,l\geq 0,j<0\ for\ k=l=0}}\left[1-e^{-2\pi i r/N}\,e^{-2\pi i(k\bar\sigma+l\bar\rho+j\bar v)}\right]^a \\ a \;&\equiv\; \sum_{s=0}^{N-1}\sum_{s'=0}^{M-1}e^{-2\pi i(s'l/M+rs/N)}c_b^{(0,s;r',s')}(4kl-j^2)\,,\end{aligned} \tag{B.8}$$

$$\widetilde{k} \;=\; \frac{1}{2}\sum_{s=0}^{N-1}\sum_{s'=0}^{M-1}c_0^{(0,s;0,s')}(0)\,. \tag{B.9}$$

Since the detailed analysis of a specific integral of this type has been carried out in [4], we shall only describe the basic steps leading to (B.7), focussing on the main differences between the general case and the special case analyzed in [4].

---

[6] Since the exponent a in (1.9), (B.8) is a real number (in fact an integer) we have $\check{\Phi}(\bar\rho,\bar\sigma,\bar v) = \overline{\widetilde{\Phi}(\rho,\sigma,v)}$.

1. We first carry out Poisson resummation over m_1 and m_2 to express $\widetilde{\mathcal{I}}_{r,s;r',s';b}$ as

$$\int_{\mathcal{F}} \frac{d^2\tau}{\tau_2^2}\, \frac{Y}{\rho_2} \Big[N \sum_{\substack{k_1\in \mathbb{Z}+\frac{s'}{M},\, k_2\in N\mathbb{Z}-s \\ n_1\in\mathbb{Z}+\frac{r'}{M},\, n_2\in N\mathbb{Z}-r,\, j\in 2\mathbb{Z}+b}} h_b^{(r,s;r',s')}(\tau) e^{\mathcal{G}(\vec{n},\vec{k},j)} - \delta_{b,0}\delta_{r,0}\delta_{r',0} c_0^{(0,s;0,s')}(0) \Big] \tag{B.10}$$

where

$$\begin{aligned} \mathcal{G}(\vec{n},\vec{k},j) \;=\; & -\frac{\pi Y}{\rho_2^2\tau_2}|\mathcal{A}|^2 - 2\pi i\sigma \det A + \frac{\pi j}{\rho_2}(v\tilde{\mathcal{A}} - \bar{v}\mathcal{A}) - \frac{\pi n_2}{\rho_2}(v^2\tilde{\mathcal{A}} - \bar{v}^2\mathcal{A}) \\ & + \frac{2\pi i v_2^2}{\rho_2^2}(n_1 + n_2\bar{\rho})\mathcal{A} + 2\pi i\tau\frac{j^2}{4}\,, \end{aligned} \tag{B.11}$$

$$Y \equiv \rho_2\sigma_2 - v_2^2\,, \qquad A \equiv \begin{pmatrix} n_1 & k_1 \\ n_2 & k_2 \end{pmatrix}, \quad \mathcal{A} \equiv (1,\rho) A \begin{pmatrix} \tau \\ 1 \end{pmatrix}, \quad \tilde{\mathcal{A}} \equiv (1,\bar{\rho}) A \begin{pmatrix} \tau \\ 1 \end{pmatrix}. \tag{B.12}$$

2. Using (B.4), (B.10) and performing the sum over j using (A.1), (B.1) we get

$$\widetilde{\mathcal{I}} = \int_{\mathcal{F}} \frac{d^2\tau}{\tau_2^2} \Big[N \sum_{k_1,n_1\in\frac{\mathbb{Z}}{M},\, k_2,n_2\in\mathbb{Z}} \mathcal{J}(A,\tau) - \sum_{s=0}^{N-1}\sum_{s'=0}^{M-1} c_0^{(0,s;0,s')}(0) \Big]\,, \tag{B.13}$$

where

$$\begin{aligned} \mathcal{J}(A,\tau) \;=\; & \frac{Y}{\rho_2} \exp\Big(-\frac{\pi Y}{\rho_2^2\tau_2}|\mathcal{A}|^2 - 2\pi i\sigma \det A \\ & - \frac{\pi n_2}{\rho_2}(v^2\tilde{\mathcal{A}} - \bar{v}^2\mathcal{A}) + \frac{2\pi i v_2^2}{\rho_2^2}(n_1 + n_2\bar{\rho})\mathcal{A} \Big) F^{(r,s;r',s')}\Big(\tau, -i\frac{v\tilde{\mathcal{A}} - \bar{v}\mathcal{A}}{2\,\rho_2}\Big) \\ & r = -n_2 \bmod N,\; s = -k_2 \bmod N,\; r' = M n_1 \bmod M,\; s' = M k_1 \bmod M\,. \end{aligned} \tag{B.14}$$

3. Using (A.4) one can show that

$$\mathcal{J}\left(A \begin{pmatrix} a & b \\ c & d \end{pmatrix}, \tau \right) = \mathcal{J}\left(A, \frac{a\tau+b}{c\tau+d} \right), \qquad \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in SL(2,\ \mathbb{Z})\,. \tag{B.15}$$

   Under the map $\tau \to (a\tau+b)/(c\tau+d)$ the fundamental region $\mathcal{F}$ of $SL(2,\ \mathbb{Z})$ gets mapped to its image. With the help of (B.15) we can restrict the sum over the matrix A to the following ranges [48]:

(a) Non-degenerate orbit:

$$A = \begin{pmatrix} k & m \\ 0 & p \end{pmatrix}, \quad k, m \in \frac{\mathbb{Z}}{M}, \quad p \in \mathbb{Z}, \quad p \neq 0, \quad 0 \leq m < k\,, \tag{B.16}$$

with the integration over τ ranging over two copies of the upper half plane.

(b) Degenerate orbit:

$$A = \begin{pmatrix} 0 & m \\ 0 & p \end{pmatrix}, \quad m \in \frac{\mathbb{Z}}{M}, \quad p \in \mathbb{Z}, \quad (m, p) \neq (0, 0)\,, \tag{B.17}$$

with the integration over τ ranging over the strip $-\frac{1}{2} \leq \tau_1 \leq \frac{1}{2}$, $\tau_2 > 0$.

(c) Zero orbit:

$$A = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}\,, \tag{B.18}$$

with the integration over τ ranging over the fundamental domain $\mathcal{F}$.

We shall briefly discuss the computation of the contribution from the non-degenerate orbits. The analysis of the contribution from the other orbits follows [4].

4. The steps needed for evaluating the contribution from the non-degenerate orbits are as follows:

   (a) We first expand $F^{(r,s;r',s')}(\tau, z)$ using (A.1) and change integration variable from τ_1 to τ_1':

   $$\tau_1' = \tau_1 + \frac{m}{k} + \frac{p}{k}\rho_1\,. \tag{B.19}$$

   Since for non-degenerate orbit the τ_1 integration ranges from $-\infty$ to ∞, τ_1' integral will also range from $-\infty$ to ∞.

   (b) After this change of variables the m dependence of the integral becomes simple. The explicit dependence on m takes the form $e^{-2\pi i m n/k}$, n and j being the integers appearing in the expansion (A.1). There is also an implicit dependence on m through $c_b^{(r,s;r',s')}(4n - j^2)$ since $s' = Mm \bmod M$ due to (B.14). The sum over m can be performed by expanding the summation range of m to $0 \leq m < Mk$ in steps of $1/M$, at the cost of having to divide the sum by a factor of M. We then sum over all values of m of the form $\frac{s'}{M}$ + integer for fixed s' and finally sum over integral s'

in the range $0 \leq s' \leq (M-1)$. For fixed s' the sum takes the form

$$\sum_{m\in \mathbb{Z}+\frac{s'}{M}, 0\leq m< Mk-1} e^{-2\pi i m n/k} = Mk\, e^{-2\pi i n s'/(Mk)} \sum_{l\in\mathbb{Z}} \delta_{n,kl} = Mk \sum_{l\in\mathbb{Z}} e^{-2\pi i l s'/M}\, \delta_{n,kl}\,. \tag{B.20}$$

The sum over n can now be performed using the Kronecker delta.

(c) Next we carry out the τ_1' integral which is Gaussian and the τ_2 integral using the identity

$$\int_0^\infty \frac{du}{u^{3/2}} e^{-au-bu^{-1}} = \sqrt{\frac{\pi}{b}} e^{-2\sqrt{ab}}\,. \tag{B.21}$$

At this stage the p dependent part of the summand takes the form

$$\frac{1}{|p|}\exp\left\{-2\pi i\sigma kp - 2\pi k|p|\sigma_2 - 2\pi kp\sigma_2 - 2\pi i lp\rho_1 - 2\pi l|p|\rho_2 - 2\pi i jpv_1 - 2\pi j|p|v_2\right\}\,. \tag{B.22}$$

(d) Finally we perform the sum over p by breaking it into contribution from $p>0$ and $p<0$ terms, making a change of variables $p\to -p$ in the $p<0$ terms, and using the identity

$$\begin{aligned}\sum_{p\in N\mathbb{Z}+s, p>0} \frac{1}{p} e^{2\pi i\alpha p} &= \frac{1}{N}\sum_{r=0}^{N-1}\sum_{p\in\mathbb{Z}, p>0} e^{2\pi i r(p-s)/N}\,\frac{1}{p}\, e^{2\pi i \alpha p} \\ &= -\frac{1}{N}\sum_{r=0}^{N-1} e^{-2\pi i r s/N}\, \ln(1-e^{2\pi i r/N} e^{2\pi i\alpha})\,. \end{aligned} \tag{B.23}$$

5. At the end of this manipulation we get the contribution from the non-degenerate orbits to be

$$\begin{aligned}-2\sum_{r,s=0}^{N-1}\sum_{r',s'=0}^{M-1}\sum_{b=0}^{1} \sum_{k\in\mathbb{Z}+\frac{r'}{M}, l\in\mathbb{Z}, j\in 2\mathbb{Z}+b, k>0, l\geq 0} & e^{-2\pi i rs/N} e^{-2\pi i l s'/M} c_b^{(0,s;r',s')}(4kl-j^2) \\ \left\{\ln\left[1-e^{2\pi i r/N} e^{2\pi i(k\sigma + l\rho + jv)}\right] + \ln\left[1-e^{-2\pi i r/N} e^{-2\pi i(k\bar\sigma + l\bar\rho + j\bar v)}\right]\right\} & + \text{constant}\,. \end{aligned} \tag{B.24}$$

One can recognize (B.24) as the contribution from $-2\ln\widetilde\Phi(\rho,\sigma,v) - 2\ln\check\Phi(\bar\rho,\bar\sigma,\bar v)$ except for the $k=0$ terms and the overall multiplicative factors in the product representation (1.9) of $\widetilde\Phi$ and (B.8) of $\check\Phi$. By carefully analyzing the contribution from the degenerate and the zero orbits one recovers the complete set of terms on the left hand side of (B.7).

C Zeroes of $\widetilde{\Phi}$

In this appendix we shall determine the locations of the zeroes of the function $\widetilde{\Phi}$. From (B.7) it follows that at the locations of the zeroes and poles of $\widetilde{\Phi}$ we have logarithmic divergences in $\widetilde{\mathcal{I}}$. Thus we can determine the locations of the zeroes and poles of $\widetilde{\Phi}$ by determining the singularities of $\widetilde{\mathcal{I}}$. Since the integrand in $\widetilde{\mathcal{I}}$ is finite for finite τ, and in its original form given in (B.4), (B.5) the integration over τ runs over the fundamental domain of $SL(2, \mathbb{Z})$, the only possible source of divergence is from the region of large τ_2. This requires that the powers of $q (\equiv e^{2\pi i\tau})$ and $\bar{q}$ be equal so that the τ_1 integral for large τ_2 does not vanish, and non-positive so that the τ_2 integral diverges. Since the only dependence on $\bar{q}$ is through the $\bar{q}^{p_R^2/2}$ term, and since p_R^2 is positive semi-definite, this requires p_R^2 to vanish. Furthermore p_L^2 is also positive semidefinite (although it is not directly apparent from its definition), and hence the only possible way to produce a divergence is to get a non-positive power of q from the expansion of $h_b^{(r,s;r',s')}(\tau)$.[7] Such terms are quite restricted, and one finds that the possible divergences in $\widetilde{\mathcal{I}}$ arise at [6, 40]

$$n_2(\rho\sigma - v^2) - m_1\rho + n_1\sigma + m_2 + jv = 0\,, \tag{C.1}$$

for values of (m_1, n_1, m_2, n_2, j) satisfying

$$\begin{aligned} & m_1 n_1 + m_2 n_2 + \frac{j^2}{4} = \frac{1}{4} - \beta, \qquad 0 \le \beta < \frac{1}{4}\,, \\ & m_1 \in \mathbb{Z}, \quad m_2 \in \mathbb{Z}/N, \quad n_2 \in \mathbb{Z}, \quad n_1 \in \mathbb{Z}/M, \quad j \in 2\,\mathbb{Z} + 1\,. \end{aligned} \tag{C.2}$$

At this point p_R^2 vanishes and $p_L^2/2 = (1/4) - \beta$ so that the $q^{p_L^2/2}\bar{q}^{p_R^2/2}$ factor becomes purely a function of τ and not of $\bar{\tau}$. This has to be cancelled against a similar τ dependent factor in h_b so that the τ_1 integral is finite and we get a logarithmically divergent τ_2 integral. The coefficient of the divergent term can be easily determined from (B.5), (B.1) and (B.7) and we get, near this point,[8]

$$\begin{aligned} \widetilde{\Phi}(\rho,\sigma,v) \;\sim\;& \left(n_2(\rho\sigma - v^2) - m_1\rho + n_1\sigma + m_2 + jv\right)^{\sum_{s'=0}^{M-1}\sum_{s=0}^{N-1} e^{2\pi i m_1 s'/M} e^{-2\pi i m_2 s} c_1^{(r,s;r',s')}(-1+4\beta)}\,, \\ & r = -n_2 \bmod N, \quad r' = M n_1 \bmod M\,. \end{aligned} \tag{C.3}$$

---

[7] There is a further restriction coming from the fact that for $p_L^2 = p_R^2 = 0$ all the m_i's, n_i's and j must vanish. The divergence in the τ_2 integral from such a term is removed by the subtraction term in (B.5). Thus a divergent τ_2 integral requires p_L^2 to be strictly positive. This explains the strict inequality $\beta < \frac{1}{4}$ in (C.2).

[8] We need to account for the fact that the terms in the expression for $\widetilde{\mathcal{I}}$ with (m_i, n_i, j) and $(-m_i, -n_i, -j)$ give identical results.

Let us first focus on the $r = r' = 0$ terms, i.e. configurations with $n_2 \in N\,\mathbb{Z}$, $n_1 \in \mathbb{Z}$. In this case it follows from (C.2) that β must vanish and so the right hand side of (C.3) involves $c_1^{(0,s;0,s')}(-1)$. Using (2.8) we now get, for $\mathcal{M} = K3$,

$$\sum_{s'=0}^{M-1}\sum_{s=0}^{N-1} e^{2\pi i m_1 s'/M} e^{-2\pi i m_2 s} c_1^{(0,s;0,s')}(-1) = \begin{cases} 2 \text{ for } m_1 \in M\,\mathbb{Z},\, m_2 \in \mathbb{Z} \\ 0 \text{ otherwise}\,, \end{cases} \tag{C.4}$$

and for $\mathcal{M} = T^4$,

$$\sum_{s'=0}^{M-1}\sum_{s=0}^{N-1} e^{2\pi i m_1 s'/M} e^{-2\pi i m_2 s} c_1^{(0,s;0,s')}(-1) = \begin{cases} 2 \text{ for } m_1 \in M\,\mathbb{Z},\, m_2 \in \mathbb{Z} \\ -1 \text{ for } m_1 \in M\,\mathbb{Z} \pm 1,\, m_2 \in \mathbb{Z} \mp \frac{1}{N} \\ 0 \text{ otherwise}\,. \end{cases} \tag{C.5}$$

In either case the exponent is positive, producing zeroes of $\widetilde{\Phi}$, only for $m_1 \in M\,\mathbb{Z}$ and $m_2 \in \mathbb{Z}$. Thus the net result is that the only zeroes of $\widetilde{\Phi}$ for $r = r' = 0$ are of the form:

$$\begin{aligned} \widetilde{\Phi}(\rho,\sigma,v) \quad &\sim \quad \left(n_2(\rho\sigma - v^2) - m_1\rho + n_1\sigma + m_2 + jv\right)^2\,, \\ &m_1 \in M\,\mathbb{Z}, \quad m_2 \in \mathbb{Z}, \quad n_1 \in \mathbb{Z}, \quad n_2 \in N\,\mathbb{Z}\,. \end{aligned} \tag{C.6}$$

Let us now analyze the contribution to the exponent in (C.3) when r and/or r' is non-zero. From the definition of the coefficients $c_b^{(r,s;r',s')}$ given in (1.10) it follows that the exponent in (C.3) can be interpreted as the number of states weighted by $(-1)^{J_L+J_R}$ in the sector twisted by $g_N^r g_M^{r'}$, and carrying g_M eigenvalue $e^{-2\pi i m_1/M}$, g_N eigenvalue $e^{2\pi i m_2}$, $J_L = \pm 1$, $L_0 = \beta$ and $\bar{L}_0 = 0$. If $g_M^{r'} g_N^r$ does not have a fixed point in $\mathcal{M}$ then this number is zero since by taking the size of $\mathcal{M}$ to be sufficiently large we can ensure that there will be no twisted sector state with $\bar{L}_0 = 0$. If $g_M^{r'} g_N^r$ has fixed points in $\mathcal{M}$, then we can compute this number by taking the size of $\mathcal{M}$ to be large so that near the fixed points we can regard the space as almost flat, with $g_N^r g_M^{r'}$ acting as rotation by some angle θ in one plane and by $-\theta$ in an orthogonal plane. Under such rotations all the bosons and fermions in the sigma model with target space $\mathcal{M}$ are twisted and hence there are no zero modes. Thus we have a unique ground state with ($J_L = J_R = 0$). Even after we apply left-moving oscillators to create states with $L_0 = \beta$, $J_L = \pm 1$, the states will continue to have $J_R = 0$. Thus the weight factor $(-1)^{J_L+J_R}$ is always -1 for $J_L = \pm 1$ and hence the exponent of (C.3) is always negative. This shows that (C.3) never gives a zero of $\widetilde{\Phi}$ for r and/or r' non-zero, and the only zeroes of $\widetilde{\Phi}$ are of the form given in (C.6).

GENERALIZED MOONSHINE IV: MONSTROUS LIE ALGEBRAS

SCOTT HUAI-LEI CARNAHAN

ABSTRACT. For each element of the Fischer-Griess Monster sporadic simple group, we construct an infinite dimensional Lie algebra equipped with a projective action of the centralizer of that element. Our construction is given by a string-theoretic "add a spacetime torus and quantize" functor applied to an abelian intertwining algebra that is formed from a family of twisted modules of the Monster vertex operator algebra. We prove that for all Fricke elements in the Monster, the characters of centralizers acting on the corresponding irreducible twisted modules are Hauptmoduln. From these results, we resolve Norton's Generalized Moonshine Conjecture.

1. INTRODUCTION

For each element g of the Monster, we construct an infinite dimensional Lie algebra equipped with a canonical projective action of the centralizer of g. For those g satisfying the Fricke property, we show that the Lie algebras are Borcherds-Kac-Moody with a real simple root, and we use the resulting twisted denominator identities to prove Norton's Generalized Moonshine Conjecture for the class of irreducible twisted $V^\natural$-modules.

1.1. Generalized Moonshine.

We give a brief reminder of monstrous moonshine before describing its generalization. In the late 1970s, McKay observed that the q^1-term in the q-expansion of the normalized modular function $J = q^{-1} + 196884q + 21493760q^2 + \cdots$ is one more than the dimension of the smallest nontrivial complex representation of the Fischer-Griess Monster simple group $\mathbb{M}$, which is a sporadic simple group of order about 8×10^{53}. This observation suggested a relationship between the J-function and representations of the Monster that was further reinforced by additional computations by McKay and Thompson. Conway and Norton then did a massive computation with characters, producing evidence that there is an infinite dimensional graded representation $V = \bigoplus_{n=0}^{\infty} V_n$ of the Monster, such that the graded trace $T_g(\tau) = \sum_{n=0}^{\infty} \mathrm{Tr}(g|V_n)q^{n-1}$ of any element is the Fourier expansion (under $q = e^{2\pi i\tau}$) of a holomorphic function on the complex upper half-plane $\mathfrak{H}$ that is moreover a Hauptmodul [Conway-Norton-1979]. That is, for each $g \in \mathbb{M}$, there is a group $\Gamma_g \subset SL_2(\mathbb{R})$ under which $T_g(\tau)$ is invariant, such that the quotient curve $X_g = \mathfrak{H}/\Gamma_g$ is genus zero, and T_g generates the field of meromorphic functions on X_g. A candidate representation $V^\natural$ was constructed by Frenkel, Lepowsky, and Meurman, who showed that it is a vertex operator algebra whose automorphism group is precisely $\mathbb{M}$, and its graded dimension T_1 is J [Frenkel, et al, 1988]. Borcherds then proved Conway and Norton's conjecture for $V^\natural$ [Borcherds-1992].

In the Conway-Norton paper, the authors suggest that there may be moonshine-like phenomena for groups other than $\mathbb{M}$, and shortly afterward, Queen did some computations that yielded concrete evidence that one can obtain Hauptmoduln from characters of a variety of large finite groups [Queen-1981]. In particular, the low-order coefficients of many such modular functions can be assembled from representations of sporadic simple groups other than the Monster.

For illumination, we consider a level 2 example. The irreducible representations of the Baby Monster sporadic simple group $\mathbb{B}$ have dimension $1, 4371, 96255, \ldots$, while the power series $q^{-1} + 4372q + 96256q^2 + \cdots$ is the q-expansion of $\frac{\Delta(\tau)}{\Delta(2\tau)} + \frac{\Delta(2\tau)}{\Delta(\tau)} + 24$, which is a Hauptmodul for $\Gamma_0(2)^+$. It is difficult to resist the temptation to decompose the coefficients as small combinations of dimensions of irreducible representations: $4372 = 4371 + 1$ and $96256 = 96255 + 1$. Furthermore, we encounter promising evidence in the form of the character of an element in conjugacy class 2A: the first term yields $q^{-1} - 492q + O(q^2)$, and there is a well-known modular function $\sqrt{j(2\tau) - 1728} = q^{-1} - 492q - 22590q^3 - \cdots$ that is a Hauptmodul for $\Gamma_0(2|2)$. However, a complication arises: the q^2 term in our character does not vanish, since the trace of 2A on $\underline{96255}$ is 4863, not -1. Despite the initial promising evidence, we find that the Baby Monster group does not yield moonshine-like behavior. However, there is a central extension $2.\mathbb{B}$, with an irreducible representation of dimension 96256, where the trace of 2A is zero. By replacing the Baby Monster with its central extension, we eliminate this obstruction to assembling the characters into modular functions. Similar behavior appears when considering the sporadic group Fi_{24}, where one needs to pass to a triple cover to get a representation of dimension 783, yielding a level 3 modular function $q^{-1} + 783q + \cdots$. What these examples have in common is that both $2.\mathbb{B}$ and $3.Fi_{24}$ are centralizers of elements of the Monster.

Norton employed these computations and many of his own to formulate the following conjecture:

Conjecture. *(Generalized Moonshine [Norton-1987], revised in [Norton-2001]) There exists a rule that assigns to each element g of the Monster simple group $\mathbb{M}$ a graded projective representation $V(g) = \bigoplus_{n \in \mathbb{Q}} V(g)_n$ of the centralizer $C_{\mathbb{M}}(g)$, and to each pair (g, h) of commuting elements of $\mathbb{M}$ a holomorphic function $Z(g, h, \tau)$ on the complex upper half-plane $\mathfrak{H}$, satisfying the following conditions:*

(1) *There is some lift $\tilde{h}$ of h to a linear transformation on $V(g)$ such that*

$$Z(g, h, \tau) = \sum_{n \in \mathbb{Q}} Tr(\tilde{h}|V(g)_n)q^{n-1}.$$

(2) *$Z(g, h, \tau)$ is invariant up to constant multiplication under simultaneous conjugation of the pair (g, h) in $\mathbb{M}$.*

(3) *$Z(g, h, \tau)$ is either constant, or a Hauptmodul for some genus zero congruence group.*

(4) *For any $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in SL_2(\mathbb{Z})$, $Z(g^a h^c, g^b h^d, \tau)$ is proportional to $Z(g, h, \frac{a\tau + b}{c\tau + d})$.*

(5) $Z(g,h,\tau) = J(\tau) = \frac{E_4(\tau)^3}{\Delta(\tau)} - 744 = q^{-1} + 196884q + \cdots$ *if and only if* $g = h = 1 \in \mathbb{M}$.

This is a generalization of the Monstrous Moonshine Conjecture, in the sense that fixing $g = 1$ yields an assertion that one has a graded representation of $\mathbb{M}$ whose characters form Hauptmoduln. It also subsumes the example observation above, in the sense that if $q^{-1}+4372q+96256q^2+\cdots$ is the Moonshine character of an element g in class 2A of the Monster, then $Z(g,1,\tau)$ is proportional to $q^{-1/2}+4372q^{1/2}+96256q+\cdots$, and these coefficients decompose into well-behaved representations of $2.\mathbb{B}$, the centralizer of an element in class 2A of the Monster.

In contrast to the situation with the original Monstrous Moonshine conjecture, we do not have a list of conjugacy classes of commuting pairs of elements in $\mathbb{M}$, or a list of character tables of central extensions of centralizers of elements at our disposal. Conversations with group theorists suggest that these explicit data are still beyond current technology, so at the moment, we cannot solve the conjecture by computational brute force. Instead, one needs to find an interpretation of the spaces $V(g)$ and the functions Z, and one must seek general methods for proving that traces like Z yield Hauptmoduln, and for showing that traces are $SL_2(\mathbb{Z})$-compatible.

Shortly after Norton published this conjecture, Dixon, Ginsparg, and Harvey found a physical interpretation for claims 1,2,4, and 5: For each $g \in \mathbb{M}$, the space $V(g)$ is the "Hilbert space twisted by g" in a conformal field theory with $\mathbb{M}$ symmetry, and $Z(g,h)$ is a genus one partition function for a torus twisted in "space" by g and in "time" by h [Dixon-Ginsparg-Harvey-1988]. In algebraic language, we would say that for each $g \in \mathbb{M}$, we have a distinguished irreducible g-twisted module $V^\natural(g)$ of the Monster vertex operator algebra, and one may hope that such objects exist and are unique up to isomorphism.

The first major mathematical breakthrough toward a solution of this conjecture then came in [Dong-Li-Mason-2000], with the following results:

1. Theorem 10.3 asserts that for any $g \in \mathbb{M}$, there exists an irreducible g-twisted $V^\natural$-module, and it is unique up to isomorphism. By Schur's Lemma, such a module $V^\natural(g)$ admits a canonical projective action of $C_{\mathbb{M}}(g)$. By general nonsense about conjugation, this resolves Claim 2, at least on the level of formal power series.
2. Theorem 8.1 implies the series $\sum_{n\in\mathbb{Q}} Tr(\tilde{h}|V(g)_n)q^{n-1}$ converges absolutely uniformly on compact subsets of the complex upper half-plane to a holomorphic function, for any lift $\tilde{h}$ of an element $h \in C_{\mathbb{M}}(g)$. We can therefore define $Z(g,h,\tau)$ to be this function for some choice of $\tilde{h}$. This resolves Claim 1, and translates the power-series version of Claim 2 to a holomorphic function version.
3. Theorem 10.3 also contains an assertion that implies $Z(g,1,\tau)$ is a constant multiple of $Z(1,g,-1/\tau)$. This resolves Claim 5, essentially by the fact that $Z(1,g,\tau)$ has level greater than 1 for any $g \neq 1$.
4. Theorem 10.1 reduces Claim 4 to an conjecture about g-rationality of $V^\natural$, i.e., that any g-twisted $V^\natural$-module is isomorphic to a direct sum of copies of $V^\natural(g)$.

Claim 4 was recently resolved: By Corollary 5.26 of [Carnahan-Miyamoto-2016], g-rationality holds for any simple regular non-negatively graded vertex operator algebra with an invariant bilinear form, and $V^\natural$ satisfies these properties. The final remaining claim is Claim 3, the Hauptmodul-or-constant property, and this is the subject of this paper.

Under the current interpretation, Claims 1,2,4, and 5 are in fact general claims about non-negatively graded holomorphic C_2-cofinite vertex operator algebras and their automorphisms. That is, these claims hold true for an infinite class of examples, and don't have much to do with the Monster, except for the fact that $V^\natural$ is a particularly well-behaved vertex operator algebra. Claim 3 has a more exceptional, moonshine-like quality, since there are only finitely many Hauptmoduln, and the restriction on level gives an indication of smallness. For this reason, a solution cannot be expected to appear directly from general facts about vertex operator algebras or conformal field theory. Perhaps unsurprisingly, this is the only claim that was not given a physical interpretation by Dixon-Ginsparg-Harvey. Proving such an exceptional claim seems to require a specialized strategy, and this is where we come to our second major breakthrough.

In an unpublished preprint [Höhn-2003b], Höhn resolved the Hauptmodul claim for the case where g is an element in the conjugacy class 2A. The resolution of this case is by itself a substantial advance, but more importantly, Höhn's preprint contained a general strategy for proving that Generalized Moonshine trace functions are Hauptmoduln. Alternatively, one may say that Höhn worked out precisely the ingredients needed to extend Borcherds's proof of the Monstrous Moonshine Conjecture to the general case in question. We shall call this the Borcherds-Höhn program:

1. Build an abelian intertwining algebra structure on the direct sum $\bigoplus_{i=0}^{|g|-1} V^\natural(g^i)$.
2. Add a spacetime torus: Make a conformal vertex algebra of central charge 26 by taking a graded tensor product with the abelian intertwining algebra of a suitable hyperbolic lattice.
3. Quantize: Apply a bosonic string quantization functor to the conformal vertex algebra. This yields a Lie algebra $\mathfrak{m}_g$ equipped with a canonical projective action of $C_{\mathbb{M}}(g)$ by automorphisms.
4. Generate a Lie algebra L_g whose denominator identity is some automorphic infinite product. This Lie algebra has a "nice shape", in the sense that its simple roots and homology are well-controlled.
5. Comparison: Show that the Lie algebra $\mathfrak{m}_g$ is isomorphic to L_g. By *transport de structure*, we obtain a Lie algebra with both a group action and nice shape.
6. Hauptmodul conclusion: Use the twisted denominator identity to produce recursion relations on the characters that are strong enough to conclude that the characters are Hauptmoduln.

When $g = 1$, this program gives an outline of Borcherds's proof [Borcherds-1992], with the first step given by Frenkel-Lepowsky-Meurman's construction of $V^\natural$. When g is an element of type 2A, this program gives an outline of Höhn's proof of Generalized Moonshine for $2.\mathbb{B}$ [Höhn-2003b]. In both of those cases, the last step was settled by combining recursion relations with an explicit computation of the first few terms, to match the proposed functions with the actual characters. In general, we do not have character tables for central extensions of centralizers in the Monster, so such explicit computations are out of the question. Instead, we found a general Hauptmodul criterion involving equivariant Hecke operators in [Carnahan-2010], generalizing the results of [Cummins-Gannon-1997]. While Cummins-Gannon could be applied to remove the computations from Borcherds's proof of the Monstrous Moonshine conjecture [Borcherds-1992], our methods could be used to eliminate explicit computations for all cases we expected to encounter, including Höhn's proof. This settles the last step, conditional on the constructions in the previous steps.

The step with L_g was resolved in [Carnahan-2012], i.e., we constructed automorphic infinite products and candidate Lie algebras for each element of the Monster. We also defined a precise condition, called "Fricke-compatibility", on a projective action of $C_{\mathbb{M}}(g)$ on L_g that suffices for showing that the Hauptmodul condition holds for g of Fricke type. The question of producing such an action is essentially equivalent to the question of constructing $\mathfrak{m}_g$ and showing that $\mathfrak{m}_g \cong L_g$, and this is precisely what we resolve in this paper.

The first step is the most technically challenging. For example, in the case $g = 1$, this is the construction of the moonshine module $V^\natural$, which takes up the whole book [Frenkel, et al, 1988]. Before my recent project with Miyamoto culminating in [Carnahan-Miyamoto-2016], I had formed an elaborate plan to construct suitable abelian intertwining algebras using the theory of conformal blocks on twisted nodal curves together with some work eliminating homological obstructions. Some of this theory was sketched in my dissertation [Carnahan-2007], and the third paper in this series

[Carnahan≥2016] is intended to present a full development. I believe the methods are still useful in a general mathematical sense, and the first installment of results should appear in the near future.

We therefore come to the third major breakthrough, which rendered my plan superfluous for the purpose of proving Generalized Moonshine. In [van Ekeren, et al, 2015], the authors showed that there is an abelian intertwining algebra structure on a sum of twisted modules of a well-behaved vertex operator algebra, by an ingenious application of the Verlinde formula [Huang-2008] together with the fixed-point regularity results of [Carnahan-Miyamoto-2016]. Furthermore, they determined the precise characters of modules of the fixed point vertex algebra $(V^\natural)^{\langle g \rangle}$. Thus, their results essentially establish the first step, and go a long way toward the comparison step.

We now describe how the results of this paper fit in. In order to construct $\mathfrak{m}_g$, we need a functorial way to pass from abelian intertwining algebras to Lie algebras. We will employ an "add a spacetime torus and quantize" functor that has existed in some form for over 40 years, but we supply some necessary details that have not appeared in the literature. Adding a torus is just a degree-wise tensor product with the abelian intertwining algebra of a well-chosen hyperbolic rational lattice. The quantization functor takes conformal vertex algebras of central charge 26 to Lie algebras. We exploit the "cancellation of oscillators" phenomenon to describe the homogeneous spaces of the Lie algebras explicitly in terms of the input object. This theory was one of the main engines behind Frenkel's bound on root multiplicities of the Lie algebra whose simple roots form the Leech Lattice as its Dynkin diagram [Frenkel-1985], Borcherds's proof of the Monstrous Moonshine conjecture, and Hoehn's proof of Generalized Moonshine in the 2A case.

Once $\mathfrak{m}_g$ is constructed, we show that it is a Borcherds-Kac-Moody algebra by introducing a new criterion that is particularly well-suited to considering the output of the quantization functor. Then, the homogeneous subspaces become root spaces, and they are canonically identified with certain subspaces of twisted modules as representations of some central extension of $C_{\mathbb{M}}(g)$. The comparison isomorphism $\mathfrak{m}_g \cong L_g$ then follows from a comparison of root multiplicities, and this is made possible by the precise character work in [van Ekeren, et al, 2015].

The reader may be interested to know just how much information about $V^\natural$ and the Monster was necessary for our proof to work. In fact, we need almost no fine structure at all. By examining the proof in this paper, together with the work on which it depends, we see that in fact we have the following result:

Theorem 1.1.1. *Let V be a holomorphic C_2-cofinite vertex operator algebra of central charge 24 whose character is $J(\tau)$, and let G be a finite order group of automorphisms of V. Then any rule assigning to each $g \in G$ the irreducible g-twisted module $V(g)$, and to each commuting pair (g,h) the function $Z(g,h;\tau) = \mathrm{Tr}(\tilde{h} q^{L_0 - 1} | V(g))$ for some lift $\tilde{h} \in \widetilde{C_G(g)}$ of h to a linear transformation on $V(g)$, satisfies the conditions of Norton's conjecture, with G in place of $\mathbb{M}$.*

This is quite similar to the situation with Borcherds's proof of the Monstrous moonshine conjectures - one only needs central charge 24, an invariant bilinear form, and the character J to get completely replicable functions (which were later shown to be either highly degenerate or Hauptmoduln in [Cummins-Gannon-1997]). However, without the construction of $V^\natural$ in [Frenkel, et al, 1988], this result loses most of its value, since the connection to the Monster is lost. As it happens, Frenkel-Lepowsky-Meurman conjectured in section 3 of the introduction of *loc. cit.* that any V satisfying (more or less) the hypotheses in this theorem is isomorphic to $V^\natural$, so if we assume a suitable variant of the FLM Uniqueness Conjecture, then the statement given here becomes essentially the same as our Main Theorem (Theorem 4.2.2).

We note that there is previous work on Generalized Moonshine that establishes some Hautpmodul results for twisted modules - perhaps the most advanced was [Ivanov-Tuite-2002]. However, these results were conditional on both the Uniqueness Conjecture and the construction of holomorphic orbifolds established in [van Ekeren, et al, 2015].

We do not consider this the end of the Generalized Moonshine story. There are conjectural refinements of our main theorem, and intriguing conjectural relations between Generalized Moonshine and other fields of mathematics and physics. We focus on three further questions:

1. Norton has suggested stronger versions of this conjecture based on computational evidence [Norton-2001]. In particular, he asserts that the constant ambiguity can be reduced to a root of unity (in particular a 24th root), and that for any (g, h), there is some rational k such that each coefficient of $Z(g, h, \tau + k)$ generates a field extension of $\mathbb{Q}$ with Galois group of exponent 2. Terry Gannon has proposed a further refinement of the root-of-unity restriction, asserting that the proportionality constants are completely controlled by a 3-cocycle in the cohomology of $\mathbb{M}$, with coefficients in $U(1)$. The precise conjectural relationship between a suitable 3-cocycle and the proportionality constants is detailed in section 2 of [Gaberdiel-Persson-Volpato-2013]. Such a cocycle is expected from orbifold conformal field theory considerations [Dijkgraaf-Pasquier-Roche-1990], and an analogue of this refinement for M_{24} moonshine was established in [Gaberdiel, et al, 2012]. We note that this refinement is a general statement about twistings of holomorphic C_2-cofinite vertex operator algebras, and does not have a substantial connection to the Hauptmodul problem we solve in this paper.
2. Recall that almost all of the claims in the Generalized Moonshine conjecture were given physical interpretations in [Dixon-Ginsparg-Harvey-1988], and the remaining claim concerns Hauptmoduln. As it happens, there is a conjectural connection between Hauptmoduln and physics through Rademacher sums, as suggested in [Duncan-Frenkel-2011]. The general picture is that AdS/CFT correspondence seems to relate 2+1-dimensional gravity in the extreme quantum regime with conformal field theories satisfying smallness conditions. In particular, Duncan and Frenkel propose the existence of a class of second-quantized twisted chiral quantum gravity theories that can be manipulated to produce the monstrous Lie algebras $\mathfrak{m}_g$ constructed in this paper.
3. There are intriguing conjectural connections between moonshine and equivariant elliptic cohomology. The folklore idea is that elliptic cohomology is somehow controlled by, or is a shadow of, conformal field theory. Concretely, an element of the elliptic cohomology of the classifying space of a finite group G is a datum that includes a family of modular forms parametrized by a pair of commuting elements of G, satisfying an $SL_2(\mathbb{Z})$-compatibility condition. It was noted quite early (and I am not sure who was first - perhaps Mason) that the weight zero version of this condition is precisely given as claim 4 in the Generalized Moonshine conjecture. While elliptic cohomology does not play a direct role in our proof of the Generalized Moonshine conjecture, it was essential in an inspirational sense. Indeed, equivariant Hecke operators, seen as power operations in equivariant elliptic cohomology, were the key to the formulation of a good Hauptmodul criterion in [Carnahan-2010]. I believe the precise formula was first written in [Ganter-2009], where one may also find a topological interpretation of replicability. This piece of history, together with hints relating the formation of $\mathfrak{m}_g$ to exponential operations, suggests that the Hauptmodul claim may be amenable to a topological interpretation.

We would be interested in seeing any developments toward the refined versions of this conjecture, and the establishment of stronger connections to other mathematical disciplines.

1.2. **Overview.** In section 2, we introduce some vertex algebraic constructions, such as abelian intertwining algebras and the "add a torus" functors. The main purpose of this section is to take the results of [van Ekeren, et al, 2015], and transmute their construction into a form that is amenable to quantization.

In section 3, we construct Lie algebras, using a generalization of Borcherds's method for constructing the Monster Lie algebra. Due to the functorial nature of the construction, we obtain canonical group actions by homogeneous automorphisms. We show that for Fricke elements, the resulting Lie algebras are necessarily Borcherds-Kac-Moody, and we show that the root multiplicities match the dimensions of certain eigenspaces in twisted modules.

In section 4, we compare root multiplicities. For Fricke elements, this then yields isomorphisms with the Lie algebras constructed in [Carnahan-2012], and we find that characters of centralizers are Hauptmoduln. This then implies the full conjecture.

1.3. **Acknowledgments.** The author would like to thank Richard Borcherds, Jethro van Ekeren, Jeff Harvey, Yoshitake Hashimoto, Gerald Höhn, Satoshi Kondo, Gregory Moore, Luboš Motl, Yu Nakayama, Simon Norton, and Nils Scheithauer for helpful conversations and advice. Kazuya Kawasetsu, Sven Möller, and Hiromichi Yamada offered suggestions and corrections to an earlier version of this article.

2. Vertex algebraic input

Algebraic structures related to vertex algebras are essential to moonshine, but we will not need to spend much time on fine details, since most of the technical aspects have been worked out. We will review some basic facts, then pursue some consequences of the work of [van Ekeren, et al, 2015].

We will use the notation $e(s)$ to denote the normalized exponential $e^{2\pi i s}$.

2.1. Vertex algebras and twisted modules.

Definition 2.1.1. A vertex algebra over $\mathcal{C}$ is a complex vector space V equipped with a distinguished vector $\mathbf{1} \in V$, a distinguished linear transformation $T : V \to V$, and a left multiplication map $Y : V \to (\operatorname{End} V)[[z, z^{-1}]]$, written $Y(a,z) = \sum_{n \in \mathbb{Z}} a_n z^{-n-1}$ satisfying the following conditions:

1. $Y(\mathbf{1}, z) = id_V = id_V z^0$, and $Y(a,z)\mathbf{1} \in a + zV[[z]]$.
2. For any $a, b \in V$, $Y(a,z)b \in V((z))$, i.e., $a_n b = 0$ for n sufficiently large.
3. $[T, Y(a,z)] = \frac{d}{dz} Y(a,z)$
4. The Jacobi identity: for any $a, b \in V$,

$$x^{-1}\delta\left(\frac{y-z}{x}\right) Y(a,y)Y(b,z) - x^{-1}\delta\left(\frac{z-y}{-x}\right) Y(b,z)Y(a,y) = z^{-1}\delta\left(\frac{y-x}{z}\right) Y(Y(a,x)b,z)$$

where $\delta(z) = \sum_{n \in \mathbb{Z}} z^n$ and $\delta(\frac{y-z}{x})$ is expanded as a formal power series in z.

An automorphism of a vertex algebra V is a linear transformation $g : V \to V$ that fixes $\mathbf{1}$, and satisfies $Y(ga,z)gb = gY(a,z)b$ for all $a, b \in V$.

Definition 2.1.2. A conformal vertex algebra of central charge $c \in \mathbb{C}$ is a vertex algebra equipped with a distinguished nonzero vector ω, satisfying the following conditions:

1. If we write $Y(\omega, z) = \sum_{n \in \mathbb{Z}} L_n z^{-n-2}$, then the coefficients $L_n \in \operatorname{End} V$ satisfy the Virasoro relations:
$$[L_m, L_n] = (m-n)L_{m+n} + c\frac{m^3 - m}{12}\delta_{m+n,0} id_V$$
2. L_0 acts semisimply on V, with integer eigenvalues.
3. $L_{-1} = T$.

An automorphism of a conformal vertex algebra is an automorphism of the underlying vertex algebra that fixes ω. A vertex operator algebra is a conformal vertex algebra for which the eigenvalues of L_0 are bounded below and have finite multiplicity.

We will only consider one vertex operator algebra in this paper, namely the Monster vertex operator algebra $V^\natural$ that was constructed in [Frenkel, et al, 1988].

Vertex algebras have a more complicated representation theory than ordinary algebras, because modules may be twisted by automorphisms of the vertex algebra.

Definition 2.1.3. Let V be a vertex algebra over $\mathbb{C}$, and let g be an automorphism of order n. Then a g-twisted V-module is a complex vector space M equipped with an action map $Y^M : V \to (\operatorname{End} M)[[z^{1/n}, z^{-1/n}]]$, written $Y^M(a,z) = \sum_{k \in \frac{1}{n}\mathbb{Z}} a_k z^{-k-1}$ satisfying the following conditions:

1. $Y^M(\mathbf{1}, z) = id_M$
2. For any $a \in V$, $u \in M$, $Y^M(a,z)u \in M((z^{1/n}))$, i.e., $a_k u = 0$ if k is sufficiently large.
3. If $a \in V$ satisfies $ga = e(k/n)a$ for some $k \in \mathbb{Z}$, then $Y^M(a,z) \in z^{k/n}(\operatorname{End} M)[[z, z^{-1}]]$.
4. The twisted Jacobi identity holds: if $ga = e(k/n)a$, then for any $b \in V$,

$$x^{-1}\delta\left(\frac{y-z}{x}\right)Y^M(a,y)Y^M(b,z) - x^{-1}\delta\left(\frac{z-y}{-x}\right)Y^M(b,z)Y^M(a,y) =$$
$$= z^{-1}\left(\frac{y-x}{z}\right)^{-k/n}\delta\left(\frac{y-x}{z}\right)Y^M(Y(a,x)b,z)$$

If V is a vertex operator algebra, these conditions define the notion of "weak g-twisted V-module". An "admissible g-twisted V-module" is a weak g-twisted V-module that admits a $\frac{1}{n}\mathbb{Z}_{\geq 0}$-grading that is compatible with the L_0-grading on V. An "ordinary g-twisted V-module" is an admissible g-twisted V-module for which L_0 acts semisimply, with finite dimensional eigenspaces, and eigenvalues that are bounded below in each coset of $\mathbb{Z}$ in $\mathbb{C}$. When $g = 1$, we replace "g-twisted V-module" with "V-module".

Definition 2.1.4. Here are a few more technical conditions about vertex algebras. We won't use them in any specific way, but they appear as conditions in the theorems we need.

1. A vertex algebra V is C_2-cofinite if the subspace $C_2(V)$ spanned by $\{a_2 b | a, b \in V\}$ satisfies the property that $V/C_2(V)$ is finite dimensional.
2. A vertex operator algebra V is g-rational if all admissible g-twisted V-modules are direct sums of irreducible ordinary g-twisted V-modules.
3. A vertex operator algebra V is holomorphic if all admissible V-modules are isomorphic to direct sums of V.
4. A vertex operator algebra V is of CFT type if L_0 has only non-negative eigenvalues, and the kernel of L_0 is spanned by $\mathbf{1}$.

Remark 2.1.5. Theorem 10.3 in [Dong-Li-Mason-2000] asserts that if a vertex operator algebra V is C_2-cofinite and holomorphic, then there exists a unique irreducible g-twisted V-module, which we will write as $V(g)$. For any automorphism h of V, one may change the action of V on the underlying vector space of $V(g)$ to produce a module isomorphic to $V(h^{-1}gh)$. By Schur's Lemma, we obtain a canonical projective action of $C_{\operatorname{Aut} V}(g)$ on the underlying vector space of $V(g)$, which is compatible with the action on V (but it is not an action by twisted module automorphisms, since those are just scalars).

Definition 2.1.6. We write $\operatorname{Aut} V(g)$ to denote the group of vector space automorphisms of $V(g)$ that are compatible with automorphisms of V - it is a central extension of $C_{\operatorname{Aut} V}(g)$ by $\mathbb{C}^\times$.

2.2. Abelian intertwining algebras.

Dong and Lepowsky introduced abelian intertwining algebras essentially as vertex algebras with some monodromy obstructing commutativity. We describe them briefly, and we describe the theorem we need from [van Ekeren, et al, 2015].

Definition 2.2.1. ([MacLane-1952]) Let A be an abelian group. The Eilenberg-Mac Lane cochain complex with coefficients in $\mathbb{C}^\times$ has the following description in low degree:

$$K^1 \xrightarrow{d^1} K^2 = \{f : A \times A \to \mathbb{C}^\times\} \xrightarrow{d^2} K^3 = \{(F,\Omega) : A^{\oplus 3} \times A^{\oplus 2} \to \mathbb{C}^\times\} \xrightarrow{d^3} \cdots$$

where:

1. $K^1 = \{\phi : A \to \mathbb{C}^\times\}$ and $K^2 = \{f : A \times A \to \mathbb{C}^\times\}$ are groups of set-theoretic maps.
2. $K^3 = \{(F,\Omega) : A^{\oplus 3} \times A^{\oplus 2} \to \mathbb{C}^\times\}$ is a group of pairs of set-theoretic maps.
3. The map $d^1 : K^1 \to K^2$ is given by the usual group cohomology coboundary $\phi \mapsto d^1\phi$, defined by $d^1\phi(i,j) = \phi(j) - \phi(i+j) + \phi(i)$.
4. The map $d^2 : K^2 \to K^3$ is given by the group cohomology coboundary $d^2 f(i,j,k) = f(j,k) - f(i+j,k) + f(i,j+k) - f(i,j)$ together with the antisymmetrizer: $(i,j) \mapsto \frac{f(i,j)}{f(j,i)}$.
5. The map $d^3 : K^3 \to K^4$ vanishes if and only if the following conditions are satisfied:
   (a) $F(i,j,k)F(i,j+k,\ell)F(j,k,\ell) = F(i+j,k,\ell)F(i,j,k+\ell)$ for all $i,j,k,\ell \in A$
   (b) $F(i,j,k)^{-1}\Omega(i,j+k)F(j,k,i)^{-1} = \Omega(i,j)F(j,i,k)^{-1}\Omega(i,k)$
   (c) $F(i,j,k)\Omega(i+j,k)F(k,i,j) = \Omega(j,k)F(i,k,j)\Omega(i,k)$

The kernel of d^n is written $Z^n_{ab}(A,\mathbb{C}^\times)$, and elements are called abelian n-cocycles. The cohomology of the Eilenberg-MacLane complex is called abelian cohomology, and written $H^n_{ab}(A,\mathbb{C}^\times)$. An abelian 3-cocycle is normalized if $F(i,j,0) = F(i,0,k) = F(0,j,k) = 1$ and $\Omega(i,0) = \Omega(0,j) = 1$ for all $i,j,k \in A$.

We note that any cohomology class has a normalized representative.

Lemma 2.2.2. *([MacLane-1952] Theorem 3) If (F,Ω) is an abelian 3-cocycle, then the map $Q : A \to \mathbb{C}^\times$ defined by $i \mapsto \Omega(i,i)$ is a quadratic function, i.e., $Q(i) = Q(-i)$ for all $i \in A$, and $\frac{Q(i+j+k)Q(i)Q(j)Q(k)}{Q(i+j)Q(i+k)Q(j+k)} = 1$ for all $i,j,k \in A$. Furthermore, the trace map $(F,\Omega) \mapsto (i \mapsto \Omega(i,i))$ induces a bijection from $H^3_{ab}(A,\mathbb{C}^\times)$ to the set of $\mathbb{C}^\times$-valued quadratic functions on A.*

Proof. This is proved as [Eilenberg-Mac Lane-1954], theorem 26.1. □

Definition 2.2.3. Let A be an abelian group, let (F,Ω) be an abelian 3-cocycle on A. We write $q_\Omega : A \to \mathbb{C}/\mathbb{Z}$ for the unique quadratic map such that $e(q_\Omega(a)) = \Omega(a,a)$ for all $a \in A$, and we write $b_\Omega : A \times A \to \mathbb{C}/\mathbb{Z}$ for the induced bilinear form.

We take the following definition from [Dong-Lepowsky-1993]

Definition 2.2.4. Let A be an abelian group, let (F,Ω) be a normalized abelian 3-cocycle on A. Then an abelian intertwining algebra of level $N \in \mathbb{Z}_{\geq 1}$ and central charge $c \in \mathbb{Q}$ associated to the datum (A,F,Ω) is a complex vector space V equipped with

1. a $\frac{1}{N}\mathbb{Z} \times A$-grading $V = \bigoplus_{n \in \frac{1}{N}\mathbb{Z}} V_n = \bigoplus_{i \in A} V^i = \bigoplus_{n \in \frac{1}{N}\mathbb{Z}, i \in A} V^i_n$
2. a left-multiplication $Y : V \to (\operatorname{End} V)[[z^{1/N}, z^{-1/N}]]$ written $Y(a,z) = \sum_{n \in \frac{1}{N}\mathbb{Z}} a_n z^{-n-1}$, and
3. distinguished vectors $\mathbf{1} \in V^0_0$ and $\omega \in V^0_2$

satisfying the following conditions for any $i,j,k \in A$, $a \in V^i$, $b \in V^j$, $u \in V^k$, and $n \in \frac{1}{N}\mathbb{Z}$:

1. $a_n b \in V^{i+j}$.
2. $a_n b = 0$ for n sufficiently large.
3. $Y(\mathbf{1},z)a = a$
4. $Y(a,z)\mathbf{1} \in a + zV[[z]]$.
5. $Y(a,z)b = \sum_{k \in b_\Omega(i,j)+\mathbb{Z}} a_k b z^{-k-1}$.

(6) The Jacobi identity:

$$x^{-1}\left(\frac{y-z}{x}\right)^{b_\Omega(i,j)}\delta\left(\frac{y-z}{x}\right)Y(a,y)Y(b,z)u$$
$$-B(i,j,k)x^{-1}\left(\frac{z-y}{e^{i\pi}x}\right)^{b_\Omega(i,j)}\delta\left(\frac{z-y}{-x}\right)Y(b,z)Y(a,y)u=$$
$$=F(i,j,k)z^{-1}\delta\left(\frac{y-x}{z}\right)Y(Y(a,x)b,z)\left(\frac{y-x}{z}\right)^{-b_\Omega(i,k)}u$$

where $B(i,j,k)=\frac{\Omega(i,j)F(i,j,k)}{F(j,i,k)}$.

(7) The coefficients of $Y(\omega,z)=\sum_{k\in\mathbb{Z}}L_kz^{-k-2}$ satisfy the Virasoro relations at central charge c.

(8) $L_0a=na$ if $a\in V_n$.

(9) $\frac{d}{dz}Y(a,z)=Y(L_{-1}a,z)$.

Given a suitably nondegenerate abelian intertwining algebra (namely one where left multiplication by elements of V^i is not the zero map), one has an additional $\mathbb{C}/\mathbb{Z}$-valued quadratic form q_Δ on A, given by setting $q_\Delta(i)$ to be the conformal weight of V^i. It is not hard to show that the associated bilinear forms satisfy $b_\Omega=-b_\Delta$ (see, e.g., the discussion in [van Ekeren, et al, 2015] after Theorem 4.2). Furthermore, it is often the case that we have $q_\Omega=-q_\Delta$ - when this holds, we say that the abelian intertwining algebra is "even".

Dong and Lepowsky give the following generalization of the lattice vertex algebra construction: for any finite rank free abelian group L with a $\frac{1}{N}\mathbb{Z}$-valued quadratic form, we may produce the abelian intertwining algebra $V=V_L$ attached to L. It is L-graded, and the L-homogeneous pieces are the usual modules $\pi_\lambda^{L\otimes\mathbb{C}}$ of the Heisenberg vertex algebra $\pi_0^{L\otimes\mathbb{C}}$ for the quadratic vector space $L\otimes\mathbb{C}$ attached to vectors $\lambda\in L$. This abelian intertwining algebra is even, i.e., it satisfies $q_\Delta=-q_\Omega$. One needs to choose a cocycle (F,Ω) in the cohomology class of q_Ω to obtain an abelian intertwining algebra, but we have the following way to pass between different choices.

Lemma 2.2.5. *Given an abelian intertwining algebra V with cocycle (F,Ω), and any function $f\in K^2$ satisfying $f(i,0)=f(0,j)=1$, the tuple $(V,1,\omega,f\cdot Y)$ is an abelian intertwining algebra with cocycle $d_2f\cdot(F,\Omega)$. Here, $f\cdot Y$ is the map $V\to(\operatorname{End}V)[[z^{1/N},z^{-1/N}]]$ that takes a pair $a\in V^i$, $b\in V^j$ to $f(i,j)\cdot Y(a,z)b$.*

Proof. This is Remark 12.23 in [Dong-Lepowsky-1993]. ☐

Definition 2.2.6. Let q be a quadratic form on an abelian group A that takes values in $\frac{1}{N}\mathbb{Z}/\mathbb{Z}$. We define $AIA^c_{(A,q)}$ to be the following groupoid: objects are abelian intertwining algebras of level N with central charge c, associated to the datum (A,F,Ω) for some abelian 3-cocycle (F,Ω) such that $q_\Omega=e(q)$. Morphisms are homogeneous isomorphisms of abelian intertwining algebras.

By Lemma 2.2.5, this groupoid is equipped with an action of the abelian 3-coboundary group by autofunctors.

The last structure we introduce is a graded tensor product.

Definition 2.2.7. Let V be an object in $AIA^c_{(A,q)}$ with cocycle (F,Ω), and let W be an object in $AIA^{c'}_{(A,q')}$ with cocycle (F',Ω'). Then we define $V\otimes^A W$ to be the following object in $AIA^{c+c'}_{(A,qq')}$ with cocycle $(FF',\Omega\Omega')$:

(1) The underlying graded vector space is $\bigoplus_{i\in A}V^i\otimes W^i$

(2) Multiplication is induced by tensor product maps. That is, $Y(a\otimes a',z)(b\otimes b')=Y(a,z)b\otimes Y(a',z)b'$ for $a,b\in V$, and $a',b'\in W$.

(3) $\mathbf{1}_{V\otimes^A W}=\mathbf{1}_V\otimes\mathbf{1}_W$

(4) $\omega_{V\otimes^A W} = \omega_V \otimes \mathbf{1}_W + \mathbf{1}_V \otimes \omega_W$

The following theorem describes the results of van Ekeren, Möller, and Scheithauer that we need.

Theorem 2.2.8. *Let V be a holomorphic C_2-cofinite vertex operator algebra of CFT type, let g be an automorphism of V of order $n \in \mathbb{Z}_{\geq 1}$, and let $G = \langle g \rangle$ be the cyclic group generated by g. Suppose the L_0-spectrum of the irreducible twisted module $V(g^i)$ is strictly positive whenever $g^i \neq 1$. Then there is a distinguished element $t \in \mathbb{Z}/n\mathbb{Z}$ and a unique assignment of homomorphisms $\phi_i : G \to \operatorname{Aut} V(g^i)$ satisfying the following conditions:*

1. *If we let $V^{(i,j)} = \{v \in V(g^i) | \phi_i(g)v = e(j/n)v\}$, then the set $\{V^{(i,j)}\}_{i,j\in\mathbb{Z}/n\mathbb{Z}}$ forms a complete list of isomorphism classes of irreducible V^G-modules. They are simple currents, whose fusion rules satisfy $V^{(i,j)} \boxtimes V^{(k,l)} \cong V^{(i+k,j+l+c_{2t}(i,k))}$, where c_{2t} is the "add with carry" 2-cocycle $\mathbb{Z}/n\mathbb{Z} \times \mathbb{Z}/n\mathbb{Z} \to \mathbb{Z}/n\mathbb{Z}$ given by $c_{2t}(i,k) = \begin{cases} 0 & i_n + k_n < n \\ 2t & i_n + k_n \geq n \end{cases}$. Here, i_n and k_n denote the unique elements of $\{0, \dots, n-1\}$ to which i and k reduce modulo n, respectively, and we let D denote the central extension of $\mathbb{Z}/n\mathbb{Z}$ by $\mathbb{Z}/n\mathbb{Z}$ defined by the 2-cocycle c_{2t}.*
2. *There exists an abelian intertwining algebra ${}^gV \cong \bigoplus_{i\in\mathbb{Z}/n\mathbb{Z}} V(g^i) \cong \bigoplus_{i,j\in\mathbb{Z}/n\mathbb{Z}} V^{(i,j)}$, whose multiplication is compatible with the fusion rules on $V^{(i,j)}$, graded by the abelian group D, with $q_\Omega(i,j) = -\frac{ij}{n} - \frac{i_n^2 t_n}{n^2}$. Furthermore, ${}^gV$ is even, i.e., $q_\Delta(i,j) = -q_\Omega(i,j)$.*

Furthermore, if we write

$$T(v,i,j,\tau) = \operatorname{Tr}(o(v)\phi_i(g^j)q^{L_0-c/24}|V(g^i))$$
$$T_{(i,j)}(v;\tau) = \operatorname{Tr}(o(v)q^{L_0-c/24}|V^{(i,j)})$$

for all $v \in V^G$, $i,j \in \mathbb{Z}/n\mathbb{Z}$ and $q = e(\tau)$, where $o(v)$ is the zero-mode map (which is $v_{wt(v)-1}$ for homogeneous v), we obtain holomorphic functions on $\mathfrak{H}$ that satisfy the following modular transformation rules:

$$T(v,i,j,\tau+1) = e(\frac{i_n^2 t_n}{n^2} - \frac{c}{24})T(v,i,j+i,\tau)$$
$$T(v,i,j,\frac{-1}{\tau}) = \tau^{wt[v]}e(\frac{-2ti_nj_n}{n^2})T(v,j,-i,\tau)$$
$$T_{(i,j)}(v;\tau+1) = e(\frac{ij}{n} + \frac{i_n^2 t_n}{n^2} - \frac{c}{24})T_{(i,j)}(v;\tau)$$
$$T_{(i,j)}(v;\frac{-1}{\tau}) = \frac{1}{n}\tau^{wt[v]} \sum_{k,l\in\mathbb{Z}/n\mathbb{Z}} e(-\frac{kj+il}{n})e(\frac{-2ti_nk_n}{n^2})T_{(k,l)}(v;\tau)$$

where $wt[v]$ denotes the conformal weight with respect to Zhu's bracket grading [Zhu-1996].

Proof. We point out where the specific claims are given in [van Ekeren, et al, 2015]. The identification of eigenspaces with irreducible V^G-modules is Proposition 5.2, and the fact that they are simple currents is Proposition 5.6.

The fusion rules, conformal weights and S-matrix entries are given in Theorem 5.12. The modular transformation rules for $T(v,i,j,\tau)$ and $T_{(i,j)}(v;\tau)$ then follow from the identification of S-matrix entries and the conformal weights of modules.

The existence and properties of the abelian intertwining algebra are given in Theorem 4.1. □

We now show that this theorem can be applied to the object of our interest. Recall that an element g in the Monster is called Fricke if its McKay-Thompson series $T_g(\tau)$ is proportional to $T_g(-1/N\tau)$ for some N. Note that this is a definition that depends on the construction of the moonshine module $V^\natural$ in [Frenkel, et al, 1988]. By Borcherds's proof of the Monstrous Moonshine

Conjecture [Borcherds-1992], we have the following necessary and sufficient conditions for g to be Fricke: T_g has a pole at zero, or $T_g(\tau)$ is equal to $T_g(-1/N\tau)$ for some N. The Fricke property is conjugation-invariant, since the McKay-Thompson series is a trace. The conjectural enumeration of functions in [Conway-Norton-1979] (proved to be valid by Borcherds) shows that 120 of the 171 distinct McKay-Thompson series are Fricke, and 143 of the 194 conjugacy classes in the Monster are Fricke.

Theorem 2.2.9. *The Monster vertex operator algebra $V^\natural$ is holomorphic, C_2-cofinite, and of CFT type. For any nontrivial element g of the Monster, the L_0-spectrum of $V(g)$ is strictly positive. That is, the conditions of Theorem 2.2.8 are satisfied for any automorphism of $V^\natural$.*

Proof. The holomorphic property is proved in [Dong-1994], the C_2-cofinite property is proved in [Dong-Li-Mason-2000], and CFT type is clear from the construction [Frenkel, et al, 1988]. By Theorem 13.1 of [Dong-Li-Mason-2000], the character of $V^\natural(g)$ is a constant multiple of $T_g(-1/\tau)$, where $T_g(\tau) = Tr(gq^{L_0-1}|V^\natural)$ is the McKay-Thompson series. If T_g is regular at $\tau = 0$ (i.e., g is non-Fricke), then the lowest-weight space of $V(g)$ has L_0-eigenvalue at least 1. If T_g has a pole at $\tau = 0$ (i.e., g is Fricke), then the pole has order $1/N$, where N is the level of T_g, and the lowest-weight space of $V^\natural(g)$ has L_0-eigenvalue $1 - 1/N$. We conclude that as long as g is nontrivial, the lowest weight space has positive L_0-eigenvalue. ☐

We may then determine the precise graded dimension of twisted modules of $V^\natural$ - this eliminates the scalar ambiguity in [Dong-Li-Mason-2000].

Corollary 2.2.10. *For any $g \in \mathbb{M}$, hypothesis A_g from section 4.4 of [Carnahan-2012] is satisfied, i.e., $\sum_{n\in\mathbb{Q}} \dim V^\natural(g)_n q^{n-1} = T_g(-1/\tau)$.*

Proof. The left side of the equation is $T(\mathbf{1}, 1, 0, \tau)$, and the right side is $T(\mathbf{1}, 0, 1, -1/\tau)$, as defined in Theorem 2.2.8. By Theorem 2.2.9, we may apply Theorem 2.2.8 to $V^\natural$ and its twisted modules, so the two quantities are equal. ☐

Corollary 2.2.11. *If $V = V^\natural$, and $g \in \mathbb{M}$ has eigengroup $\Gamma_0(n|h) + e_1, e_2, \dots$ (in the notation of [Conway-Norton-1979]), then the distinguished element $t \in \mathbb{Z}/n\mathbb{Z}$ given in Theorem 2.2.8 is equal to $-n/h$ if g is Fricke and n/h if g is non-Fricke.*

Proof. The value of t is uniquely determined by the transformation $\tau \mapsto \tau + n$ on the graded dimension of $V^\natural(g)$. Theorem 2.2.8 gives us $T(\mathbf{1}, 1, 0, \tau - n) = e(-\frac{t_n}{n})T(\mathbf{1}, 1, 0, \tau)$, and Section 5 of [Conway-Norton-1979] gives us the transformation rule $T_g(\tau)|_0 \left(\begin{smallmatrix} 1 & 0 \\ n & 1 \end{smallmatrix}\right) = e(\pm 1/h)T_g(\tau)$, where we have a plus sign if and only if g is Fricke. The latter Möbius transformation conjugates to the $\tau \mapsto \tau - n$ transformation on $T(\mathbf{1}, 1, 0, \tau)$, so we have $t_n = \mp n/h$. ☐

2.3. **Unrolling.** In Section 3.1 of [Carnahan-2012] we introduce vector-valued modular functions $\hat{F}$ and F, which are uniquely determined by the $SL_2(\mathbb{Z})$ action on McKay-Thompson series. In section 4.1, we will need to match the functions $T(\mathbf{1}, i, j, \tau)$ with $\hat{F}_{i,j}(\tau)$ and $T_{(i,j)}(\tau)$ with $F_{i,j}(\tau)$ in order to show that certain Lie algebras are isomorphic. However, this is only possible when $t = 0$ given our current setup, because that is the only way the modular transformation rules can match. We will fix this problem by "unrolling" the abelian intertwining algebra into a $\mathbb{Z}/N\mathbb{Z} \times \mathbb{Z}/N\mathbb{Z}$-graded object in a unique way, for N any multiple of $\frac{n^2}{(n,t)}$. By passing to the unrolled object, the modular transformation rules match in all cases.

Lemma 2.3.1. *Let $V_A = \bigoplus_{a\in A} V_a$ be an abelian intertwining algebra with cocycle (F_A, Ω_A). Let (B, q) be an abelian group with $\mathbb{C}/\mathbb{Z}$-valued quadratic form, and let $\pi : (B, q) \to (A, (a \mapsto \Omega_A(a, a)))$ be the quotient by a null subgroup $I \subset B^\perp$. Then there is a unique "pullback" abelian intertwining algebra $W_B = \bigoplus_{b\in B} W_b$ satisfying the following properties:*

(1) $W_b = \begin{cases} V_a & b \in B, \pi(b) = a \\ 0 & b \notin B \end{cases}$
(2) *The multiplication map* $W_b \otimes W_{b'} \to W_{b+b'}\{z\}$ *is given by the multiplication* $V_a \otimes V_{a'} \to V_{a+a'}\{z\}$ *from* V_A *when* $b, b' \in B$, $\pi(b) = a$, *and* $\pi(b') = a'$.

The cocycle (F_B, Ω_B) *attached to* W_B *is precisely the pullback of the cocycle* (F_A, Ω_A) *attached to* V_A.

Proof. The fact that W_B satisfies the axioms of an abelian intertwining algebra follows straightforwardly from our definition of the multiplication operation - the Jacobi identity for W_B reduces immediately to the Jacobi identity for V_A. ☐

Lemma 2.3.2. *If* $i : (A, q_A) \to (B, q_B)$ *is a quadratic embedding (i.e.,* i *is an injective homomorphism of abelian groups, and* $q_B \circ i = q_A$*), and* V_A *is an* (A, q_A)*-graded abelian intertwining algebra, then there is a unique "extension by zero" abelian intertwining algebra* $W_B = \bigoplus_{b\in B} W_b$ *satisfying the following properties*

(1) $W_b = \begin{cases} V_a & b = i(a) \\ 0 & b \notin i(A) \end{cases}$
(2) *The multiplication map* $W_b \otimes W_{b'} \to W_{b+b'}\{z\}$ *is given by the multiplication* $V_a \otimes V_{a'} \to V_{a+a'}\{z\}$ *from* V_A *when* $b = i(a)$, *and* $b' = i(a')$. *For all other values of* b *and* b', *at least one of the input spaces is zero, so multiplication is trivial.*

The cocycle (F_B, Ω_B) *attached to* W_B *is uniquely determined by* (F_A, Ω_A) *up to a coboundary that vanishes identically on* $i(A)$.

Proof. Omitted. ☐

Definition 2.3.3. Given a diagram $(A, q) \xleftarrow{\pi} (A', q') \xhookrightarrow{i} (A'', q'')$ of quadratic spaces, we define the unrolling functor $AIA^c_{(A,q)} \to AIA^c_{(A'',q'')}$ as the composite of the pullback given in Lemma 2.3.1 and the extension by zero given in Lemma 2.3.2.

The following proposition shows that we can make the modular transformation rules in Theorem 2.2.8 somewhat cleaner by unrolling.

Proposition 2.3.4. *Let* V *be a holomorphic* C_2*-cofinite vertex operator algebra of CFT type, let* g *be an automorphism of* V *of order* $n \in \mathbb{Z}_{\geq 1}$, *such that the* L_0*-spectrum of the irreducible twisted module* $V(g^i)$ *is strictly positive whenever* $g^i \neq 1$. *Let* $t \in \mathbb{Z}/n\mathbb{Z}$ *be the distinguished element given by Theorem 2.2.8, and let* $N = \frac{rn^2}{(n,t)}$ *for some* $r \in \mathbb{Z}_{\geq 1}$. *Finally, let* B *denote the group* $\mathbb{Z}/N\mathbb{Z} \times \mathbb{Z}/N\mathbb{Z}$ *with quadratic form* $(a, b) \mapsto e(\frac{ab}{N})$. *Then the subgroup* $B' \subset B$ *generated by* $(0, \frac{rn}{(n,t)})$ *and* $(1, \frac{t_n r}{(n,t)})$ *admits a quadratic-form-preserving quotient map* $B' \to D$ *by* $a(1, \frac{t_n r}{(n,t)}) + b(0, \frac{rn}{(n,t)}) \mapsto (a_n, b_n + 2t_n\lfloor a/n \rfloor)$, *and there exists a unique set of homomorphisms* $\{\psi_a : \mathbb{Z}/N\mathbb{Z} \to \operatorname{Aut} V(g^a)\}_{a=0}^{N-1}$ *such that the abelian intertwining algebra* ${}^g_N W \cong \bigoplus_{(a,b)\in B} W^{(a,b)} \cong \bigoplus_{a=0}^{N-1} V(g^a)$ *unrolled from* ${}^gV$ *satisfies the following conditions:*

(1) *For each* $a, b \in \mathbb{Z}/N\mathbb{Z}$, *we have* $W^{(a,b)} = \{v \in V(g^a) | \psi_a(1)v = e(\frac{b}{N})v\}$, *and when* $W^{(a,b)} \neq 0$, *it is a simple current (in particular, an irreducible module) for the fixed-point algebra* V^g.
(2) *For any* $a, b \in \mathbb{Z}/N\mathbb{Z}$, *we have the equality* $\psi_a(b) = \phi_a(g^b)e(b\frac{a_n t_n}{n^2} - b\frac{t_n\lfloor a/n \rfloor}{n})$ *of automorphisms of* $V(g^a)$.
(3) *If we define* $T(a, b, \tau) = \operatorname{Tr}(\psi_a(b)q^{L_0 - c/24}|V(g^a))$ *and* $T_{(a,b)}(\tau) = \operatorname{Tr}(q^{L_0-c/24}|W^{(a,b)})$ *for all* $a, b \in \mathbb{Z}/N\mathbb{Z}$ *and* $q = e(\tau)$, *then we obtain holomorphic functions on* $\mathfrak{H}$ *that satisfy the*

following modular transformation rules:

$$\begin{aligned} T(a,b,\tau+1) &= e(-\frac{c}{24})T(a,b+a,\tau) \\ T(a,b,\frac{-1}{\tau}) &= T(b,-a,\tau) \\ T_{(a,b)}(\tau+1) &= e(\frac{ab}{N}-\frac{c}{24})T_{(a,b)}(\tau) \\ T_{(a,b)}(\frac{-1}{\tau}) &= \frac{1}{N}\sum_{p,q\in\mathbb{Z}/n\mathbb{Z}} e(-\frac{bp+aq}{N})T_{(p,q)}(\tau) \end{aligned}$$

In particular (following [Carnahan-2012] Lemma 3.6), if c is a multiple of 24, then the collection $\{T_{(a,b)}\}_{a,b\in\mathbb{Z}/N\mathbb{Z}}$ forms a vector-valued modular function of type ρ_M for $M = II_{1,1}(N)$, and the collection $\{T(a,b,\tau)\}_{a,b\in\mathbb{Z}/N\mathbb{Z}}$ describes a function on the moduli space $\mathcal{M}_{Ell}^{\mathbb{Z}/N\mathbb{Z}}$ of elliptic curves with $\mathbb{Z}/N\mathbb{Z}$-torsors.

Proof. We first check that $B' \to D$ preserves the quadratic form: $q_{B'}(a(1,\frac{t_n r}{(n,t)}) + b(0,\frac{rn}{(n,t)})) = \frac{ab}{n} + \frac{a^2 t_n}{n^2} + \mathbb{Z}$, while $q_D(a_n, b_n + 2t_n\lfloor a/n\rfloor) = \frac{a_n b_n + 2a_n t_n \lfloor a/n\rfloor}{n} + \frac{a_n^2 t_n}{n^2} + \mathbb{Z}$. Because $a = n\lfloor a/n\rfloor + a_n$, we have $\frac{a^2 t_n}{n^2} + \mathbb{Z} = \frac{a_n^2 t_n}{n^2} + \frac{2a_n t_n\lfloor a/n\rfloor}{n} + \mathbb{Z}$, so the two expressions agree.

We therefore have a well-defined unrolling functor, and an abelian intertwining algebra ${}^g_N W$ whose B-homogeneous components and multiplication maps are either pulled back from ${}^g V$ or zero. The homomorphisms ψ_a are uniquely determined by the B-grading on ${}^g_N W$. The simple current property follows from the first listed claim in 2.2.8.

We now check that $\psi_a(b) = \phi_a(g^b)e(b\frac{a_n t_n}{n^2} - b\frac{t_n\lfloor a/n\rfloor}{n})$ on $V(g^a)$. For any $a(1,\frac{t_n r}{(n,t)}) + j(0,\frac{rn}{(n,t)}) \in B'$, we have $\psi_a(1)|_{W^{a(1,\frac{t_n r}{(n,t)})+j(0,\frac{rn}{(n,t)})}} = e(\frac{at_n}{n^2} + \frac{j}{n})$. The module is the pullback of $V^{(a_n, j_n + 2t_n\lfloor a/n\rfloor)}$, where $\phi_a(g)$ acts as $e(\frac{j_n + 2t_n\lfloor a/n\rfloor}{n})$. Dividing the two answers, and taking the bth power yields the answer we want.

It remains to consider the modular transformation properties. We reduce the first two equations to the last two equations by noting that $\{T(a,b,\tau)\}$ and $T_{(a,b)}(\tau)$ are related by a discrete Fourier transform. That is, the equations

$$T(a,b,\tau) = \sum_{k\in\mathbb{Z}/N\mathbb{Z}} e\left(\frac{bk}{N}\right) T_{(a,k)}(\tau)$$

$$T_{(a,b)}(\tau) = \frac{1}{N}\sum_{k\in\mathbb{Z}/N\mathbb{Z}} e\left(\frac{-bk}{N}\right) T(a,k,\tau)$$

allow us to pass from one equation to the other - this is essentially Lemma 3.3 of [Carnahan-2012] but we multiply by the additional character $\left(\begin{smallmatrix}1&1\\0&1\end{smallmatrix}\right) \mapsto e(-c/24)$, $\left(\begin{smallmatrix}0&-1\\1&0\end{smallmatrix}\right) \mapsto 1$ of $SL_2(\mathbb{Z})$.

Since $W^{(a(1,\frac{t_n r}{(n,t)})+b(0,\frac{rn}{(n,t)}))} = V^{(a_n, b_n+2t_n\lfloor a/n\rfloor)}$, we have

$$T_{(a(1,\frac{t_n r}{(n,t)})+b(0,\frac{rn}{(n,t)}))}(\tau) = T_{(a_n,b_n+2t_n\lfloor a/n\rfloor)}(\mathbf{1},\tau)$$

for all $a,b\in\mathbb{Z}/N\mathbb{Z}$, and $T_{(a,b)}(\tau) = 0$ for $(a,b)\notin B'$. By our computation of the quadratic form in the first paragraph of this proof, we find that

$$\begin{aligned} T_{(a(1,\frac{t_n r}{(n,t)})+b(0,\frac{rn}{(n,t)}))}(\tau+1) &= T_{(a_n,b_n+2t_n\lfloor a/n\rfloor)}(\mathbf{1},\tau+1) \\ &= e\left(\frac{a_n(b_n+2t_n\lfloor a/n\rfloor)}{n} + \frac{a_n^2 t_n}{n^2} - \frac{c}{24}\right) T_{(a_n,b_n+2t_n\lfloor a/n\rfloor)}(\mathbf{1},\tau) \end{aligned}$$

Then $\frac{a_n(b_n+2t_n\lfloor a/n\rfloor)}{n} + \frac{a_n^2 t_n}{n^2} = \frac{ab}{n} + \frac{a^2 t_n}{n^2} = \frac{abrn+a^2t_nr}{N(n,t)} = \frac{a\left(\frac{at_nr}{(n,t)}+\frac{brn}{(n,t)}\right)}{N}$, so we obtain

$$T_{(a(1,\frac{t_nr}{(n,t)})+b(0,\frac{rn}{(n,t)}))}(\tau+1) = e\left(\frac{a\left(\frac{at_nr}{(n,t)}+\frac{brn}{(n,t)}\right)}{N} - \frac{c}{24}\right) T_{(a(1,\frac{t_nr}{(n,t)})+b(0,\frac{rn}{(n,t)}))}(\tau).$$

This proves the third equation.

For the fourth equation, we note that by Theorem 2.2.8, the S-matrix entries $S_{(i,j),(k,l)}$ for ${}^gV$ are given by $\frac{1}{n}e(b_\Omega((i,j),(k,l)))$, where b_Ω is -1 times the inner product induced by q_D. Since the map $B' \to D$ preserves the quadratic form, hence -1 times the $\mathbb{Q}/\mathbb{Z}$-valued inner product, if we write b'_Ω for the pullback of b_Ω, we have

$$\begin{aligned}
T_{(a(1,\frac{t_nr}{(n,t)})+b(0,\frac{rn}{(n,t)}))}(\frac{-1}{\tau}) &= T_{(a_n,b_n+2t_n\lfloor a/n\rfloor)}(\mathbf{1},\frac{-1}{\tau}) \\
&= \frac{1}{n}\sum_{x\in D} e(b_\Omega((a_n,b_n+2t_n\lfloor a/n\rfloor),x))T_x(\mathbf{1},\tau) \\
&= \frac{1}{N}\sum_{y\in B'} e(b'_\Omega((a,\frac{at_nr+brn}{(n,t)}),y))T_y(\tau) \\
&= \frac{1}{N}\sum_{p,q\in\mathbb{Z}/n\mathbb{Z}} e\left(-\frac{\frac{at_nr+brn}{(n,t)}p+aq}{N}\right)T_{(p,q)}(\tau),
\end{aligned}$$

so the fourth equation holds for $(a,b)\in B'$. For $(a,b)\notin B'$, we need a vanishing result, and it suffices to show that $\sum_{p,q\in\mathbb{Z}/n\mathbb{Z}} e(-\frac{bp+aq}{N})T_{(p,q)}(\tau) = 0$. This sum reduces to a sum over B', and it suffices to show that for any $x\in D$, the sum over preimages of x in B' vanishes. The kernel of $B'\to D$ is generated by $(n,\frac{-nrt_n}{(n,t)}) = n(1,\frac{t_nr}{(n,t)}) - 2t_n(0,\frac{rn}{(n,t)})$, so we fix $p(1,\frac{t_nr}{(n,t)})+q(0,\frac{rn}{(n,t)})\in B'$ and compute the coefficient on $T_{p(1,\frac{t_nr}{(n,t)})+q(0,\frac{rn}{(n,t)})}(\mathbf{1},\tau)$:

$$\begin{aligned}
&\sum_{k=0}^{N/n-1} e\left(\frac{b(p+kn)+a(\frac{pt_nr+qrn-knrt_n}{(n,t)})}{N}\right) \\
&\quad= \sum_{k=0}^{N/n-1} e\left(\frac{bp(n,t)+bkn(n,t)+aprt_n+aqrn+aknrt_n}{N(n,t)}\right) \\
&\quad= e\left(\frac{bp(n,t)+aprt_n+aqrn}{N(n,t)}\right)\sum_{k=0}^{N/n-1} e\left(k\frac{bn(n,t)+anrt_n}{N(n,t)}\right)
\end{aligned}$$

The last sum vanishes if and only if the numerator $bn(n,t)+anrt_n$ is nonzero modulo $N(n,t)$, and by fixing a, a short calculation shows that this is precisely when $(a,b)\notin B'$. ☐

Generalized Moonshine for cyclic groups was proved in [Dong-Li-Mason-2000] up to a scalar ambiguity. We can eliminate the ambiguity by using a central extension, essentially given by unrolling the corresponding abelian intertwining algebra.

Definition 2.3.5. For any $g\in\mathbb{M}$, and let N be any positive integer such that the McKay-Thompson series $T_g(\tau) = \mathrm{Tr}(gq^{L_0-1}|V^\natural)$ is $\Gamma_0(N)$-invariant. By [Carnahan-2012] Corollary 3.25, we may define the vector-valued function $\hat{F}^g = \{\hat{F}^g_{i,j}\}_{i,j=0}^{N-1}$ by $\hat{F}^g_{i,j} = T_{g^{(i,j,N)}}(\tau)|_0 A$ for $A = \begin{pmatrix} * & * \\ \frac{i}{(i,j,N)} & \frac{j}{(i,j,N)}\end{pmatrix} \in SL_2(\mathbb{Z}/\frac{N}{(i,j,N)}\mathbb{Z})$. Similarly, we may define the vector valued function $F^g_{i,j} =$

$\{F^g_{i,j}\}_{i,j=0}^{N-1}$ by the discrete Fourier transform $F^g_{i,j}(\tau) = \frac{1}{N}\sum_{k\in\mathbb{Z}/N\mathbb{Z}} e\left(\frac{-jk}{N}\right)\hat{F}^g_{i,k}(\tau)$. This is a vector-valued modular function for the Weil representation $\rho_{II_{1,1}(1/N)}$. We write $c^g_{i,j}(n)$ for the q^n coefficient of $F^g_{i,j}$.

Corollary 2.3.6. *For any $g \in \mathbb{M}$, hypothesis B_g from section 4.4 of [Carnahan-2012] is satisfied, i.e., if $T_g(\tau)$ has level N, then there are actions $\{\psi_i\}_{i=0}^{N-1}$ of $\mathbb{Z}/N\mathbb{Z}$ on the twisted modules $V^\natural(g^i)$, compatible with the action of $\langle g\rangle$ on $V^\natural$, such that $\mathrm{Tr}(\psi^i(j)q^{L_0-1}|\dim V^\natural(g^i)) = \hat{F}^g_{i,j}(\tau)$, and $\psi_i(i) = e(L_0)$.*

Proof. The actions ψ_i given in Proposition 2.3.4 satisfy these identities, and $V^\natural$ satisfies the hypotheses of that proposition by Theorem 2.2.9. □

2.4. **Adding a spacetime torus.** In order to produce a Lie algebra from a quantization functor, we need a conformal vertex algebra of central charge 26. Our abelian intertwining algebras ${}^gV$ and ${}^g_NV$ have central charge 24, so we have to increase the central charge by two and cancel the braiding. Our functors amount to taking a graded tensor product with the abelian intertwining algebra attached to a well-chosen 2-dimensional hyperbolic lattice.

Definition 2.4.1. Let L be an integer lattice of signature $(1,1)$, and let (D,q) be the discriminant form $L^\vee/L$. We define the "add a torus" functor AT_L from $AIA^c_{(D,q)}$ to the category of L-graded conformal vertex algebras of central charge $c+2$ as follows:

(1) For any object $W = \bigoplus_{a\in D} W_a$ in $AIA^c_{(D,q)}$ with abelian 3-cocycle (F,Ω), we choose an abelian 3-coboundary to endow $V_{L^\vee(-1)}$ with the abelian 3-cocycle $(\frac{1}{F},\frac{1}{\Omega})$, and take the graded tensor product $W\otimes^D V_{L^\vee(-1)} = \bigoplus_{a\in D} W_a \otimes V_{L_{-1}+a}$.
(2) For any isomorphism $W \to W'$ in $AIA^c_{(D,q)}$, the corresponding isomorphism of $L^\vee$-graded conformal vertex algebras is given by taking the tensor product.

For any $\lambda \in L^\vee$, the λ-graded piece is the tensor product $W_{\lambda+L}\otimes\pi^{L\otimes\mathbb{C}}_\lambda$.

Lemma 2.4.2. *Let V be a holomorphic C_2-cofinite vertex operator algebra of central charge c, let g be an automorphism of order n such that $V(g^i)$ has strictly positive L_0-spectrum for $g^i \neq 1$, and let ${}^gV$ be the abelian intertwining algebra given in Theorem 2.2.8. Then there is a lattice L of signature $(1,1)$ and an abelian intertwining algebra $V_{L^\vee(-1)}$ whose abelian 3-cocycle cancels that of ${}^gV$. In particular, adding a torus is well-defined on ${}^gV$, and yields an $L^\vee(-1)$-graded conformal vertex algebra of central charge $c+2$.*

Proof. Let L be the lattice identified in [van Ekeren, et al, 2015] by its Gram matrix $\left(\begin{smallmatrix} -2t_n & n \\ n & 0\end{smallmatrix}\right)$. Then the quadratic form on $L^\vee/L$ is precisely q_Ω for ${}^gV$. Thus, there exists a suitable coboundary for $V_{L^\vee(-1)}$ such that the resulting abelian 3-cocycle cancels that of ${}^gV$. □

Proposition 2.4.3. *Adding a torus 2-commutes with both unrolling against hyperbolic lattice embeddings and twisting against abelian 3-coboundaries. That is, different choices of unrolling or coboundaries on an abelian intertwining algebra yield isomorphic conformal vertex algebras.*

Proof. The claim about coboundaries follows from the fact that if one twists against a coboundary for the object in $AIA^c_{(D,q)}$, the opposite coboundary is chosen on $V_{L^\vee(-1)}$. Thus, the graded tensor product is unchanged.

Suppose we are given an embedding $L \subset M$ of integral lattices of signature $(1,1)$, and let $(A,q_A) = M^\vee/M$ and $(B,q_B) = L^\vee/L$. We have the diagram $M^\vee/M \twoheadleftarrow M^\vee/L \hookrightarrow L^\vee/L$ of morphisms of quadratic groups, so the unrolling functor yields an abelian intertwining algebra on $L^\vee/L$ that is supported on $M^\vee/L$. Adding a torus to the A-graded object yields an $M^\vee(-1)$-graded conformal vertex algebra, while adding a torus to the B-graded object yields an $L^\vee(-1)$-graded conformal vertex algebra that is supported on the sublattice $M^\vee(-1)$. Furthermore, the homogeneous components are isomorphic, and the multiplication laws match, since the multiplication law on the $L^\vee(-1)$-graded vertex algebra is given by a tensor product of a lattice algebra with a multiplication rule pulled back from the A-graded abelian intertwining algebra. $\square$

Definition 2.4.4. For any $g \in \mathbb{M}$, we write ${}^gV^\natural$ for the abelian intertwining algebra in $AIA^{24}_{q_D}$ given by Theorem 2.2.8 and Theorem 2.2.9. We write ${}^g_NV^\natural$ for the "unrolled" abelian intertwining algebra in $AIA^{24}_{q_B}$ given by Proposition 2.3.4.

Recall that by forgetting some multiplicative structure, we may view ${}^gV^\natural$ as a direct sum of irreducible g^i-twisted $V^\natural$-modules, as g^i ranges over the cyclic group generated by g. We note that similarly, ${}^g_NV^\natural$ can be viewed as $\bigoplus_{i=0}^{N-1} V^\natural(g^i)$.

Corollary 2.4.5. *For any $g \in \mathbb{M}$, and any multiple N of the level of $T_g(\tau)$, any choice of lattice embedding $I\!I_{1,1}(N) \hookrightarrow L$ (for $L^\vee/L$ the discriminant form for ${}^gV^\natural$) induces an isomorphism $AT_L({}^gV^\natural) \cong AT_{I\!I_{1,1}(N)}({}^g_NV^\natural)$ of $I\!I_{1,1}(-1/N)$-graded conformal vertex algebras of central charge 26.*

Proof. Theorem 2.2.9 implies Proposition 2.4.3 is applicable, and the result immediately follows. $\square$

2.5. **Projective action of centralizer.** We show that for any finite order automorphism g of a holomorphic C_2-cofinite vertex operator algebra V of CFT type, there is a natural action by a central extension of the centralizer of g by homogeneous automorphisms on the abelian intertwining algebra ${}^gV$, the unrolled object ${}^g_NW$, and the conformal vertex algebra given by adding a torus.

Lemma 2.5.1. *Let V be a holomorphic C_2-cofinite vertex operator algebra of CFT type, and let g be an automorphism of order n such that $V(g^i)$ has strictly positive L_0-spectrum for $g^i \neq 1$. Let $h \in C_{\mathrm{Aut}\,V}(g)$. Then the set of homogeneous automorphisms of the abelian intertwining algebra ${}^gV$ that restrict to h on V has precisely n elements, and a natural simply transitive action of $\mu_n(\mathbb{C})$.*

Proof. If $\tilde{h}$ is a homogeneous automorphism of the abelian intertwining algebra ${}^gV$ that restricts to h on V, then for each $g^i \in \langle g \rangle$, the restriction of $\tilde{h}$ to $V(g^i)$ is an element of $\mathrm{Aut}\,V(g^i)$ over h. Now, suppose we choose arbitrary elements $h_i \in \mathrm{Aut}\,V(g^i)$ over h for all i. By Remark 2.1.5, the set of lifts of h to an automorphism of $V(g^i)$ has a simply transitive action of $\mathbb{C}^\times$, so we can measure the failure of $\{h_i\}_{i=0}^{n-1}$ to form an automorphism of ${}^gV$ by setting $\lambda_{i,j} \in \mathbb{C}^\times$ to be the unique constant such that $Y(h_ia, z)h_jb = \lambda_{i,j}h_{i+j}Y(a, z)b$ for all $a \in V(g^i)$ and $b \in V(g^j)$. By the associativity and commutativity of fusion, $\lambda = \{\lambda_{i,j}\}$ is a normalized symmetric 2-cocycle on $\mathbb{Z}/n\mathbb{Z}$ with values in $\mathbb{C}^\times$, hence it defines an abelian central extension E of $\mathbb{Z}/n\mathbb{Z}$ by $\mathbb{C}^\times$. Because $\mathbb{C}^\times$ is divisible, the defining exact sequence splits, and $E \cong \mathbb{Z}/n\mathbb{Z} \oplus \mathbb{C}^\times$. In particular, the cocycle λ is a coboundary, and the set of 1-cochains in the preimage of λ under the differential is a torsor under the group $\mathrm{Hom}(\mathbb{Z}/n\mathbb{Z}, \mathbb{C}^\times) \cong \mu_n(\mathbb{C})$ of 1-cocycles. Concretely, this means any normalized symmetric 2-cocycle λ is attainable by a suitable choice of $\{h_i\}$, and those $\{h_i\}$ that yield an automorphism of ${}^gV$ (namely those for which $\lambda = 1$) form a torsor under $\mu_n(\mathbb{C})$, where the action is by rescaling: For each $\zeta \in \mu_n(\mathbb{C})$, one replaces h_i with ζ^ih_i. $\square$

Proposition 2.5.2. *Let V be a holomorphic C_2-cofinite vertex operator algebra of CFT type, and let g be an automorphism of order n such that $V(g^i)$ has strictly positive L_0-spectrum for $g^i \neq 1$. Then there is a central extension $\widetilde{C_{\mathrm{Aut}\,V}(g)}$ of $C_{\mathrm{Aut}\,V}(g)$ by $\mu_n(\mathbb{C})$ with a natural action on the abelian intertwining algebra ${}^gV$, the unrolled object ${}^g_NW$, and the conformal vertex algebra given by adding a torus.*

Proof. By Lemma 2.5.1, the set of all lifts of elements of $C_{\mathrm{Aut}\,V}(g)$ is a $\mu_n(\mathbb{C})$-torsor over $C_{\mathrm{Aut}\,V}(g)$, so in order to prove it is a central extension, we need to show that it is closed under multiplication, the torsor structure map is a homomorphism, and all lifts of identity are central. All lifts of identity are central, because the restriction of a lift of identity to any $V(g^i)$ is a scalar, and all lifts of elements are sums of linear automorphisms of the twisted modules $V(g^i)$. The remaining claims about the multiplicative structure follow from the following calculation: if $\tilde{h} = \{h_i\}$ and $\tilde{k} = \{k_i\}$ are lifts of $h, k \in C_{\operatorname{Aut} V}(g)$, then for all $a \in V(g^i), b \in V(g^j)$,

$$\begin{aligned} h_{i+j}k_{i+j}Y(a,z)b &= h_{i+j}Y(k_i a, z)k_j b \\ &= Y(h_i k_i u, a)h_j k_j v b \end{aligned}$$

Therefore, $\tilde{h}\tilde{k}$ is a lift of hk to ${}^gV$.

We thus obtain a natural action of $\widetilde{C_{\operatorname{Aut} V}}(g)$ on ${}^gV$. Since unrolling and adding a torus are functors, we get natural actions of the same group on the resulting objects. ☐

Lemma 2.5.3. *For any N divisible by the level of $T_g(\tau)$, the $II_{1,1}(1/N)$-homogeneous conformal vertex algebra isomorphism between $AT_L({}^gV^\natural)$ and $AT_{II_{1,1}(N)}({}^g_NV^\natural)$ given in Corollary 2.4.5 can be made $\widetilde{C_{\mathbb{M}}(g)}$-equivariant.*

Proof. Promotion to $\widetilde{C_{\mathbb{M}}(g)}$-equivariance follows from the structure of the unrolling functor - the corresponding graded pieces are identified as $\widetilde{C_{\mathbb{M}}(g)}$-modules, and the multiplication maps are equivariant. ☐

We summarize the results of this section.

Theorem 2.5.4. *Let g be an automorphism of $V^\natural$, i.e., an element of the Monster simple group $\mathbb{M}$, and suppose the McKay-Thompson series $T_g(\tau)$ has level N. Let $B = \mathbb{Z}/N\mathbb{Z} \times \mathbb{Z}/N\mathbb{Z}$ with the quadratic form $q_B(a,b) = e(ab/N)$. Then there is a central extension $\widetilde{C_{\mathbb{M}}(g)}$ of the centralizer $C_{\mathbb{M}}(g)$ by $\mu_{|g|}(\mathbb{C})$ equipped with a distinguished lift $\tilde{g}$ of g, and an abelian intertwining algebra ${}^g_NV^\natural \in AIA^{24}_{q_B}$ with a homogeneous action of $\widetilde{C_{\mathbb{M}}(g)}$ by autmorphisms, satisfying the following properties:*

1. *${}^g_NV^\natural$ decomposes into $\bigoplus_{a=0}^{N-1} V^\natural(g^a)$ as a direct sum of twisted $V^\natural$-modules.*
2. *The action of $\tilde{g}$ restricted to $V^\natural(g)$ is given by $e(L_0)$.*
3. *The (a,b)-graded component of ${}^g_NV^\natural$ is $\{v \in V^\natural(g^a) | \tilde{g}v = e(b/N)v\}$. This is nonzero if and only if $(a,b) \in B'$ (where $B' \subseteq B$ is a subgroup uniquely determined by the symmetries of T_g), and in that case it is a simple current as a $(V^\natural)^g$-module, and it is endowed with a $\widetilde{C_{\mathbb{M}}(g)}$-action.*
4. *The graded dimension of the (a,b)-graded component ${}^g_NV^\natural$ is given by the component form $F^g_{a,b}(\tau)$ given in Definition 2.3.5, and in particular, the coefficient $c^g_{a,b}(n)$ is equal to the dimension of $\{v \in V^\natural(g^a) | \tilde{g}v = e(b/N)v, L_0 v = (n+1)v\}$. That is, the vector-valued graded dimension of ${}^g_NV^\natural$ is equal to F^g, a vector valued modular function for the Weil representation attached to the lattice $II_{1,1}(N)$.*

The conformal vertex algebra $AT_{II_{1,1}(N)}({}^g_NV^\natural)$ has central charge 26, and is graded by $II_{1,1}(-1/N)$, with an action of $\widetilde{C_{\mathbb{M}}(g)}$ by homogeneous automorphisms.

Proof. As before, Theorem 2.2.9 allows us to use the general results for a holomorphic C_2-cofinite vertex operator algebra V of CFT type equipped with an automorphism g for which $V(g^i)$ has strictly positive L_0-spectrum whenever $g^i \neq 1$.

By Lemma 2.5.1, a lift of g to an automorphism of ${}^g_NV^\natural$ is uniquely determined by what it does to $V^\natural(g)$, and by the $\tau \mapsto \tau + 1$ property given in Proposition 2.3.4, setting $\psi_1 = e(L_0)$ yields a lift $\tilde{g}$ such that the (a,b)-graded component of ${}^g_NV^\natural$ is $\{v \in V^\natural(g^a) | \tilde{g}v = e(b/N)v\}$. The claim that the (a,b)-component is nonzero if and only if $(a,b) \in B'$ is straightforward from the definition of unrolling, and the simple current assertion is given by the first listed claim in Proposition 2.3.4.

The claims about graded dimension follow from the properties of the functions $T(a,b;\tau)$ and $T_{(a,b)}(\tau)$ given in Proposition 2.3.4. In particular, [Carnahan-2012] Lemma 3.6 implies the functions

$\{T(a,b,\tau)\}_{a,b\in\mathbb{Z}/N\mathbb{Z}}$ and $\{F^g_{a,b}(\tau)\}_{a,b\in\mathbb{Z}/N\mathbb{Z}}$ on $\mathcal{M}^{\mathbb{Z}/N\mathbb{Z}}_{Ell}$ are uniquely determined by $T(0,m,\tau)$ and $F^g_{0,m}(\tau)$ for m ranging over divisors of N, and in both cases, these are given by the McKay-Thompson series $T_{g^m}(\tau)$. The discrete Fourier transform then gives an equality between $T_{(a,b)}(\tau)$ and $F^g_{a,b}(\tau)$, matching the coefficient $c^g_{a,b}(n)$ with the dimension of the stated eigenspace.

The remaining claims follow from Proposition 2.5.2 and Corollary 2.4.5. □

3. Lie algebras

In this section we construct the monstrous Lie algebras. Our construction employs the physical principle first articulated in [Lovelace-1971] and demonstrated in [Goddard-Thorn-1972] and [Brower-1972], that in the critical dimension $d = 26$ of bosonic string theory, Virasoro-type Ward identities cancel two full sets of oscillators. This principle now has at least three methods of realization in physics (cf. [Green-Schwarz-Witten-1987] chapters 2,3): Covariant quantization, passage to the light-cone gauge (also called "construction of the transversal space"), and BRST cohomology. The use of the BRST method for quantizing strings was pioneered in [Kato-Ogawa-1983].

The use of this cancellation principle in mathematics is also far from new. For example, BRST cohomology was used in [Frenkel-Garland-Zuckerman-1986] to compute the character of the space of physical states for a bosonic string propagating in Lorentzian 26-space. The covariant quantization method is also used in the analysis of three Lie algebras, each of which was named the "Monster Lie algebra" upon construction:

1. The first example is the Kac-Moody Lie algebra whose simple roots are those of the reflection group of the even unimodular Lorentzian lattice $II_{1,25}$. The existence of a Monster action was suggested in [Borcherds-Conway-Queen-Sloane-1984], and Frenkel [Frenkel-1985] used the no-ghost theorem to bound its root multiplicities by coefficients of the modular form $1/\Delta$.
2. The second example is the Borcherds-Kac-Moody Lie algebra whose real simple roots are those given in the first example, but it has additional imaginary simple roots of multiplicity 24 on positive multiples of the Weyl vector. This was constructed in [Borcherds-1986], and is now known as the "fake Monster Lie algebra". In [Borcherds-1990], Borcherds showed that the root multiplicities saturate the $1/\Delta$ bound given by Frenkel.
3. The third and last example is the generalized Kac-Moody Lie algebra constructed in [Borcherds-1992]. This is the only example known to have a faithful Monster action.

Supersymmetric variants of this construction have been used, e.g., in [Scheithauer-2000].

3.1. **Virasoro preliminaries.** Recall the Virasoro algebra vir is the complex vector space with a distinguished basis given by symbols $K, \{L_n\}_{n\in\mathbb{Z}}$, with the Lie bracket defined by $[L_m, L_n] = (m-n)L_{m+n} + \frac{m^3-m}{12}\delta_{m+n,0}K$ for all $m,n \in \mathbb{Z}$, and $[L_n, K] = 0$ for all $n \in \mathbb{Z}$. We write vir^+ for the subalgebra spanned by $\{L_n\}_{n\geq 1}$, vir^- for the subalgebra spanned by $\{L_n\}_{n\leq -1}$, and vir^0 for the 2-dimensional subalgebra spanned by L_0 and K.

Definition 3.1.1. Let V be a representation of the Virasoro algebra, i.e., a complex vector space equipped with operators $\{L_n\}_{n\in\mathbb{Z}}$ and K that satisfy the Virasoro relations.

1. We say that V is positive-energy if:
   (a) L_0 acts diagonalizably, i.e., V splits into a direct sum of L_0-eigenspaces.
   (b) vir^+ acts locally nilpotently, i.e., for all $v \in V$, there exists $N > 0$ such that for all sequences $n_1, \dots, n_k$ of positive integers satisfying $n_1 + \cdots + n_k > N$, we have $L_{n_1} \cdots L_{n_k} v = 0$.
2. We say that V has central charge $c \in \mathbb{C}$ if $Kv = cv$ for all $v \in V$.
3. A bilinear or sesquilinear form $(,)$ on V is Virasoro-invariant if for each $n \in \mathbb{Z}$, L_n is adjoint to L_{-n}.

(4) We say that V is unitarizable if it admits a positive-definite hermitian Virasoro-invariant form.

(5) A vector $v \in V$ is:
  (a) primary (or physical) if $L_i v = 0$ for all $i > 0$, i.e., if vir^+ acts trivially.
  (b) spurious if it has the form $L_{-i}w$, for some $w \in V$ and some $i > 0$.
  (c) null if it is primary and spurious.

  We write P^r to denote the subspace of primary vectors v such that $L_0 v = rv$. We may write P^r_V when there is more than one representation under consideration. We write $null^r_V$ to denote the subspace of null vectors of weight r in V.

Given $c, h \in \mathbb{C}$, we define the Verma module $M_{h,c}$ as the induced module $vir \otimes_{vir^+ \oplus vir^0} \mathbb{C}_{h,c}$, where $\mathbb{C}_{h,c}$ is the one dimensional vector space with trivial action of vir^+, such that L_0 has eigenvalue h, and K has eigenvalue c. We write $L_{h,c}$ for the unique irreducible quotient of $M_{h,c}$ with highest weight h.

We note that any Verma module $M_{h,c}$ is positive-energy and admits a canonical invariant bilinear form, called the Shapovalov form, which is nonsingular if and only if $M_{h,c}$ is irreducible (see [Feigin-Fuchs-1984] or [Kac-Raina-1987]). In the following lemma, we set $c = 24$, because that is the case we will use. Similar results hold for other central charges in the open interval $(1, 25) \subset \mathbb{R}$.

Lemma 3.1.2. *Let V be a positive energy vir-module of central charge $c = 24$. Then V is unitarizable if and only if the L_0-spectrum of V is non-negative and L_{-1} annihilates the zero weight subspace $V_0 = \operatorname{Ker} L_0$. If these conditions hold, then V decomposes as an orthogonal direct sum of irreducible vir-modules as follows:*

$$V \cong \bigoplus_{h \geq 0} P^h_V \otimes L_{h,24} \cong (V_0 \otimes L_{0,24}) \oplus \bigoplus_{h>0} P^h_V \otimes M(c,h)$$

Proof. The Kac determinant formula yields the following unitarizability and irreducibility results (where detailed proofs can be found in the first four sections of [Kac-Raina-1987]):

(1) If $h \neq 0$, then $M_{h,24}$ is irreducible (i.e., equal to $L_{h,24}$), and the category of lowest weight vir-modules with central charge 24 and lowest weight h is completely reducible, with $L_{h,24}$ as its unique irreducible object.
(2) For the case $h = 0$, $M_{0,24}$ has a unique proper submodule $M_{1,24}$, and $L_{0,24} = M_{0,24}/M_{1,24}$.
(3) $M_{h,24}$ is unitarizable if and only if $h > 0$. $L_{h,24}$ is unitarizable if and only if $h \geq 0$.

Given V unitarizable, we choose a Virasoro-invariant Hermitian form. By self-adjointness of L_0, any two L_0-eigenspaces with different eigenvalues are orthogonal. For any coset $h + \mathbb{Z}$, we let $V_{h+\mathbb{Z}}$ denote the subspace spanned by L_0-eigenvectors with eigenvalues in $h+\mathbb{Z}$. Then any disjoint cosets of $\mathbb{Z}$ yield orthogonal subspaces of V, so we may consider one coset at a time. Within each coset, the decomposition follows from induction by L_0-eigenvalue, noting that within each L_0-eigenspace the primary subspace is orthogonal to the spurious subspace. The necessary and sufficient condition then follows immediately. □

Lemma 3.1.3. *Let g be an automorphism of $V^\natural$. Then the irreducible g-twisted module $V^\natural(g)$ is unitarizable. If $g \neq 1$, then $V^\natural(g)$ decomposes as a direct sum of Virasoro submodules of the form $M(c,h)$ as h ranges over a multiset of positive rational numbers of the form $\frac{k}{|g|^2}$.*

Proof. For the case $g = 1$, it suffices to show that $V^\natural$ is unitarizable - this is well-known, and follows straightforwardly from its conformal structure. By Theorem 2.2.9, if $g \neq 1$, then the lowest weight space of $V^\natural(g)$ has positive L_0-eigenvalue, so by Lemma 3.1.2, we may decompose $V^\natural(g)$ as a sum of unitarizable Verma modules. □

Lemma 3.1.4. *Let $\lambda \in \mathbb{R}^{r,s}$, and let $\pi^{r,s}_\lambda$ denote the corresponding irreducible Heisenberg module, endowed with the Virasoro action arising from the conformal element $\frac{1}{2}\sum_\mu a^\mu_{-1} b^\mu_{-1} 1 \in \pi^{r,s}_0$. Then*

$\pi^{r,s}_\lambda$ is a positive-energy vir-module of central charge 2 that admits a natural Virasoro-invariant Hermitian form for which b^μ_n is adjoint to b^μ_{-n}, for all $n \in \mathbb{Z}$ and all vectors $b^\mu \in \mathbb{R}^{r,s}$.

Proof. By irreducibility, the conditions on the Hermitian form determine it up to a normalization. See, e.g., section 2.2 of [Frenkel-Garland-Zuckerman-1986]. ☐

Lemma 3.1.5. *Let V be a Virasoro representation equipped with a Virasoro-invariant bilinear form $(,)$.*

1. *The L_0-eigenspaces in V are pairwise orthogonal with respect to the form.*
2. *$L_{-1}P^0 \subseteq P^1$. In particular, $L_{-1}P^0 \subseteq null^1_V$.*
3. *A vector in P^1 is orthogonal to all other vectors in P^1 if and only if it lies in $null^1_V$.*

Proof. All claims follow from straightforward calculations. ☐

There is a stronger notion of invariance for vertex algebras (found, e.g., in [Frenkel, et al, 1993]).

Definition 3.1.6. Let V be a conformal vertex algebra. A bilinear form $(,)$ on V is invariant if for all $u, v, w \in V$, the identity $(Y(u,z)v, w) = (v, Y(e^{zL_1}(-z^{-2})^{L_0}u, z^{-1})w)$ holds. Equivalently, if u has conformal weight i, then the adjoint of the operator u_n is $(-1)^i \sum_{j\geq 0}(L_1^j(u))_{2i-j-n-2}/j!$.

Lemma 3.1.7. *Let V be a conformal vertex algebra. Then any invariant bilinear form is Virasoro-invariant.*

Proof. This follows from evaluating the defining identity with u chosen to be the Virasoro vector ω. ☐

Proposition 3.1.8. *Let V be a holomorphic C_2-cofinite vertex operator algebra of CFT type, and let g be a finite order automorphism of V such that the twisted modules $V(g^i)$ have strictly positive L_0-spectrum for all $g^i \neq 1$. Let L be a hyperbolic lattice such that $L^\vee/L$ has the discriminant form of ${}^gV$, let $M \subset L$ be a hyperbolic sublattice of finite index, and consider the conformal vertex algebra W given by applying AT_M to the $M^\vee/M$-graded abelian intertwining algebra given by unrolling ${}^gV$ (by Proposition 2.4.3, this is isomorphic to $AT_L({}^gV)$ viewed as an $M^\vee(-1)$-graded vertex algebra supported on $L^\vee(-1)$). Let $\langle,\rangle_W$ be the bilinear form on W induced by the contragradient pairings between the component modules $V^{(i,j)}$ in ${}^gV$ and the contragradient pairings between the modules $\pi^{1,1}_\lambda$ and $\pi^{1,1}_{-\lambda}$ for the Heisenberg vertex algebra for $\mathbb{R}^{1,1}$, normalized such that*

$$\langle \mathbf{1}, Y(e^{zL_1}(-z^2)^{-L_0}u, z^{-1})v\rangle_W = \langle Y(u,z)\mathbf{1}, v\rangle_W$$

for all $u \in ({}^gV)^\lambda \otimes \pi^{1,1}_\lambda$ and $v \in ({}^gV)^{-\lambda} \otimes \pi^{1,1}_{-\lambda}$. Then $\langle,\rangle_W$ is an invariant bilinear form on W satisfying the following conditions:

1. *For any $i, j \in L^\vee$ satisfying $i + j \neq 0$, we have $\langle u, v\rangle_W = 0$ for any $u \in ({}^gV)^i$ and $v \in ({}^gV)^j$.*
2. *If $L_0u = \underbrace{ru \text{ and}}_{} L_0v = sv$, and $r \neq s$, then $\langle u, v\rangle_W = 0$.*
3. *If $h \in C_{\operatorname{Aut} V}(g)$, then $\langle hu, hv\rangle_W = \langle u, v\rangle_W$.*

Proof. By Theorem 2.13 in [Scheithauer-1998] (which generalizes earlier results like [Li-1994] Theorem 3.1 to the setting we need), if A is a conformal vertex algebra on which L_1 acts locally nilpotently, the dual space $\operatorname{Hom}(A_0/L_1A_1, \mathbb{C})$ is isomorphic to the space of invariant bilinear forms on A, and an isomorphism is given by sending a map f to the form $(u, v) = (f \circ \pi)(u^*_{-1}v)$, where

1. π is the projection from A to the weight zero space A_0.
2. $u^*_n = (-1)^i \sum_{j\geq 0}(\frac{L_1^j}{j!}u)_{2i-j-n-2}$ when $L_0u = iu$.

We consider the unique functional f on W_0 that sends the unit $\mathbf{1}$ to 1, and annihilates all weight zero $a \otimes b$ for $a \in \pi^{1,1}_\lambda$ and $b \in ({}^gV)^\lambda$ when $\lambda \in L^\vee(-1) \setminus \{0\}$. Since f annihilates all vectors in the image of L_1 on the weight one subspace, it corresponds to an invariant bilinear form $(,)_f$. Since $({}^gV)^0 \otimes \pi^{1,1}_0$ has a unique invariant bilinear form up to normalization, the contragradient pairing coincides with $(,)_f$ on this subspace. It is clear that both $\langle,\rangle_W$ and $(,)_f$ satisfy the homogeneity and $\widetilde{C_{\mathrm{Aut}\,V}}(g)$-invariance conditions listed in the statement of the proposition. It remains to show that $(,)_f$ coincides with $\langle,\rangle_W$ in general, and for that it suffices to restrict our view to a pairing between $u \in ({}^gV)^\lambda \otimes \pi^{1,1}_\lambda$ and $v \in ({}^gV)^{-\lambda} \otimes \pi^{1,1}_{-\lambda}$. In this case,

$$\begin{aligned}(u,v)_f &= (f \circ \pi)(u^*_{-1}v) \\ &= (\mathbf{1}, u^*_{-1}v)_f \\ &= \langle \mathbf{1}, u^*_{-1}v\rangle_W\end{aligned}$$

By our normalization, we have the equality

$$\langle \mathbf{1}, Y(e^{zL_1}(-z^2)^{-L_0}u, z^{-1})v\rangle_W = \langle Y(u,z)\mathbf{1}, v\rangle_W$$

of elements of $\mathbb{C}[z]$. Isolating the constant term yields $\langle \mathbf{1}, u^*_{-1}v\rangle_W = \langle u,v\rangle_W$. We conclude that $(u,v)_f = \langle u,v\rangle_W$, so $\langle,\rangle_W$ is invariant.

□

3.2. **Old covariant quantization.** In covariant quantization, one begins with a naïve space of states, that has redundancies due to internal symmetry. In the case of internal Virasoro symmetry, to obtain the relevant space of states that couple, one considers the "physical" subspace of states that are invariant under the action of vir^+, and quotients by the "spurious" subspace, which is spanned by the image of the augmentation ideal in $U(vir^-)$ together with the radical of the induced Hermitian form.

An enhancement of the original covariant approach was used in [Borcherds-1992] to construct the Monster Lie algebra as the space of physical states arising from the vertex algebra $V^\natural \otimes V_{II_{1,1}(-1)}$. We will use a variant of this method to construct our monstrous Lie algebras.

Definition 3.2.1. Let $\mathrm{Rep}^+_c(vir)$ denote the groupoid whose objects are positive energy Virasoro representations of central charge c with Virasoro-invariant bilinear forms, and whose morphisms are Virasoro-equivariant isometries. We define the functor OCQ, from $\mathrm{Rep}^+_c(vir)$ to the groupoid of vector spaces with bilinear forms, as $V \mapsto P^1_V/null^1_V$.

Lemma 3.2.2. *We list some relatively straightforward facts:*

1. *If W is a conformal vertex algebra that is positive-energy, then $P^1/L_{-1}P^0$ has a Lie algebra structure induced by setting $[u,v] = u_0v$, i.e., the coefficient of z^{-1} in $Y(u,z)v$. If a group G acts on W by conformal vertex algebra automorphisms, then G acts on $P^1/L_{-1}P^0$ by Lie algebra automorphisms.*
2. *If W is a positive-energy conformal vertex algebra equipped with an invariant bilinear form (in particular, with L_i adjoint to L_{-i} for each $i \in \mathbb{Z}$), then the Lie algebra $P^1/L_{-1}P^0$ has an invariant inner product induced from W, and the radical of that inner product is an ideal. In particular, $OCQ(W) = (P^1/L_{-1}P^0)/rad(,)$ is a Lie algebra equipped with a nondegenerate invariant inner product. If a group G acts on W by conformal vertex algebra automorphisms, and the invariant bilinear form is G-invariant, then $OCQ(W)$ has a natural G action by Lie algebra automorphisms, and the induced bilinear form is G-invariant.*

Proof. The first sentence of the first claim is given in section 3 of [Borcherds-1992]. The Lie algebra structure of $W/L_{-1}W$ is known from [Borcherds-1986], so it suffices to show that a_0b is primary if a and b are. This follows from the formula $L_n(a_0b) = a_0L_nb + \sum_{m\geq -1}\binom{n+1}{m+1}(L_ma)_{n-m}b$ for $n \geq -1$ together with the L_{-1}-derivative rule. The second sentence follows from the fact that automorphisms preserve the Virasoro action (hence the property of being primary, the grading, and the L_{-1} operator), and the Lie bracket $(u,v) \mapsto u_0v$.

The first sentence of the second claim is given in the proof of Theorem 6.1 of [Borcherds-1992]. Invariance follows immediately from the adjunction formula $u^*_n = (-1)^i \sum_{j\geq 0}(\frac{L_1^j}{j!}u)_{2i-j-n-2}$ when

$n = 0$, $i = 1$, and $L_1 u = 0$. The ideal property follows immediately from invariance. The part about group actions follows from the same reason as in the first claim. ☐

The following proposition seems to capture the core of Lovelace's principle of oscillator cancellation. It is sometimes given the name "No Ghost Theorem", because it immediately implies that quantization yields a positive-definite space of states. That is, if we choose a unitary structure on V, then transport of structure along the component isomorphisms yields a unitary structure on the output. Here, the word "ghost" means negative-norm state, whose absence is important in physics, since the existence of such ghosts obstructs reasonable formulations of causality. In the next section, we will consider a different type of ghost, named after Faddeev-Popov, and they get their name from their violation of the spin-statistics theorem.

Proposition 3.2.3. *Let V be a unitarizable Virasoro representation of central charge 24 equipped with a non-degenerate Virasoro-invariant bilinear form, let $\pi^{1,1}_\alpha$ be the Heisenberg module attached to the linear function α on $\mathbb{R}^{1,1}$, and let $W = V \otimes \pi^{1,1}_\alpha$. Then:*

1. *If $\alpha \neq 0$, then $OCQ(W)$ is isomorphic to the subspace $V_{1-(\alpha,\alpha)}$ of V on which L_0 acts by $1-(\alpha,\alpha)$, where $(,)$ is the induced bilinear form on the dual space of $\mathbb{R}^{1,1}$.*
2. *If $\alpha = 0$, then $OCQ(W)$ is isomorphic to $V_0 \otimes (\pi^{1,1}_0)_1 \oplus V_1 \otimes (\pi^{1,1}_0)_0 \cong V_0 \oplus V_0 \oplus V_1$, where V_1 is the subspace of V on which L_0 acts by identity.*

Proof. One may find a full proof of a slightly altered version of this claim in the appendix of [Jurisich-1998]. It is an expansion of the sketch of a proof for Theorem 5.1 in [Borcherds-1992], which is in turn a minor alteration of the argument in [Goddard-Thorn-1972]. In order to pass from the proof in [Jurisich-1998] to a proof of our claim, we need to make the following changes:

1. The vector α here is r there, and we remove the restriction that it lie in the lattice $II_{1,1}$, since that restriction is never used in the proof.
2. We remove the unnecessary assumption that V is a vertex operator algebra, as the proof does not use any extra structure on the vector space V except the Virasoro action.
3. The space W here is $\mathcal{H}$ there.
4. Although it isn't necessary for this paper, we remove the assumption that the weight 0 subspace V_0 of V, defined as the kernel of L_0, is one dimensional. One should therefore ignore the paragraph concerning the case $r = 0$ at the end of the proof in [Jurisich-1998]. Instead, we note that all weight one elements of $V \otimes \pi^{1,1}_0$ are primary, so $P^1 \cong V_0 \oplus V_0 \oplus V_1$. The fact that L_{-1} annihilates P^0 follows from the classification of unitarizable Virasoro representations of central charge 24, given in Lemma 3.1.2. By our assumption on V and the fact that $(\pi^{1,1}_0)_1$ has a natural real structure identified with $\mathbb{R}^{1,1}$, the bilinear form on the quotient $P^1_W / L_{-1} P^0_W$ is nondegenerate, i.e., the radical vanishes.

☐

Definition 3.2.4. For each $g \in \mathbb{M}$, we define:

$$\mathfrak{m}_g = OCQ \circ AT_{II_{1,1}(N)}({}^g_N V^\natural)$$

where N is the level of $T_g(\tau)$. This is a Lie algebra, by Lemma 3.2.2, and we call it the monstrous Lie algebra attached to g.

Remark 3.2.5. By Proposition 2.4.3, $\mathfrak{m}_g$ is isomorphic to $OCQ \circ AT_L({}^g V^\natural)$ for any L such that $L^\vee / L$ is the discriminant form for ${}^g V^\natural$. Furthermore, we may replace N with any multiple rN, and get an isomorphic object (although it is now a $II_{1,1}(-1/rN)$-graded Lie algebra supported on the sublattice $II_{1,1}(-1/N)$).

Proposition 3.2.6. *Let $g \in \mathbb{M}$. Then the Lie algebra $\mathfrak{m}_g$ satisfies the following properties:*

(1) $\mathfrak{m}_g$ *is graded by* $II_{1,1}(-1/N)$*, and its degree (0,0) subspace is* $\mathbb{C}^2$*, identified with the weight one space* $(\pi_0^{1,1})_1$ *in the Heisenberg module. Furthermore, the degree is given by the eigenvalue under the adjoint action of the degree* $(0,0)$*-subspace.*

(2) $\mathfrak{m}_g$ *has a nondegenerate invariant bilinear form, and if* u *and* v *are homogeneous vectors of degree* $a, b \in II_{1,1}(-1/N)$ *such that* $a + b \neq 0$*, then* u *and* v *are orthogonal.*

(3) $\mathfrak{m}_g$ *has a canonical action of* $\widetilde{C_{\mathbb{M}}(g)}$ *by homogeneous Lie algebra automorphisms that preserve the bilinear form.*

(4) *For each nonzero* $(a, b) \in II_{1,1}(-1/N)$*, the degree* (a, b) *subspace is isomorphic as a* $\widetilde{C_{\mathbb{M}}(g)}$*-module to the subspace of* $V^\natural(g^a)$ *on which* $\tilde{g}$ *acts by* $e(\frac{b}{N})$ *and* L_0 *acts by* $1 + \frac{ab}{N}$*. The dimension of this subspace is equal to the coefficient* $c^g_{a,b}(ab/N)$ *of the vector-valued modular function* $F^g(\tau)$ *given in Definition 2.3.5. In particular, we have a graded vector space isomorphism between* $\mathfrak{m}_g$ *and the Lie algebra* L_g *defined in [Carnahan-2012] section 4.2 (written* W_g *in Proposition 4.4 of that paper).*

Proof. We prove the claims in the order they are stated.

(1) The grading property follows from the fact that $AT_{II_{1,1}(N)}({}^g_N V^\natural)$ is graded by $II_{1,1}(-1/N)$. Because $({}^gV^0)_1 = 0$ and $({}^gV^0)_0 = \mathbb{C}\mathbf{1}$, Proposition 3.2.3 identifies the degree $(0,0)$ space with $V_0 \otimes (\pi_0^{1,1})_1 = (\pi_0^{1,1})_1$. The eigenvalue assertion follows from the identification of the degree $(0,0)$ subalgebra, and the fact that for $u \in (\pi_0^{1,1})_1$ and $v \in \pi_\alpha^{1,1}$, the z^{-1}-coefficient of $Y(u,z)v$ is $\alpha(u)v$.

(2) The fact that the form is nondegenerate and invariant is given in Lemma 3.2.2. The degree restriction follows from the corresponding property of $AT_{II_{1,1}(N)}({}^g_N V^\natural)$, given in Proposition 3.1.8.

(3) By Proposition 2.5.2 (and Theorem 2.2.9), there is a canonical homogeneous action of $\widetilde{C_{\mathbb{M}}(g)}$ on ${}^gV^\natural$ by homogeneous automorphisms, and this endows $AT_{II_{1,1}(N)}({}^g_N V^\natural)$ with a corresponding action. By the third claim of Lemma 3.2.2, homogeneous automorphisms of $AT_{II_{1,1}(N)}({}^g_N V^\natural)$ are taken to homogeneous Lie algebra automorphisms of $\mathfrak{m}_g$.

(4) The identification of $\widetilde{C_{\mathbb{M}}(g)}$-modules follows from Proposition 3.2.3. By the third listed claim of Theorem 2.5.4, the dimension of this space is equal to the Fourier coefficient $c^g_{a,b}(ab/N)$ of F^g. To compare with the graded parts of L_g, we note that by [Carnahan-2012] Proposition 4.4, the $(a, b/N)$ root space of L_g also has dimension equal to the Fourier coefficient $c^g_{a,b}(ab/N)$ of the vector-valued modular form F^g.

□

3.3. **BRST cohomology.** In addition to covariant quantization, there is the "modern" method of Brecchi, Rouet, and Stora (with Tyutin's independent unpublished work often credited), where one extracts the relevant space of states as a cohomology group. This has the advantage of being "very functorial", but the disadvantage of being rather complicated - one extracts the BRST current and the resulting differential by way of a super-variational principle. In the string-theoretic context, BRST quantization was pioneered in [Kato-Ogawa-1983]. One may find string-theoretic expositions of this method in chapter 3 of [Green-Schwarz-Witten-1987], Chapter 4 of [Polchinski-1998], and section 7 of [D'Hoker-1997], the last of which is intended for a more mathematical audience.

In the mathematical world, BRST quantization of Virasoro representations was introduced using semi-infinite cohomology in [Feigin-1984], and generalized in [Frenkel-Garland-Zuckerman-1986]. Proofs can be found in [Lian-Zuckerman-1991]. Borcherds's use of the no-ghost theorem for moonshine was reinterpreted in terms of BRST cohomology in [Lian-Zuckerman-1995]. We will give a modified presentation that is applicable to the vertex algebra objects we have constructed in the previous section.

We introduce the ghost vertex superalgebra V_{ghost} of central charge -26. By boson-fermion correspondence, for any half-integer λ, there is an isomorphism between the bosonic vertex superalgebra attached to the odd positive definite lattice $\mathbb{Z}$ with conformal vector shifted by λ, and the ghost bc-system of weight $\frac{1}{2}+\lambda$. With the notation of [Frenkel, et al, 1988], the bc system of weight $\frac{1}{2}+\lambda$ is generated by the "anti-ghost" field $b(z)$ that is identified with the bosonic lattice field $z^{-\lambda}X(1,z)$ of conformal weight $\frac{1}{2}-\lambda$, and the "ghost" field $c(z)$ identified with $z^{\lambda}X(-1,z)$ of conformal weight $\frac{1}{2}+\lambda$. The conformal vector is then given by $\frac{1}{2}h(-1)^2+\lambda h(-2)$, and it has central charge $1-12\lambda^2$. For V_{ghost}, we set $\lambda=\frac{3}{2}$.

We briefly describe some cohomology functors and some key properties. There is nothing original in this subsection except perhaps the method of presentation.

Definition 3.3.1. Given a Virasoro ("matter") representation V^m of central charge D and energy-momentum tensor $T^m(z)=\sum_n L^m(n)z^{-n-2}$, we define the Virasoro module $C^{\infty/2+*}(vir,V^m)=V^m\otimes V_{ghost}$, which has central charge $D-26$. The old and new BRST currents are defined to be $j^{BRST,old}=cT^m+\frac{1}{2}:cT^{bc}:$ and $j^{BRST,new}=j^{BRST,old}+\frac{3}{2}\partial^2 c$. The $U(1)_{bc}$ current is $j^{bc}=:bc:$. We consider the following operations on $C^{\infty/2+*}(vir,V^m)$:

(1) The old and new BRST operators

$$\begin{aligned} Q^{old} &= j_0^{BRST,old}=\frac{1}{2\pi i}\oint dz j^{BRST,old}(z)\\ &=\sum_n L^m(n)c_{-n}+\sum_{m<n}(m-n):b_{m+n}c_{-m}c_{-n}:\\ Q^{new} &= j_0^{BRST,new}=\frac{1}{2\pi i}\oint dz j^{BRST,new}(z)\\ &=\sum_{r\in\mathbb{Z}}(L_r^{(m)}-\delta_{r,0})c_{-r}-\frac{1}{2}\sum_{r,s\in\mathbb{Z}}(r-s):c_{-r}c_{-s}b_{r+s}: \end{aligned}$$

(2) The old and new ghost number operators

$$\begin{aligned} U^{old} &= j_0^{bc}=\frac{1}{2}(c_0b_0-b_0c_0)+\sum_{n=1}^{\infty}(c_{-n}b_n-b_{-n}c_n)\\ U^{new} &= U^{old}+\frac{3}{2}=1+c_0b_0+\sum_{n=1}^{\infty}(c_{-n}b_n-b_{-n}c_n) \end{aligned}$$

An eigenvector of U with eigenvalue k is said to have ghost number k.

When $Q^2=0$, we call $C^{\infty/2+*}(vir,V^m)$ the "BRST complex". We also define the "relative subcomplex" ([Zuckerman-1989], section 4) to be the subspace of $V\otimes V_{ghost}$ annihilated by b_0.

Remark 3.3.2. We have "old" and "new" versions of Q and U, to reflect the use in the literature. Papers from the 1980s and early 1990s (e.g., [Kato-Ogawa-1983], [Frenkel-Garland-Zuckerman-1986], [Green-Schwarz-Witten-1987], [Lian-Zuckerman-1991]) use the old versions, while the sources starting from the mid-1990s (e.g., [Polchinski-1998], [D'Hoker-1997], [Lian-Zuckerman-1995]) add an additional $\frac{3}{2}\partial^2 c$ to the BRST current and a constant $3/2$ to the ghost number. This change impacts the output of various functors in the following ways:

(1) The addition of the derivative term makes the new BRST current a "$(1,0)$-form as a quantum operator". Concretely, this means the OPE with the total stress-energy tensor T^m+T^{bc} has the form $T(z)j^{BRST}(0)\sim\frac{1}{z^2}j^{BRST}(0)+\frac{1}{z}\partial j^{BRST}(0)$. In the absence of the derivative, one has a pole of order 3 as the leading term. The extra simplicity makes many calculations easier, especially when quantizing in higher genus settings. However, it is irrelevant for the case at hand, since we just want to compute the cohomology spaces.

(2) When we work out the space of physical states, we find that it lies in ghost degree $-1/2$ in the old convention and 1 in the new convention. In particular, the space of interest was written $H^{-1/2}_{BRST}$ in older work, but is written H^1_{BRST} now. The older convention has the convenient property that Poincaré duality gives a symmetry around zero (see [Frenkel-Garland-Zuckerman-1986] Theorem 1.6 and the remark before Theorem 2.5), while the newer convention is more manageable when considering Gerstenhaber or BV structures on cohomology ([Lian-Zuckerman-1993]).

The calculations relevant to us are unchanged, because a total derivative integrates to zero when evaluating charges. That is, the old and new BRST cohomology functors are naturally isomorphic. To avoid unnecessary confusion, we will write H^1_{BRST} even when referring to results that use the old convention.

Lemma 3.3.3. *Let V^m be a positive-energy representation of Virasoro (called the "matter representation" in the physics literature). We have the following operator calculations in $V^m \otimes V_{ghost}$:*

1. *$Q^2 = 0$ if and only if $D = 26$. That is, $C^{\infty/2+*}(V^m)$ is a complex with differential Q if and only if V^m has central charge 26.*
2. *$[U, Q] = Q$, so Q increases ghost number by one.*
3. *$[U, L_0] = 0$, so ghost number and L_0-eigenvalue provide a bigrading.*

Now, suppose V^m has central charge $D = 26$, so Q gives $V^m \otimes V^{ghost}$ the structure of a complex of vector spaces.

1. *$[Q, L_0] = 0$, so the BRST complex and cohomology are graded by L_0-eigenvalues.*
2. *$[Q, b_0] = L_0$. This implies the relative subcomplex is in fact a subcomplex, and all BRST-closed states with nonzero L_0-eigenvalue are BRST-exact. In particular, the cohomology is supported in weight zero.*

Proof. These claims follow from standard OPE calculations. One may find them enumerated in section 4 of [Zuckerman-1989].

□

Lemma 3.3.4. *If V is a conformal vertex algebra of central charge 26, then $H^1_{BRST}(V)$ is a Lie algebra, and morphisms of conformal vertex algebras are taken to maps of Lie algebras under this functor. In particular, if a group G acts on V by conformal vertex algebra automorphisms, then G naturally acts on $H^1_{BRST}(V)$ by Lie algebra automorphisms.*

Proof. For the Lie algebra claim, see [Lian-Zuckerman-1993] Theorem 2.2. While the authors do not make the explicit claim that morphisms of conformal vertex algebras are taken to Lie algebra homomorphisms, the statement follows from the explicit formulas in their proof together with the faithfulness of the "underlying vector space" functors. The claim about group actions then follows from the functoriality. □

We now have the BRST version of oscillator cancellation.

Proposition 3.3.5. *Let $\alpha \in \mathbb{R}^{1,1}$, and let $\pi^{1,1}_\alpha$ be the Heisenberg representation attached to α. If V is a unitarizable Virasoro representation of central charge 24, then $H^1_{BRST}(V \otimes \pi^{1,1}_\alpha)$ is isomorphic to the subspace $V_{1-\alpha^2}$ of V on which L_0 acts with eigenvalue $1 - \alpha^2$ (if $\alpha \neq 0$), and $V_0 \oplus V_0 \oplus V_1$ (if $\alpha = 0$). In particular, any positive definite Hermitian form on V induces a positive definite Hermitian form on $H^1_{BRST}(V \otimes \pi^{1,1}_\alpha)$.*

Proof. The case $\alpha \neq 0$ is covered in [Zuckerman-1989] Theorem 4.9 under the following translation of notation:

1. $\pi^{1,1}_\alpha$ is written $\mathcal{H}(D, p)$, with $D = 2$ and $p = \alpha$.
2. V is written $\mathcal{K}$.

(3) The BRST differential on $\mathcal{H}(D,p) \otimes \mathcal{K} \otimes V^{gh}$ is written Q_{mod}.
(4) $H^{u+3/2}_{BRST}(V \otimes \pi^{1,1}_\alpha)$ is written $H^u_{Q_{mod}}(p)$ for the same values of u, and $p = \alpha$.
(5) The character $Tr(q^{L_0}|V)$ of $\mathcal{K}$ is written $\chi(\mathcal{K},q) = trq^{J_0}$.

The conclusion of the theorem is that $H^{-1/2}_{Q_{mod}}(p) \cong H^0_{rel}(p, Q_{mod})$, and that $\dim H^0_{rel}(p, Q_{mod})$ is the coefficient of $q^{-(p,p)/2}$ in the shifted character $Tr(q^{L_0-1}|V)$. (The statement given in the paper contains an erroneous division by Δ rather than q - this can be checked by comparison with the free boson case in Theorem 3.4, or using Corollary 2.27 in [Lian-Zuckerman-1991], which is proved in more detail.) This completes the case $\alpha \neq 0$.

The case $\alpha = 0$ follows from an explicit computation of cocycle representatives, following the example of Proposition 2.9 in [Frenkel-Garland-Zuckerman-1986]: One obtains a basis of BRST cohomology given by $\{x \otimes L'_{-1} \wedge L'_{-2} \wedge \cdots\}$ as x ranges over a basis of $(\pi^{1,1}_0 \otimes V)_1 = ((\pi^{1,1}_0)_1 \otimes V_0) \oplus ((\pi^{1,1}_0)_0 \otimes V_1) \cong V_0 \oplus V_0 \oplus V_1$.

As we remarked shortly before the statement of Proposition 3.2.3, the positive definite Hermitian form on $H^1_{BRST}(V \otimes \pi^{1,1}_\alpha)$ is inherited from V by the oscillator cancellation.

□

We conclude with a natural isomorphism between the two quantization functors. Let $\mathbf{1} \in V_{ghost}$ be the ghost vacuum vector - it is the unique (up to scaling) vector that is annihilated by $\{b_n\}_{n\geq 0}$ and $\{c_n\}_{n>0}$, and it has ghost number one.

Lemma 3.3.6. *The map $W \hookrightarrow W \otimes V_{ghost}$ given by $w \mapsto w \otimes \mathbf{1}$ induces a natural isomorphism $OCQ \Rightarrow H^1_{BRST}$, as the input W ranges over* $\mathrm{Rep}^+_{26}(vir)$.

Proof. This is proved at the end of section 4.4 in [Polchinski-1998]. Partial arguments can be found in section 3.2.1 of [Green-Schwarz-Witten-1987] and section 4.6 of [D'Hoker-1997] (which is in lecture 7 part F on the IAS web site).

When W is restricted to be a direct sum of representations of the form $V \otimes \pi^{r,1}_\lambda$ for V unitarizable of central charge $25 - r$ and $r \leq 25$, one may instead appeal to the no-ghost theorem together with complete reducibility in the V part. This is the argument of Lemma 6.7 in [Lian-Zuckerman-1995].

□

3.4. **Borcherds-Kac-Moody property.**

We discuss a class of infinite dimensional Lie algebras defined by Borcherds in [Borcherds-1988], where he called them "generalized Kac-Moody algebras". Borcherds-Kac-Moody algebras are quite similar to Kac-Moody Lie algebras, since they are defined by generators and relations encoded by a generalized Cartan matrix, and they admit representation-theoretic data like Weyl character formulas. They differ in the sense that the conditions defining a suitable generalized Cartan matrix are weaker, and most importantly, simple roots are allowed to be imaginary. We will show that the Monstrous Lie algebras defined earlier in this section are Borcherds-Kac-Moody algebras, using a minor variant of the characterization from [Borcherds-1995], Theorem 1.

The definitions of Borcherds-Kac-Moody algebras (or generalized Kac-Moody algebras) are not uniform in the literature. We will use the definition given in [Jurisich-1996] and [Jurisich-2004], because that is the definition that is both general enough to account for the Lie algebras we need and for which there is a published proof of a homological description of the denominator formula. We needed the homological description in order to produce twisted denominator identities in [Carnahan-2012].

Definition 3.4.1. If I is a countable index set, a matrix $A = (a_{i,j})_{i,j\in I}$ of real numbers is called a generalized Cartan matrix if it satisfies the following conditions:

(1) A is symmetrizable, i.e., there is a diagonal matrix Q whose diagonal entries $Q_{i,i} = q_i$ are positive real numbers, such that QA is symmetric.

(2) $a_{i,j} < 0$ if $i \neq j$.
(3) If $a_{i,i} > 0$, then $a_{i,i} = 2$ and for all $j \in I$, $a_{i,j} \in \mathbb{Z}$.

Given a generalized Cartan matrix $(a_{i,j})_{i,j\in I}$, its universal Borcherds-Kac-Moody algebra $\mathfrak{g}(A)$ is the Lie algebra with generators $\{h_i, e_i, f_i\}_{i,j\in I}$, and the following relations:

1. $\mathfrak{sl}_2$ relations: $[h_i, e_k] = a_{i,k}e_k$, $[h_i, f_k] = -a_{i,k}f_k$, $[e_i, f_j] = \delta_{i,j}h_i$.
2. Serre relations: If $a_{i,i} > 0$, then $\mathrm{ad}(e_i)^{1-2a_{i,j}}(e_j) = \mathrm{ad}(f_i)^{1-2a_{i,j}}(f_j) = 0$.
3. Orthogonality: If $a_{i,j} = 0$, then $[e_i, e_j] = [f_i, f_j] = 0$.

A Borcherds-Kac-Moody algebra is a Lie algebra of the form $(\mathfrak{g}(A)/C).D$, where C is a central ideal, and D is a commutative Lie algebra of outer derivations.

From these starting data, one can build up a theory that closely mirrors that of finite dimensional semisimple Lie algebras, but with some complications. The general theory is substantially developed with proofs in [Jurisich-1996].

There are two main differences between this definition and others:

1. Other definitions may start with the symmetrized matrix QA instead of A. This means one often sees the condition that if $a_{i,i} > 0$, then for all $j \in I$, $2a_{i,j}/a_{i,i} \in \mathbb{Z}$.
2. Other definitions may have central generators $h_{i,j}$ for $i \neq j$, with the relation $[e_i, f_j] = \delta_{i,j}h_i$ replaced with $[e_i, f_j] = h_{i,j}$. As we will see in the next lemma, these necessarily vanish in the cases of interest to us. That is, if we were to use the more general definitions, these generators would end up in the central ideal C.

Most of the Borcherds-Kac-Moody algebras that have naturally appeared in mathematical practice have infinitely many simple roots, but a finite dimensional Cartan subalgebra, i.e., I is infinite, but one chooses C to have finite codimension in the span of $\{h_i\}_{i\in I}$. We give a method to recognize most of the interesting cases:

Lemma 3.4.2. *Any complex Lie algebra $\mathfrak{g}$ satisfying the following conditions is Borcherds-Kac-Moody:*

1. *$\mathfrak{g}$ admits a nonsingular invariant symmetric bilinear form, i.e., $(x, y) = (y, x)$, $(x, [y, z]) = ([x, y], z)$ for all $x, y, z \in \mathfrak{g}$, and if $(x, y) = 0$ for all $y \in \mathfrak{g}$, then $x = 0$.*
2. *$\mathfrak{g}$ has a self-centralizing subalgebra H, called a Cartan subalgebra, such that $\mathfrak{g}$ is the sum of eigenspaces under the action of H, and the nonzero eigenvalues, called roots, have finite multiplicity.*
3. *H has a totally real structure $H_{\mathbb{R}} \subset H$ (i.e., such that $H = H_{\mathbb{R}} \oplus \sqrt{-1}H_{\mathbb{R}}$), such that the restriction of the bilinear form is real-valued, and all roots are elements of the dual $H_{\mathbb{R}}^{\vee}$.*
4. *There exists an element $h \in H_{\mathbb{R}}$, such that:*
    - (a) *the centralizer of h in $\mathfrak{g}$ is H,*
    - (b) *for any $M \in \mathbb{R}$, there exist at most finitely many roots α such that $|\alpha(h)| < M$.*

    This vector h is called a regular element. If $\alpha(h) < 0$ then we say that α is negative, and if $\alpha(h) > 0$ then we say that α is positive.
5. *The norms of roots under the inner product $(,)$ are bounded above.*
6. *Any two roots of non-positive norm that are both positive or both negative have inner product at most zero, and if the inner product is zero, then their root spaces commute.*

Proof. This is essentially theorem 1 in [Borcherds-1995], but we remove the hypothesis that $\mathfrak{g}$ is defined over the real numbers. Borcherds's proof still works, because the reconstruction of $\mathfrak{g}$ by recursively adding simple roots following increasing values of $\alpha(h)$ only uses the real structure on H, not on $\mathfrak{g}$. To match Borcherds's definition with ours, we would need to allow the generators $h_{i,j}$, but Borcherds shows in the course of his proof that $h_{i,j} = [e_i, f_j] = 0$ when $i \neq j$. Thus, the proof shows that we obtain a Borcherds-Kac-Moody algebra in our restricted sense. $\square$

Recall that an element $g \in \mathbb{M}$ is Fricke if and only if the McKay-Thompson series T_g is invariant under the level N Fricke involution $\tau \mapsto \frac{-1}{N\tau}$ for some N.

Proposition 3.4.3. *For each Fricke element $g \in \mathbb{M}$, the Lie algebra $\mathfrak{m}_g$ from Definition 3.2.4 is a Borcherds-Kac-Moody Lie algebra.*

Proof. It suffices to check that the conditions in Lemma 3.4.2 hold.

1. The bilinear form is induced from the contragradient form, as shown in Proposition 3.1.8.
2. We define H to be the $(0,0)$-graded piece of $\mathfrak{m}_g$. By the first claim in Proposition 3.2.6, this is isomorphic to $\mathbb{C}^2$. Furthermore, the left multiplication by H is given by the Heisenberg action on the tensor product vertex algebra, and their eigenvalues are given by degree. The fact that anything not in H has nonzero eigenvalue implies the self-centralizing condition is satisfied.
3. H is naturally identified with $II_{1,1}(-1/N) \otimes_{\mathbb{Z}} \mathbb{C}$, which has a natural real structure $H_{\mathbb{R}} = II_{1,1}(-1/N) \otimes_{\mathbb{Z}} \mathbb{R}$. The inner product on $H_{\mathbb{R}}$ is real valued, and the roots, viewed as elements of the lattice, lie in $H_{\mathbb{R}}^{\vee}$.
4. By identifying $H_{\mathbb{R}}$ with $II_{1,1}(-1/N) \otimes_{\mathbb{Z}} \mathbb{R}$, we let h be any negative norm element whose inner product with any root is nonzero. A standard choice is $(1,2)$, under the identification $II_{1,1}(-1/N) \cong \mathbb{Z} \oplus \frac{1}{N}\mathbb{Z} \subset \mathbb{R}^{1,1}$.
5. If we write the norm of a root at $r \in II_{1,1}(-1/N)$ as r^2, then the fourth claim of Proposition 3.2.6 implies the root space at r is identified with a subspace of ${}^{g}_{N}V^{\natural}$ whose vectors have L_0-eigenvalue equal to $1 - r^2$. The L_0-eigenvalues in ${}^{g}_{N}V^{\natural}$ are bounded below by zero, so the norms of roots are bounded above by 1.
6. Because H has a real Lorentzian structure, we can identify the real span of the root space with $\mathbb{R}^{1,1}$, and any pair of imaginary positive (resp. negative) roots lies in a single quadrant, where their inner products are bounded above by zero. Two such roots are orthogonal if and only if they are positive multiples of the same norm zero vector. We claim that because g is Fricke, there are no positive roots of norm zero. Such a root would have the form $(a,0)$ or $(0,b/N)$ in $II_{1,1}(-1/N)$ for $a,b > 0$, and by the last claim in Proposition 3.2.6, the multiplicities of those root spaces are given by the coefficients $c^g_{a,0}(0)$ and $c^g_{0,b}(0)$ of F^g. By Corollary 3.25 of [Carnahan-2012], these coefficients are in turn the exponents attached to $(1 - p^a q^0)$ and $(1 - p^0 q^{b/N})$ in the product expansion
$$T_g(\sigma) - T_g(-1/\tau) = p^{-1} \prod_{m>0, n \in \frac{1}{N}\mathbb{Z}} (1 - p^m q^n)^{c^g_{m,Nn}(mn)}.$$
Because g is Fricke, we may rewrite the left side as $T_g(\sigma) - T_g(\tau/N)$, and we find that the product expansion has the form $p^{-1}(1 - pq^{-1/N})$ times a product for which m and n are strictly positive. Thus, the coefficients vanish, and there are no roots of norm zero.

□

When g is non-Fricke, the last condition is somewhat more complicated to verify due to the presence of norm zero simple roots. Since the non-Fricke case is not needed in this paper, we postpone it to future work.

The following lemma will be useful in the next section, when we consider concrete quantitative questions. It is well-known to experts, but we couldn't find a statement in the literature that was both precise and concise.

Lemma 3.4.4. *Let $\mathfrak{g}_1$ and $\mathfrak{g}_2$ be Borcherds-Kac-Moody Lie algebras with finite dimensional Cartan subalgebras $\mathfrak{h}_1, \mathfrak{h}_2$. Given an inner-product-preserving isomorphism $f : \mathfrak{h}_1 \to \mathfrak{h}_2$, there exists an extension to a Lie algebra isomorphism $\mathfrak{g}_1 \to \mathfrak{g}_2$ if and only if the root multiplicities are identical under the isometry f.*

Proof. It is clear that an isomorphism of Lie algebras that restricts to an isometry of Cartan subalgebras preserves root multiplicities.

Now, assume $\mathfrak{g}_1$ and $\mathfrak{g}_2$ have identical root multiplicities under the isometry $\mathfrak{h}_1 \to \mathfrak{h}_2$. It is well-known that the Weyl-Kac-Borcherds denominator formula may be used to uniquely determine the simple roots of a Borcherds-Kac-Moody algebra from the root multiplicities. Indeed, the set of values of $\alpha(h)$ as α ranges over positive roots is a discrete subset of the positive reals (in particular, well-ordered), and this allows us to recursively match the truncated evaluations of both sides of the Weyl-Kac-Borcherds denominator formula by adding simple roots as necessary. Indeed, this is essentially the same reconstruction process as the one sees in the proof of Lemma 3.4.2. Thus, under a choice of matching regular elements, $\mathfrak{g}_1$ and $\mathfrak{g}_2$ have the same simple roots, i.e., the simple roots that are identified under the isometry $\mathfrak{h}_1 \to \mathfrak{h}_2$ have equal multiplicity. Abstractly, this implies that both $\mathfrak{g}_1$ and $\mathfrak{g}_2$ are isomorphic to the Borcherds-Kac-Moody Lie algebra given by generators and relations from the same generalized Cartan matrix. More concretely, the simple root spaces are isomorphic vector spaces, and any choice of isomorphism between simple root spaces that are identified through the isometry $\mathfrak{h}_1 \to \mathfrak{h}_2$ extends uniquely to a Lie algebra isomorphism. □

Remark 3.4.5. Theorem 7.2 of [Borcherds-1992] is essentially an application of the previous lemma to identify the Monster Lie algebra $M = \mathfrak{m}_1$ defined by applying the no-ghost theorem to $V^\natural$ with the abstract Lie algebra $N = L_1$ defined by a specification of simple roots.

4. Comparison theorems

4.1. **Lie algebra comparison.** In [Carnahan-2012] section 4, we defined for each $g \in \mathbb{M}$ a Borcherds-Kac-Moody Lie algebra L_g (written W_g in Proposition 4.4 of that paper), whose Weyl-Kac-Borcherds denominator identity is an infinite product expansion of $T_g(\sigma) - T_g(-1/\tau)$. We now show that the quantization functor yields an isomorphic Lie algebra.

Proposition 4.1.1. *Let $g \in \mathbb{M}$ be a Fricke element. Then there exists a homogeneous Lie algebra isomorphism $\mathfrak{m}_g \to L_g$.*

Proof. By Proposition 3.4.3, $\mathfrak{m}_g$ is a Borcherds-Kac-Moody Lie algebra whose Cartan subalgebra has a real Lorentzian structure. By Theorem 4.2 of [Carnahan-2012], L_g is a Borcherds-Kac-Moody Lie algebra whose Cartan subalgebra has a real Lorentzian structure. By Lemma 3.4.4, if we are given two Borcherds-Kac-Moody Lie algebras and an inner-product-preserving isomorphism between their Cartan subalgebras, this isomorphism can be extended to an isomorphism of the full Lie algebras if and only if the root multiplicities are equal.

If $T_g(\tau)$ has level N, then the root lattices of both Lie algebras are identified with $II_{1,1}(-1/N)$, so it suffices to compare dimensions of the homogeneous spaces of nonzero degree. The dimensions are equal by the last claim in Proposition 3.2.6, which gives a $II_{1,1}(-1/N)$-graded vector space isomorphism $\mathfrak{m}_g \to L_g$. Thus, we have equality of dimensions of root spaces, and hence an isomorphism of Lie algebras. □

Corollary 4.1.2. *For any Fricke $g \in \mathbb{M}$, hypothesis C_g from section 4.4 of [Carnahan-2012] is satisfied, i.e., there is an action of $\widetilde{C_{\mathbb{M}}(g)}$ on L_g by Lie algebra automorphisms, such that the action on the $(a, b/N)$ root space coincides with the action on the subspace of $V^\natural(g^a)$ on which $\tilde{g}$ acts by $e(b/N)$ and L_0 acts by $1 + ab/N$.*

Proof. If we fix a Lie algebra isomorphism $\mathfrak{m}_g \to L_g$, then the action of $\widetilde{C_{\mathbb{M}}(g)}$ on L_g is given by *transport de structure*. The isomorphism between $\widetilde{C_{\mathbb{M}}(g)}$-module structures for the root spaces and the subspaces of twisted modules then follows from the corresponding fact for $\mathfrak{m}_g$, which holds by the fourth listed claim of Proposition 3.2.6. □

4.2. **Main theorem.** The following theorem is the target of this series of papers.

Theorem 4.2.1. *If g is a Fricke element, then for any $h \in C_{\mathbb{M}}(g)$, there exists a discrete group $\Gamma_{g,h} \subset PSL_2(\mathbb{R})$ containing a congruence subgroup $\Gamma(K)$ for some $K > 0$ (hence commensurable with $SL_2(\mathbb{Z})$), such that for any lift $\tilde{h}$ of h to a linear transformation on $V(g)$, the power series $Tr(\tilde{h}q^{L_0-1}|V^\natural(g))$ is the q-expansion of a modular function on $\mathcal{H}$ that is invariant under $\Gamma_{g,h}$, and generates the function field of the quotient $\mathcal{H}/\Gamma_{g,h}$.*

Proof. By Corollary 4.1.2, hypothesis C_g holds, and in particular the positive subalgebra E_g of L_g is Fricke-compatible for the data $(\widetilde{C_{\mathbb{M}}(g)}, \tilde{g}, \{V_k^{i,j} = V^\natural(g^i)^{\tilde{g}=e(j/N), L_0-1=k}\})$ in the sense of [Carnahan-2012] section 4.2. That is:

1. E_g is graded by $\mathbb{Z}_{>0} \times \frac{1}{N}\mathbb{Z}$, and decomposes as a sum $\bigoplus_{n>0, m\in\frac{1}{N}\mathbb{Z}} E_{i,j}p^iq^j$ of finite dimensional homogeneous components, where p and q denote degree shifts by $(0,1)$ and $(1,0)$.
2. E_g admits an action of $\widetilde{C_{\mathbb{M}}(g)}$ by homogeneous Lie algebra automorphisms, such that $E_{i,j} \cong V_{1+ij}^{i,j}$ as $\widetilde{C_{\mathbb{M}}(g)}$-modules.
3. The homology of E_g is given by
    - $H_0(E) = \mathbb{C}$
    - $H_1(E) = \bigoplus_{n\in\frac{1}{N}\mathbb{Z}} V_{1+n}^{1,n}pq^n$
    - $H_2(E) = p\bigoplus_{m=1}^{\infty} V_{1-1/N}^{1,-1/N} \otimes V_{1+m/N}^{m,1/N}p^m$
    - $H_i(E) = 0$ for $i > 2$.
4. $E_{1,-1/N} \cong V_{1-1/N}^{1,-1/N}$ is one dimensional.

By Proposition 6.3 in [Carnahan-2010], if E_g is Fricke-compatible for $(\widetilde{C_{\mathbb{M}}(g)}, \tilde{g}, \{V_k^{i,j}\})$, then for any $\tilde{h} \in \widetilde{C_{\mathbb{M}}(g)}$, the power series $Tr(\tilde{h}q^{L_0-1}|V^\natural(g))$ is the q-expansion of a Hauptmodul whose invariance group contains a principal congruence subgroup. □

By combining our main theorem with previously known results, we obtain a positive resolution of Norton's conjecture.

Theorem 4.2.2. *(Generalized Moonshine for twisted modules of $V^\natural$) Any rule that assigns*

- *to each $g \in \mathbb{M}$ the irreducible g-twisted $V^\natural$-module $V^\natural(g)$, with its canonical projective $C_{\mathbb{M}}(g)$-action, and*
- *to each commuting pair (g,h) the function $Z(g,h;\tau) = \mathrm{Tr}(\tilde{h}q^{L_0-1}|V^\natural(g))$ for some lift $\tilde{h}$ of h to a linear transformation on $V^\natural(g)$*

satisfies the following conditions:

1. *The formal series defining $Z(g,h;\tau)$ is the q-expansion of a holomorphic function on the upper half-plane $\mathfrak{H}$.*
2. *The function $(g,h) \mapsto Z(g,h;\tau)$ is invariant under simultaneous conjugation on the pair (g,h) in $\mathbb{M}$, up to rescaling.*
3. *$Z(g,h;\tau)$ is either a constant or a Hauptmodul.*
4. *For any $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in SL_2(\mathbb{Z})$ and any commuting pair (g,h) in $\mathbb{M}$, $Z(g,h,\frac{a\tau+b}{c\tau+d})$ is proportional to $Z(g^ah^c, g^bh^d, \tau)$.*
5. *$Z(g,h;\tau)$ is proportional to $J(\tau)$ if and only if $g = h = 1$.*

Proof. The first claim is well-known: As a statement about normal convergence of power series, it follows from Theorem 8.1 of [Dong-Li-Mason-2000].

The second claim is also well-known, and follows by general nonsense from the Dong-Li-Mason proof of existence and uniqueness for irreducible twisted $V^\natural$-modules: For any $k \in \mathbb{M}$, k-conjugation on twisted modules induces an equivalence from the category of g-twisted $V^\natural$-modules to the category of kgk^{-1}-twisted $V^\natural$-modules, taking the projective $C_{\mathbb{M}}(g)$-action on $V^\natural(g)$ to the projective $C_{\mathbb{M}}(kgk^{-1})$-action on $V^\natural(kgk^{-1})$ by conjugation. This preserves characters up to rescaling.

The third claim is relatively straightforward in light of Theorem 4.2.1 combined with the $SL_2(\mathbb{Z})$ claim. If $g^a h^c$ is Fricke for some a, c satisfying $(a, c) = 1$, then $Z(g^a h^c, g^b h^d, \tau)$ is a Hauptmodul for all b, d such that $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in SL_2(\mathbb{Z})$. The $SL_2(\mathbb{Z})$ claim then implies $Z(g, h, \tau)$ is proportional to a Möbius transform of $Z(g^a h^c, g^b h^d, \tau)$, hence is a Hauptmodul. On the other hand, if all $g^a h^c$ for $(a, c) = 1$ are non-Fricke, then the twisted modules $V^\natural(g^a h^c)$ have L_0-spectrum bounded below by 1, so $Z(g^a h^c, g^b h^d, \tau)$ is regular at infinity for all $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in SL_2(\mathbb{Z})$. Then the $SL_2(\mathbb{Z})$ claim implies $Z(g, h, \tau)$ is regular at all cusps, so the maximum modulus principle implies it is a constant function.

As we remarked in the introduction, the $SL_2(\mathbb{Z})$ claim follows immediately from combining Theorem 10.1 in [Dong-Li-Mason-2000] (which reduces the question to a g-rationality condition) with Corollary 5.26 of [Carnahan-Miyamoto-2016] (which asserts g-rationality).

The fifth claim also follows from [Dong-Li-Mason-2000]. In particular, the positivity of the L_0-spectrum of $V^\natural(g)$ for $g \neq 1$ (as given in Theorem 2.2.9) eliminates all nontrivial twistings. For the trivial twisting, the fact that the McKay-Thompson series $T_h(\tau) = Z(1, h, \tau)$ is equal to J if and only if $h = 1$ follows from the faithfulness of the monster action on $V^\natural$ as shown in [Frenkel, et al, 1988]. ☐

Abstract

We clarify the role played by BPS states in the calculation of threshold corrections of D=4, N=2 heterotic string compactifications. We evaluate these corrections for some classes of compactifications and show that they are sums of logarithmic functions over the positive roots of generalized Kac-Moody algebras. Moreover, a certain limit of the formulae suggests a reformulation of heterotic string in terms of a gauge theory based on hyperbolic algebras such as E_{10}. We define a generalized Kac-Moody Lie superalgebra associated to the BPS states. Finally we discuss the relation of our results with string duality.

October 24, 1995, Revised Jan. 9, 1996

1. Introduction

It has become clear recently that theories with extended supersymmetry have a rich dynamical structure which is nonetheless amenable to exact analysis using ideas of electromagnetic duality [1,2,3,4,5,6,7,8]. One important feature of these theories is the existence of BPS states. These states play a crucial role in the dynamics of the theory and their structure at strong coupling can in many cases be determined by a semi-classical analysis. For example, in the analysis of [5,6] certain BPS states become massless at special points in the quantum moduli space of vacua and dominate the low-energy dynamics.

In string theory there is increasing evidence that a related although undoubtedly richer structure is present, particularly in $N = 2$ theories exhibiting duality [9,10]. String theories with extended supersymmetry resulting from toroidal compactification have in fact an infinite spectrum of BPS states [11,12]. These BPS states have played a central role in much of the recent work on duality in string theory. In Type II string theory the presence of an infinite tower of non-perturbative BPS states is crucial in understanding the strong coupling behavior and duality symmetries [13,14]. These BPS states carrying Ramond-Ramond charge are also essential to the resolution of the conifold singularity in Type II string theory [15,16] and play an important role in understanding the relation between Type I and Type II string theory [17]. In the heterotic string BPS states played a central role in the original understanding of S-duality [18]. It seems fair to say that the foundations of string theory are shifting and that the structure of BPS states provides one of the most useful clues as to what type of theory unifies these disparate phenomena.

Another theme which runs through much of string theory is the search for the symmetries which underlie the structure of string theory. One symmetry structure which has been investigated in this regard is that of hyperbolic Kac-Moody and generalized Kac-Moody algebras [19,20,21,22,23,24,25,26] . Generalized Kac-Moody (GKM) algebras occur very naturally as unbroken symmetry groups in certain string ground states [23] and -contrary to what one expects in spontaneously broken gauge theory - even when these gauge symmetries are broken they nevertheless put strong constraints on the S-matrix [24]. The idea of a T-duality invariant string algebra based on a Lorentzian lattice as a gauge algebra for $N = 4$ heterotic string compactifications was discussed in [22] and is summarized in [27]. There are also close connections between these algebras and the structure of string field theory [28].

In this paper we will provide evidence for a connection between BPS states in string theory with $N = 2$ spacetime supersymmetry and GKM algebras. We will show that threshold corrections in $N=2$ heterotic string compactifications are in fact determined purely in terms of the spectrum of BPS states. What is more surprising is that these corrections are closely related to product formulae that have been studied recently by Borcherds, Gritsenko and Nikulin [29,30,31,32,33] in connection with generalized Kac-Moody algebras. We will show how this connection arises and construct a GKM Lie superalgebra in terms of vertex operators associated to BPS states.

Our results can be viewed as a generalization to string theory of some of the structures previously encountered in duality and $N=2$ Yang-Mills theory. For example, our results suggest that the BPS states in string theory should be regarded as "gauge bosons " of the GKM algebra. We find a direct generalization of the one-loop formula for the prepotential in $N=2$ Yang-Mills theory [7,8],

$$\mathcal{F} = \frac{i}{4\pi} \sum_{\vec{\alpha}>0} (\alpha \cdot A)^2 \log \frac{(\alpha \cdot A)^2}{\Lambda^2} \tag{1.1}$$

where A determines the components of the Higgs expectation value in the Cartan subalgebra $\phi = \sum A_i H_i$ and the sum in (1.1) runs over the positive roots of the Lie algebra of the gauge group G. In a certain limit we will find a similar formula in string theory where the sum over the positive roots of the Lie algebra of G is replaced by a sum over the positive roots of a GKM algebra.

The simplest example of a product formula which occurs in threshold corrections is Borcherds' remarkable product formula for the modular j function

$$j(p) - j(q) = p^{-1} \prod_{n>0, m\in Z} (1-p^n q^m)^{c(mn)} \tag{1.2}$$

where $j(q) - 744 = \sum_{n=-1} c(n) q^n$. The proof can be found in [34]and [35]. The infinite product converges for $|p|$, $|q| < e^{-2\pi}$ and is defined elsewhere by analytic continuation. An expansion of both sides for small p, q quickly reveals that it requires an infinite number of identities among the coefficients, the first of which is $c(4) = c(3) + c(1)(c(1)-1)/2$. In [36] these identities appear as "replication" formulae involving the dimensions of irreducible representations of the monster group. In [35] the product formula (1.2) is interpreted in terms of the denominator formula for the monster Lie algebra which is an example of a GKM algebra. The quantity $j(T) - j(U)$ has appeared in the recent literature in connection with threshold corrections to gauge couplings with T, U the moduli on a T^2

in the string compactification [37,38,39]. [1] In [37,38,39] this term was found by indirect methods. We will show here how it and various generalizations can be computed directly in terms of products which generalize (1.2). Indeed, using the integrals of appendix A it is straightforward to give an independent proof of (1.2).

There is a substantial literature on threshold corrections in $N = 1$ and $N = 2$ heterotic string theory [40,41,42,43,44,45,46,37,39,38,47,48]. We will make particular use of some techniques of [42] and of the result in [43][48] relating threshold corrections to the new supersymmetric index [49]. We also rely heavily on the results of [38,39] relating explicit one-loop string calculations to the quantities appearing in $N = 2$ supergravity effective Lagrangians. A connection between BPS states and threshold corrections has been suggested, directly and indirectly, in various forms, in [50,51,47,52].

The outline of this paper is as follows. In the second section we briefly review the relevant properties of $N = 2$ heterotic string compactifications and associated moduli spaces. In the third section we discuss the nature of perturbative BPS states in these compactifications. We show that threshold corrections are determined purely by the spectrum of BPS states and relate these corrections to the elliptic genus of the internal $c = 6$, $N = 4$ superconformal field theory governing the compactification. In the fourth section we determine the dependence of these corrections on either the (T, U) Narain moduli of T^2 or these plus the E_8 Wilson line moduli and show that they are naturally given by infinite sums of logarithmic functions. The fifth section contains a discussion of the relation of our work to a theorem of Borcherds. We discuss the automorphic structure of the products which result from our analysis and show how Borcherds results follow from an analysis of certain modular integrals. In section six we discuss the quantum monodromy of the prepotential. The seventh section contains a brief discussion of GKM algebras and their associated root lattices and compares the results of sections four and five to the denominator formula for these algebras. For the previous two choices of moduli we show that the product formulae we obtain are given by a product over positive roots of the monster Lie algebra and the hyperbolic Kac-Moody Lie algebra E_{10} respectively. We discuss two limiting cases of the prepotential in section eight, one of which suggests that the GKM algebra should be considered a gauge algebra in string theory. In the ninth section we construct a generalized Kac-Moody algebra which is in some sense associated to the BPS states. The tenth section has some preliminary remarks on the application of our results to $N = 2$ string duality. In the final section we conclude and offer some speculations on possible extensions of this work. Certain modular integrals needed in the evaluation of threshold corrections are computed in an appendix.

---

[1] We use both notations $j(q)$ and $j(\tau)$, depending on context.

2. Review of $D = 4, N = 2$ heterotic string compactifications

2.1. Chiral Algebra

In this paper we will be considering compactifications of the heterotic string to four spacetime dimensions with $N = 2$ spacetime supersymmetry. There is a $c = 9$, $N = 1$ internal superconformal algebra (SCA) associated to any such compactification. For such theories the spacetime supersymmetry implies that this internal SCA splits into a $c = 6$ piece with $N = 4$ superconformal symmetry and a $c = 3$ piece with $N = 2$ superconformal symmetry [53]. The $c = 3$, $N = 2$ theory is constructed from two free dimension 1/2 superfields. We will indicate this decomposition of the right-moving superconformal algebra as

$$\tilde{\mathcal{A}}^{N=2}_{\tilde{c}=3} \oplus \tilde{\mathcal{A}}^{N=4}_{\tilde{c}=6} \subset \tilde{\mathcal{A}} \quad , \tag{2.1}$$

where $\tilde{\mathcal{A}}$ is the rightmoving chiral algebra. The left-moving internal conformal field theory has $c = 22$ but is otherwise unconstrained except by modular invariance.

The $c = 3$ theory has a $U(1)$ current which we denote by $J^{(1)}$. The $c = 6$ theory is in general non-trivial and to be compatible with $N = 4$ superconformal symmetry must have a level one $SU(2)$ Kac-Moody algebra. Representations of the $c = 6$ theory can thus be labelled by the conformal weight and $SU(2)$ representation (h, I). We will also choose a $U(1)$ current $J^{(2)}$ from this $SU(2)$ algebra with the normalization $J^{(2)} = 2J^3$ where J^3 is the $SU(2)$ Cartan current. The total $U(1)$ current of the $c = 9$ theory is $J = J^{(1)} + J^{(2)}$.

2.2. Remarks on the moduli space

$N = 2$ heterotic compactifications typically have a large moduli space of vacua. The moduli decompose into hypermultiplets and vectormultiplets under the $N = 2$ spacetime supersymmetry. The $c = 6$, $N = 4$ SCA has two massless representations in the Neveu-Schwarz sector, $(h = 0, I = 0)$ and $(h = 1/2, I = 1/2)$ [54]. These are associated to vectormultiplet and hypermultiplet moduli respectively. The factorization (2.1) is reflected in spacetime through the constraints of $N = 2$ supergravity which require a local factorization of the total moduli space of the form

$$SK(n) \times Q(m) \tag{2.2}$$

where $SK(n)$ is the vectormultiplet moduli space which must be a special Kahler manifold of real dimension $2n$ and $Q(m)$ is the hypermultiplet moduli space and is quaternionic of real dimension $4m$. In fact the moduli space is a complicated and singular space; its global structure has not been fully elucidated and should prove very interesting. The classical moduli space is an algebraic variety which probably has the following structure. $\mathcal{M}$ is a singular stratified space, that is, there is a disjoint union

$$\mathcal{M} = \amalg_{\int} \mathcal{M}_{\int} \tag{2.3}$$

with smooth strata $\mathcal{M}_{\int}$ which fit together in a singular fashion. The $\mathcal{M}_{\int}$ have the structure of a fibration of a quaternionic manifold over a special Kahler manifold. [2]

The classical vectormultiplet moduli space for $N = 2$ string compactifications is given by the special Kahler manifold [55]

$$\mathcal{M}_{\mathrm{vm}}^{s+2,2} \equiv \frac{SU(1,1)}{U(1)} \times \mathcal{N}^{s+2,2} \tag{2.4}$$

where the first factor is associated with the dilaton. Here we have introduced the Narain moduli space $\mathcal{N}^{s+2,2}$. This is a quotient of the generalized upper half plane

$$\mathcal{H}^{s+1,1} \equiv O(s+2,2;\mathbb{R})/[O(s+2)\times O(2)] \tag{2.5}$$

by the left-action of the arithmetic subgroup $O(s+2,2;\mathbb{Z})$:

$$\begin{aligned} \mathcal{N}^{s+2,2} &\equiv O(s+2,2;\mathbb{Z})\backslash\mathcal{H}^{s+1,1} \\ &= O(s+2,2;\mathbb{Z})\backslash O(s+2,2;\mathbb{R})/[O(s+2)\times O(2)] \end{aligned} \tag{2.6}$$

The special geometry of (2.6) is described in some detail below.

For $N = 2$ compactifications with internal space $K3 \times T^2$ and an embedding of the spin connection in $E_8 \times E_8$ the moduli space $\mathcal{M}_{\mathrm{vm}}^{s+2,2}$ always contains a subvariety $\cong \mathcal{N}^{2,2}$, which is the Narain moduli space for the complex moduli T, U on T^2:

$$\frac{O(2,2)}{O(2)\times O(2)} \simeq \left(\frac{SU(1,1)}{U(1)}\right)_T \otimes \left(\frac{SU(1,1)}{U(1)}\right)_U . \tag{2.7}$$

---

[2] In the case of global $N = 2$ SYM with matter these statements can probably be proven from the F and D flatness equations. For gauge group G the strata should be enumerated by the possible unbroken subgroups $G_1 \subset G$. The base should be $\underline{\mathbf{t}}(G_1) \otimes \mathbb{C}/W(G_1)$ while the fibers are hyperkahler quotients.

The arithmetic group $O(2,2;\mathbb{Z})$ in this case consists of the $T \leftrightarrow U$ exchange and transformations by $PSL(2,\mathbb{Z})_T \times PSL(2,\mathbb{Z})_U$.

In $N=2$ string theory the classical special geometry of $\mathcal{M}^{s+2,2}_{\rm vm}$ receives quantum corrections. The dependence of threshold corrections on T,U moduli has been well studied in the literature and has played an important role in recent tests of string-string duality [56,57,58]. In many compactifications based on $K3\times T^2$ one finds additional vectormultiplet moduli associated to Wilson lines for the unbroken gauge group on T^2. The dependence of threshold corrections on these Wilson line moduli has been studied in [37,38,59].

In this paper we will for the most part focus on two special cases with moduli space (2.4) for $s=0$ and $s=8$ corresponding to the T,U moduli on T^2 in the first case and in the second to T,U and the Wilson line moduli associated to the unbroken E_8 factor for $K3$ compactifications given by the standard embedding of the spin connection in the gauge group. For these two cases the moduli are just the Narain moduli associated to the even self-dual lattices $\Pi^{2,2}$ and $\Pi^{10,2}$. However many of our considerations are more general and we will only specialize to these two cases when necessary.

2.3. The classical special geometry of $\mathcal{N}^{s+2,2}$ *and of* $\mathcal{M}^{s+2,2}_{\rm vm}$.

The standard Kahler geometry on the space (2.4) is special geometry described, for example, in [38,60]. We now discuss a useful parametrization of the homogeneous space

$$\mathcal{H}^{s+1,1} = \frac{O(s+2,2)}{O(s+2)\times O(2)} \tag{2.8}$$

occurring in (2.4). Further details may be found in [61,62,38,60,37].

We can represent the homogeneous space $\mathcal{H}^{s+1,1}$ as a "tube domain" in a complexified Minkowski space as follows. Let $\langle\cdot,\cdot\rangle$ be a real quadratic form of signature $(+^{s+2},-^2)$. Consider:

$$\{u\in\mathbb{C}^{s+4} : \langle u,u\rangle = 0, \langle u,\bar u\rangle < 0\}/(u\sim\lambda u) \tag{2.9}$$

This is a homogeneous space for $O(s+2,2;\mathbb{R})$. We let $y\in\mathbb{R}^{s+1,1}\otimes\mathbb{C}$, where we have a real inner product $(,)$ on $\mathbb{R}^{s+1,1}$ of signature $(+^{s+1},-^1)$. We parametrize the solutions to (2.9) by

$$y\to u(y)\equiv\Bigl(y;1,-\tfrac{1}{2}(y,y)\Bigr) \tag{2.10}$$

where the inner products are related by

$$\langle v;x_1,x_2\rangle^2 \equiv (v,v)+2x_1x_2 \tag{2.11}$$

Moreover

$$\langle u(y), \overline{u(y)} \rangle = +2(\Im y, \Im y) \tag{2.12}$$

so we must have $(\Im y)^2 < 0$, i.e., a lightlike vector [3].

The lightcone has two components, take $\Im y \in C_+$, the forward light-cone, so we realize the moduli space as a generalized upper half plane:

$$O(s+2,2)/[O(s+2) \times O(2)] \cong \mathcal{H}^{s+1,1} \equiv \mathbb{R}^{s+1,1} + iC_+^{s+1,1} \tag{2.13}$$

Sometimes when we want to be more specific about the inner product in (2.10) we take

$$\begin{aligned} v &= (\vec{v}; v_+, v_-) \\ (v,v) &= \vec{v}^2 - 2v_+v_- \end{aligned} \tag{2.14}$$

where $\vec{v}^2$ is the standard Euclidean inner product.

One important special case is the submanifold $\vec{y} = 0$, isomorphic to the case $s = 0$. Then we have two complex numbers $\Im y_+ \Im y_- > 0$. The forward lightcone then gives

$$(y_+, y_-) \to (T, U) \in \mathcal{H} \times \mathcal{H} \tag{2.15}$$

in the product of two upper half planes.

The Kahler metric on $\mathcal{N}^{s+2,2}$ is

$$K = -\log[-\tfrac{1}{2}\langle u, \bar{u}\rangle] = -\log[-(\Im y^2)] = -\log[2\Im y_+ \Im y_- - (\Im \vec{y})^2]. \tag{2.16}$$

Note that the argument of the log is positive by the definition of the domain of y and that the resulting metric is one of constant negative curvature. Similarly, the classical prepotential and Kähler potential for the space (2.4) are $\mathcal{F} = -S(y,y)$ and $K = -\log[8\Im S] - \log[-(\Im y)^2]$, respectively.

For our purposes the space $\mathcal{N}^{s+2,2}$ arises as the moduli space for Narain compactifications based on the even self-dual Lorentzian lattice $\Pi^{8t+2,2}$ when $s = 8t$. [4] We write $\Pi^{8t+2,2} \cong \Pi^{8t,0} \oplus \Pi^{2,2}$ and write lattice vectors as

$$(\vec{b}; m_+, n_-; m_0, n_0) \tag{2.17}$$

with metric

$$(\vec{b}; m_+, n_-; m_0, n_0)^2 = \vec{b}^2 - 2m_+n_- + 2m_0n_0. \tag{2.18}$$

Here $\Pi^{8t,0}$ is an even self-dual Euclidean lattice. For $t = 0$ it is the zero lattice $\{\vec{b} = 0\}$. It is unique for $t = 1$, there are two for $t = 2$, twenty-four for $t = 3$, and so forth.

---

[3] We will use both $\Re z$, $\Im z$ and z_1, z_2 to indicate the real and imaginary parts of a complex number z in this paper

[4] We use the symbol $\Pi^{p,q}$ to denote a standard even unimodular Lorentzian lattice. Lattices isomorphic to it are denoted by $\Gamma^{p,q}(y)$, where $y \in \mathcal{N}^{p,q}$.

3. Supersymmetric Index and BPS states in $N = 2$ heterotic string compactifications

3.1. BPS States

Compactifications of the heterotic string with $N = 2$ spacetime supersymmetry have a spacetime supersymmetry algebra which includes a complex central charge $\mathcal{Z}$:

$$\{Q^i_\alpha, Q^j_\beta\} = \epsilon_{\alpha\beta}\epsilon^{ij}\mathcal{Z}. \tag{3.1}$$

The central charge $\mathcal{Z}$ is determined by the right-moving momenta p_R carried by the free superfields in the $c = 3$, $N = 2$ internal SCA. The Virasoro constraints imply that the mass of any state in this theory is given by (in the Neveu-Schwarz sector)

$$M^2 = (N_R - 1/2) + \tfrac{1}{2}p_R^2 + h_R \tag{3.2}$$

where N_R is the right-moving oscillator number coming from the uncompactified coordinates and the two free superfields of the $c = 3$ theory and h_R is the conformal weight in the $c = 6$ part of the internal SCA. As a result, bosonic BPS states which must satisfy $M^2 = \frac{1}{2}p_R^2$ arise as right-moving ground states with either $N_R = 1/2$ and $h_R = 0$ or $N_R = 0$ and $h_R = 1/2$.

For Narain compactifications with lattices $\Pi^{8t+2,2}$ and lattice vectors (2.17) we have

$$\begin{aligned}\tfrac{1}{2}(p_L^2 - p_R^2) &= \tfrac{1}{2}\vec{b}^2 - m_+n_- + m_0n_0\\ \tfrac{1}{2}p_R^2 &= \frac{1}{-2(\Im y)^2}\left|\vec{b}\cdot\vec{y} - m_+y_- - n_-y_+ + n_0 - \tfrac{1}{2}m_0y^2\right|^2.\end{aligned} \tag{3.3}$$

That is, the central charges are determined by the inner product of the lattice vector (2.17) and the coordinate $u(y)$.

In contrast to theories with $N = 4$ spacetime supersymmetry, the spectrum of BPS states in $N = 2$ theories can have a "chaotic" nature, that is BPS states can appear and disappear under infinitesimal perturbations of the moduli. One simple example which illustrates this is a symmetric orbifold limit of $K3$. We consider a Z_2 orbifold of a $\Pi^{4,4}$ lattice. In the untwisted sector of the orbifold we will have states labelled by momenta $(\tilde{p}_L, \tilde{p}_R) \in \Pi^{4,4}$. Such states can be BPS states only if $\tilde{p}_R = 0$. But the existence of such states varies discontinuously as we vary the Narain moduli associated to the $\Pi^{4,4}$ lattice. For example if we focus on one S^1 factor of radius R then states with $(\tilde{p}_L \neq 0, \tilde{p}_R = 0)$ exist only for rational values of the modulus $2R^2$.

This seems to be in contradiction with the usual wisdom that BPS states must behave smoothly under perturbations of the theory. The resolution of this puzzle is simply that these chaotic BPS states always appear in hypermultiplet, vectormultiplet pairs. As one moves away from the special points these BPS states pair into long representations of the $N = 2$ spacetime supersymmetry algebra and are no longer BPS saturated. This also makes it clear that threshold corrections cannot depend only on the number and charges of BPS states if one is to obtain smooth functions of the moduli. Rather, as we will see in the following section, the threshold corrections depend only on the difference between vectormultiplet and hypermultiplet BPS states and this difference is a smooth function of the moduli.

3.2. BPS states and the supersymmetric index

It was shown in [43] that threshold corrections in $N = 2$ heterotic string compactifications can be written in terms of the "new supersymmetric index" of [49]:

$$\mathrm{Tr_R J_0 e^{i\pi J_0} q^{L_0 - c/24} \bar{q}^{\tilde{L}_0 - \tilde{c}/24}} = \frac{1}{2\pi \mathrm{i}} \frac{\partial}{\partial \theta}\Big|_{\theta = \frac{1}{2}} \mathrm{Tr}_{\mathcal{H}^{\mathrm{int}}_{\mathrm{R}}} \mathrm{q^{L_0 - c/24} \bar{q}^{\tilde{L}_0 - \tilde{c}/24} e^{2\pi i \theta J_0}} \tag{3.4}$$

where the trace is over the Ramond sector of the internal $(c, \tilde{c}) = (22, 9)$ conformal field theory and J_0 is the total $U(1)$ charge defined earlier. In the literature J_0 is often denoted by F.

We will now show that for $N = 2$ compactifications one can relate (3.4) to a sum over BPS saturated states. Using the decomposition (2.1)the Hilbert space of the internal superconformal field theory may be written as

$$\mathcal{H}^{\mathrm{int}} = \sum_{(p_R; h, I)} \mathcal{H}^{(22,0)}_{p_R; h, I} \otimes \tilde{\mathcal{H}}^{(0,3)}_{p_R} \otimes \tilde{\mathcal{H}}^{(0,6)}_{h, I} \tag{3.5}$$

where superscripts denote the Virasoro central charges $(c, \tilde{c})$, the second factor is a Fock space for the free N=2 superfield, and the third factor is a unitary irrep of the $N = 4$ SCA labelled by the conformal weight and $SU(2)$ representation (h, I). Each summand in (3.5) is a tensor product of representations of the $\tilde{\mathcal{A}}^{\tilde{c}=3}_{N=2}$ and the $\tilde{\mathcal{A}}^{\tilde{c}=6}_{N=4}$ algebras. Accordingly, the $U(1)$ current may be decomposed as $J = J^{(1)} + J^{(2)}$ and hence we may rewrite the trace on each summand in (3.5) as:

$$\begin{aligned}
&\mathrm{Tr}_{\mathrm{p_R \otimes (h,I)}} J_0 e^{i\pi J_0} q^{L_0 - c/24} \bar{q}^{\tilde{L}_0 - \tilde{c}/24} = \\
&\qquad \mathrm{Tr_{p_R} J_0^{(1)} e^{i\pi J_0^{(1)}} \bar{q}^{\tilde{L}_0 - \tilde{c}/24}} \left(\mathrm{Tr_{(h,I)} e^{i\pi J_0^{(2)}} q^{L_0 - c/24} \bar{q}^{\tilde{L}_0 - \tilde{c}/24}} \right) \\
&\qquad + \mathrm{Tr_{p_R} e^{i\pi J_0^{(1)}} \bar{q}^{\tilde{L}_0 - \tilde{c}/24}} \left(\mathrm{Tr_{(h,I)} J_0^{(2)} e^{i\pi J_0^{(2)}} q^{L_0 - c/24} \bar{q}^{\tilde{L}_0 - \tilde{c}/24}} \right)
\end{aligned} \tag{3.6}$$

Now, for an arbitrary $N=4$ representation (h,I) one has

$$\mathrm{Tr}_{(\mathrm{h},\mathrm{I})} \mathrm{J}_0^{(2)} \mathrm{e}^{\mathrm{i}\pi \mathrm{J}_0^{(2)}} \mathrm{q}^{\mathrm{L}_0 - \mathrm{c}/24} \bar{\mathrm{q}}^{\tilde{\mathrm{L}}_0 - \tilde{\mathrm{c}}/24} = 0. \tag{3.7}$$

To see this recall that the $U(1)$ current is related to the $SU(2)$ Cartan current by $J = 2J^3$ and hence has integral spectrum. Since in $SU(2)$ representations eigenvalues of J^3 come in opposite pairs (3.7) follows. Thus, only the first term on the right hand side of (3.6) survives.

We can further simplify (3.6) using N=4 representation theory. As we saw earlier BPS states correspond in the Neveu-Schwarz sector to operators in the $N=4$ theory with $h_R = 0, 1/2$. These are just the massless NS representations of the $N=4$ SCA with $(h=0, I=0)$ and $(h=1/2, I=1/2)$. The representation $(h=0, I=0)$ gives rise to the bosonic states in a BPS vectormultiplet. On the other hand the representation $(h=1/2, I=1/2)$ gives rise to the bosonic states of a BPS hypermultiplet[5].

Spectral flow in an $N=4$ theory maps these representations to Ramond representations according to

$$\begin{gathered} (h=0, I=0) \rightarrow (1/4, 1/2) \\ (h=1/2, I=1/2) \rightarrow (1/4, 0). \end{gathered} \tag{3.8}$$

These are the massless Ramond representations with Witten indices [54]:

$$\begin{gathered} \mathrm{Tr}_{\mathcal{H}^{\mathrm{N}=4}_{(\mathrm{h}=1/4,\mathrm{I}=0)}} (-1)^{2\mathrm{J}_0^3} = 1 \\ \mathrm{Tr}_{\mathcal{H}^{\mathrm{N}=4}_{(\mathrm{h}=1/4,\mathrm{I}=1/2)}} (-1)^{2\mathrm{J}_0^3} = -2 \end{gathered} \tag{3.9}$$

In fact, these are the only representations for which the Witten indices are nonzero [54]. It follows that the sum (3.4) reduces to a sum over BPS states.

The representation content of BPS multiplets with respect to the subalgebra $\tilde{\mathcal{A}}^{c=3}_{N=2} \oplus \tilde{\mathcal{A}}^{c=6}_{N=4}$ may be summarized as follows. We will denote a representation of this algebra by $(h,q) \otimes (h', I)$ where (h,q) give the conformal weight and $U(1)$ charge of the $c=3, N=2$ theory and (h', I) labels the representation of the $N=4$ algebra . With this understood vectormultiplets and hypermultiplets have the following content in the Neveu-Schwarz (NS) and Ramond (R) sectors:

---

[5] Our use of the terms "hypermultiplet" and "vectormultiplet" here is nonstandard. We define these terms based purely on the right-moving structure of the representation. For example, with this terminology the supergravity multiplet is counted as a "vectormultiplet."

$$\begin{array}{rcc} & \text{Vectormultiplets} & \text{Hypermultiplets} \\ \mathrm{NS}: & 2\times(0,0)\otimes(0,0)\oplus(1/2,\pm1)\otimes(0,0) & 2\times(0,0)\otimes(1/2,1/2) \\ \mathrm{R}: & (1/8,\pm1/2)\otimes(1/4,1/2) & 2\times(1/8,\pm1/2)\otimes(1/4,0) \end{array} \tag{3.10}$$

where all combinations of ± signs should be taken.

Combining (3.10) with (3.9) we see that each BPS vectormultiplet contributes

$$[\tfrac{1}{2}e^{i\pi/2}-\tfrac{1}{2}e^{-i\pi/2}](-2)=-2i \tag{3.11}$$

to $J_0 e^{i\pi J_0}$ while each BPS hypermultiplet contributes

$$2\times[\tfrac{1}{2}e^{i\pi/2}-\tfrac{1}{2}e^{-i\pi/2}](+1)=+2i \tag{3.12}$$

to $J_0 e^{i\pi J_0}$. Thus the BPS states contribute to (3.4) with vectormultiplets and hypermultiplets weighted with opposite signs, that is:

$$\begin{gathered} \frac{1}{\eta^2}\mathrm{Tr_R J_0 e^{i\pi J_0} q^{L_0-c/24}}\bar{q}^{\tilde{L}_0-\tilde{c}/24}= \\ -2i\left[\sum_{\text{BPS vectormultiplets}} q^{\Delta}\bar{q}^{\bar{\Delta}}-\sum_{\text{BPS hypermultiplets}} q^{\Delta}\bar{q}^{\bar{\Delta}}\right] \end{gathered} \tag{3.13}$$

Strictly speaking this equation is not completely correct because of the fact that non-physical states with $\Delta\neq\bar{\Delta}$ nonetheless contribute to modular integrals. With the understanding that the contribution of these non-physical BPS states should be included as well (3.13) is a correct equation.

Note that this is in accord with the expectation that there are no threshold corrections for $N=4$ spacetime supersymmetry and indeed $N=4$ BPS states split up into a $N=2$ hypermultiplet and a $N=2$ vectormultiplet. Another way to understand this result from the spacetime point of view is to notice that when representing the extended supertranslation algebra the massive *long* $N=2$ representations are the same as the *short* $N=4$ representations. But we know there are never any threshold corrections in $N=4$ theories, therefore we expect threshold corrections only from short $N=2$ representations, that is from BPS states.

3.3. *Elliptic genus*

From (3.6) and (3.7) we see that the new supersymmetric index (3.4) depends on $N = 4$ moduli only through

$$\mathrm{Tr}_{\mathrm{Ramond}} \mathrm{e}^{\mathrm{i}\pi \mathrm{J}_0^{(2)}} \mathrm{q}^{\mathrm{L}_0 - \mathrm{c}/24} \bar{\mathrm{q}}^{\tilde{\mathrm{L}}_0 - \tilde{\mathrm{c}}/24} \tag{3.14}$$

which, roughly speaking, is the elliptic genus [63,64,65] of the $N = 4$ conformal field theory. For a general class of backgrounds we can be more specific about the relation to the conventional elliptic genera. We assume that the gauge bundle on $T^2 \times K3$ has the structure $\pi_1^*(V_1) \oplus \pi_2^*(V_2)$, that is, in the fermionic formulation of the gauge algebra, the leftmoving fermions λ^I can be split into two disjoint sets coupling via their currents as

$$\lambda^I A_\mu^{IJ} \partial X^\mu \lambda^J + \lambda^I B_\mu^{IJ} \partial X^\mu \lambda^J \tag{3.15}$$

where A is a flat connection on T^2 for the bundle V_1, and B is an anti-self-dual instanton connection for the bundle V_2 on $K3$. We further assume that we can embed the connection B in an $SO(2n)$ subgroup of $SO(16) \subset E_8$. We can then use the bosonic formulation for one E_8 factor and the fermionic formulation for the E_8 factor containing the connection B and split the 16 fermions as $16 = 2n + (16 - 2n)$. We then couple the $2n$ fermions to the connection B via (3.15). In this case we have $(16 - 2n)$ free Majorana-Weyl fermions coupled to the flat connection A on T^2, and a $(c, \tilde{c}) = (4 + n, 6)$ heterotic sigma model on $K3$ with a gauge bundle

$$\begin{tikzcd} V_2 \arrow[d] \\ K3 \end{tikzcd} \tag{3.16}$$

satisfying the conditions

$$c_1(V_2) = 0, \qquad ch_2(V_2) = \tfrac{1}{2} c_1(V_2)^2 - c_2(V_2) = c_2(TK3) = +24. \tag{3.17}$$

We now define elliptic genera for the $(4 + n, 6)$ sigma-model as

$$\begin{aligned} \Phi^+(\hat{A}) &= Tr_{NS,R}(-1)^{F_R} q^{L_0 - c/24} \bar{q}^{\tilde{L}_0 - \tilde{c}/24} \\ \Phi^-(\hat{A}) &= Tr_{NS,R}(-1)^{F_L + F_R} q^{L_0 - c/24} \bar{q}^{\tilde{L}_0 - \tilde{c}/24} \\ \Phi(\Delta) &= Tr_{R,R}(-1)^{F_R} q^{L_0 - c/24} \bar{q}^{\tilde{L}_0 - \tilde{c}/24} \end{aligned} \tag{3.18}$$

where the subscript on the trace indicates the left-moving and right-moving boundary conditions respectively and F_L and $F_R (\equiv J_0^{(2)})$ are the left and right-moving fermion number.

The $\Phi^{\pm}$ are the elliptic generalization of the Dirac index [64] where the ± determines whether odd antisymmetric tensor representations of $SO(2n)$ are counted with a plus sign or minus sign. Φ^{+} is denoted by $H(q)$ in the first reference of [64]. The quantity $\Phi(\Delta)$ involves the elliptic generalization of the Dirac index coupled to the spinor bundles associated to V_2.

We can combine these indices together with the remaining free left-moving fermions, summed over Ramond and Neveu-Schwarz boundary conditions to obtain for the full trace

$$\begin{aligned}&\mathrm{Tr}_{\mathrm{R}} q^{L_0-c/24}\bar{q}^{\tilde{L}_0-\tilde{c}/24}J_0 e^{\pi i J_0}\\ &\quad = 2i\frac{Z_{10,2}}{\eta^{12}}\left[(\frac{\vartheta_3}{\eta})^{8-n}\Phi^{+}(\hat{A})-(\frac{\vartheta_4}{\eta})^{8-n}\Phi^{-}(\hat{A})+(\frac{\vartheta_2}{\eta})^{8-n}\Phi(\Delta)\right]\end{aligned}\tag{3.19}$$

where $Z_{10,2}/\eta^{12}(\tau)$ is the partition function for the free bosonic degrees of freedom on the $\Pi^{10,2}$ lattice constructed from the E_8 lattice and the $\Pi^{2,2}$ lattice of T^2.

Since the elliptic genus depends only on the topology of the manifold and the topology of the gauge bundle it is invariant under deformations of the hypermultiplet moduli in accord with the decompositions (2.2) and (2.1). Thus it can be evaluated by working in a special limit of the hypermultiplet moduli such as an orbifold limit. For the standard embedding of the spin connection in an $SU(2)$ subgroup of E_8 we can simply combine (3.19) with the results of [66] to obtain the answer.

4. Threshold corrections and the Prepotential

4.1. General strategy

In this section and the following we establish a connection between threshold corrections in $N=2$ compactifications of heterotic string theory and product formulae studied recently by Borcherds in connection with generalized Kac-Moody algebras. This strongly suggests the presence of a GKM algebra in such compactifications. In the ninth section we will discuss a construction of this GKM algebra in terms of vertex operators for BPS states.

We will determine the prepotential by comparing two formulae for one-loop renormalizations of nonabelian gauge couplings[6].

---

[6] In this section we follow the "string-theoretic" conventions of [48][38] for moduli. Thus, for example $\Re S>0$, $\Re T>0$, etc. The conventions which are useful for discussing automorphic properties are related by

$$y^{\mathrm{string}}=-iy^{\mathrm{automorphic}}$$

For a gauge group G the one-loop coupling renormalization is given by [48]:

$$\begin{aligned}\frac{1}{g^2(G;p^2)} &= k\Re\Big[S+\frac{1}{16\pi^2}\Delta^{\mathrm{univ}}\Big]+\frac{b(G)}{16\pi^2}\log\frac{M^2_{\mathrm{string}}}{p^2}+\frac{1}{16\pi^2}\Delta(G;y)\\ \Delta(G;y) &= \int_{\mathcal{F}}\frac{d^2\tau}{\tau_2}\Big[\mathcal{B}-b(G)\Big]\end{aligned}\tag{4.1}$$

where $\mathcal{B}$ is given by a trace over the internal Hilbert space:

$$\mathcal{B}=-\frac{i}{\eta^2}\mathrm{Tr}_{\mathcal{H}^{\mathrm{int}}_{\mathrm{R}}}\Big\{\mathrm{J}_0 \mathrm{e}^{\mathrm{i}\pi \mathrm{J}_0}\mathrm{q}^{\mathrm{L}_0-22/24}\bar{\mathrm{q}}^{\tilde{\mathrm{L}}_0-9/24}\big[\mathrm{Q}^2-\frac{\mathrm{k}}{8\pi\tau_2}\big]\Big\}\tag{4.2}$$

Here Q is a generator of the gauge group, $b(G)$ is the coefficient of the one-loop beta function normalized as in [48] and S is the dilaton field. The "universal" term Δ^{univ} is related to the "Green-Schwarz" term which governs the one-loop mixing of the axion and moduli fields and plays a role in the cancellation of sigma-model anomalies [67,68,48]. The quantity k is the level of the Kac-Moody algebra associated to G. Henceforth we set $k = 1$.

From the discussion in the previous section it is clear that (4.2) receives contributions only from BPS states. Morally speaking

$$\frac{1}{g^2}\sim\frac{1}{16\pi^2}\big[\sum_{vm}2Q^2\log m^2-\sum_{hm}2Q^2\log m^2\big]\tag{4.3}$$

in accord with the threshold rule of [38] eqn. 3.45.

We can further elaborate (4.1) using the constraints of $N = 2$ supergravity following the work of [38]. In (4.1) we may express the universal threshold correction in terms of the one-loop correction to the prepotential $h^{(1)}$:

$$\frac{1}{16\pi^2}\Delta^{\mathrm{univ}}=\frac{1}{-(\Re y)^2}\Re\Big[h^{(1)}-y_1^a\frac{\partial}{\partial y^a}h^{(1)}\Big]\tag{4.4}$$

On the other hand, using the Wilsonian coupling we may also write [48][38]:

$$\frac{1}{g^2(G;p^2)}=\Re\Big[\tilde{S}-\frac{1}{(s+4)\pi^2}\log[\Psi(y)]\Big]+\frac{b(G)}{16\pi^2}\Big[\log\frac{M^2_{\mathrm{Planck}}}{p^2}+K(S,\bar{S},y,\bar{y})\Big]\tag{4.5}$$

where

$$K=-\log[\Re(S)]-\log[-(y_1)^2]+const.\tag{4.6}$$

and a subscript 1 denotes the real part. The Planck mass is given by $M^2_{\mathrm{Planck}}=M^2_{\mathrm{string}}\Re S$. Since we are using the string theory conventions of [48,38] for the moduli the real part of y

is in the forward lightcone. The coupling $\tilde{S}$ differs from S by the addition of a holomorphic function such that $\tilde{S}$ is invariant under the duality group up to shifts. In [38] it is shown that we may write [7]:

$$\tilde{S} = S + \frac{1}{s+4}\eta^{ab}\frac{\partial}{\partial y^a}\frac{\partial}{\partial y^b}h^{(1)} \tag{4.7}$$

and under the perturbative duality group we have

$$\tilde{S} \to \tilde{S} + \frac{i}{2(s+4)}\eta^{IJ}\Lambda_{IJ} \tag{4.8}$$

where Λ_{IJ} is a real symmetric matrix.

In (4.5) $\Psi(y)$ is a holomorphic function on $\mathcal{H}^{s+1,1}$ such that

$$\Re\Big[\frac{1}{(s+4)\pi^2}\log\big[\Psi(y)\big] + \frac{b(G)}{16\pi^2}\log\big[-(y_1)^2\big]\Big] \tag{4.9}$$

is invariant under the perturbative duality group $O(s+2,2;\mathbb{Z})$. Requiring that the physical coupling be free of any singularity on $\mathcal{N}^{s+2,2}$ fixes the divisor of Ψ. These conditions determine $\Psi(y)$ up to an overall constant, since if we have two such then Ψ_1/Ψ_2 is a well-defined automorphic function extending to the compactification divisors of the variety $\mathcal{N}^{s+2,2}$ and is thus a constant. [8]

Equating (4.1) and (4.5) gives a formula for the prepotential. We now present the solution for some special cases. We will consider a compactification of the heterotic string on $K3 \times T^2$ with the standard embedding of the spin connection in the gauge group. This breaks the $E_8 \times E_8$ gauge group to $E_7 \times E_8$. In the further reduction to four dimensions on T^2 one can choose Wilson lines for the remaining unbroken subgroup leading at generic points to a low-energy gauge group $U(1)^{s+4}$ with $s = 15$ with the $U(1)^4$ arising from the two left-moving and two right-moving $U(1)$'s associated with the T^2 factor and the remaining $U(1)^{15}$ corresponding to the Cartan subalgebra of $E_7 \times E_8$.

When the unbroken gauge group is $[E_8 \times E_7 \times U(1)^2]_{left} \times [U(1)^2]_{right}$ (or an enhancement thereof) we will compute the running E_8 gauge coupling:

$$\frac{1}{g^2(E_8;p^2)} \qquad s = 0 \tag{4.10}$$

---

[7] Note the change of sign from 4.30 in [38]. We introduce $\tilde{S}$ so that we can also discuss the $(10,2)$ case. In the $(2,2)$ case it is related to the invariant coupling $S^{\rm inv}$ of [38] via: $\tilde{S} = S^{\rm inv} - L/8$.

[8] Strictly speaking one must specify appropriate asymptotic conditions to guarantee uniqueness. However we do not need the precise statement since we obtain the prepotential by direct computation.

as a function of the moduli T, U parametrizing $\mathcal{N}^{2,2}$. When the gauge group is $[E_7 \times U(1)^{10}]_{left} \times [U(1)^2]_{right}$ we will compute

$$\frac{1}{g^2(E_7; p^2)} \qquad s = 8 \tag{4.11}$$

as a function of the moduli in $\mathcal{N}^{10,2}$. The calculation for both cases can be done in parallel. The answer is given in section 4.4 below.

4.2. Computing the integrand

The first step in the calculation is the evaluation of the integrand in (4.1). As discussed in the previous section, the hypermultiplet dependence of the integrand enters only through the elliptic genus and therefore depends only on the topology of the gauge bundle and the manifold specifying the compactification. Thus, although the integrand in principle requires evaluating a partition function of a super conformal field theory on K3, we can perform the computation in an orbifold or other limit which is smoothly connected to the theory of interest. We will evaluate corrections by working in the T^4/Z_2 orbifold limit of $K3$ with the standard orbifold embedding of the twist in the gauge group. Related computations have been done for the elliptic genus of $K3$ in [66].

We start with the Narain lattice for a T^6 compactification to four dimensions with the decomposition

$$\Gamma^{22,6} = \Gamma^{10,2} \oplus \Gamma^{4,4} \oplus \Gamma^{8,0} \tag{4.12}$$

We then mod out by an involution which acts as -1 on the $\Gamma^{4,4}$ factor and as a shift $X^I \to X^I + \delta^I$ on $\Gamma^{8,0}$ with

$$\delta = (\tfrac{1}{2}, \tfrac{1}{2}, 0^6). \tag{4.13}$$

For this particular orbifold limit the unbroken gauge group at generic points is in fact $U(1)^{20}$ and the vectormultiplet moduli space is $\mathcal{N}^{18,2}$. However we will restrict ourselves in what follows to studying the dependence of the threshold corrections on the moduli of the $\Gamma^{10,2}$ factor in (4.12) for which the classical moduli space is $\mathcal{N}^{10,2}$. At least for orbifolds it should be possible to study the dependence on other moduli by generalizing the formulae in the appendix to congruence subgroups of $SL(2, Z)$.

We thus can evaluate:

$$\begin{aligned}
\eta^{-2}(\tau)\mathrm{Tr_R q^{L_0-c/24}\bar{q}^{\tilde{L}_0-\tilde{c}/24}J_0e^{\pi i J_0}} &= -2iZ_{10,2}\frac{E_6}{\eta^{24}} \\
\eta^{-2}(\tau)\mathrm{Tr_R q^{L_0-c/24}\bar{q}^{\tilde{L}_0-\tilde{c}/24}J_0e^{\pi i J_0}}[\mathrm{Q^2(E_7)}-\frac{1}{8\pi\tau_2}] &= -\frac{i}{12}Z_{10,2}\mathcal{E}_7 \\
\eta^{-2}(\tau)\mathrm{Tr_R q^{L_0-c/24}\bar{q}^{\tilde{L}_0-\tilde{c}/24}J_0e^{\pi i J_0}}[\mathrm{Q^2(E_8)}-\frac{1}{8\pi\tau_2}] &= -\frac{i}{12}Z_{2,2}\mathcal{E}_8
\end{aligned} \tag{4.14}$$

where

$$\begin{aligned}
Z_{s+2,2} &= \sum_{p\in\Gamma^{s+2,2}} q^{\frac{1}{2}p_L^2}\bar{q}^{\frac{1}{2}p_R^2} \\
\mathcal{E}_7 &= \left(\frac{(E_2-\frac{3}{\pi\tau_2})E_6-E_4^2}{\eta^{24}}\right) \\
\mathcal{E}_8 &= \left(\frac{(E_2-\frac{3}{\pi\tau_2})E_4E_6-E_6^2}{\eta^{24}}\right)
\end{aligned} \tag{4.15}$$

Here $E_{2n}(\tau)$ are the usual Eisenstein series and are given explicitly in the appendix. As a check note that the first equation in (4.14) follows from (3.19) and the results of [66].

It follows that we can rewrite the coupling in (4.1) as

$$\begin{aligned}
\frac{1}{g^2(G;p^2)} &= \Re\left[S+\frac{1}{16\pi^2}\Delta^{\mathrm{univ}}\right]+\frac{b(G)}{16\pi^2}\log\frac{M^2_{\mathrm{string}}}{p^2} \\
&\quad -\frac{1}{12}\frac{1}{16\pi^2}\left(\tilde{\mathcal{I}}_{s+2,2}-\mathcal{I}_{s+2,2}\right)
\end{aligned} \tag{4.16}$$

Here we have introduced a class of integrals defined in equations $(A.1),(A.2)$ of appendix A. The specific integrals appearing in (4.16) involve the modular forms:

$$\begin{aligned}
s=8:\qquad \frac{E_6}{\eta^{24}} &= \sum c_1(n)q^n = q^{-1}-480+\cdots \\
\frac{E_4^2}{\eta^{24}} &= \sum c_3(n)q^n = q^{-1}+504+\cdots
\end{aligned} \tag{4.17}$$

$$\begin{aligned}
s=0:\qquad \frac{E_6E_4}{\eta^{24}} &= \sum c_1(n)q^n = q^{-1}-240+\cdots \\
\frac{E_6^2}{\eta^{24}} &= \sum c_3(n)q^n = q^{-1}-984+\cdots
\end{aligned} \tag{4.18}$$

Note that the subtraction of the constant terms appearing in the definition of the integrals $\tilde{\mathcal{I}},\mathcal{I}$ and the beta function are consistent for

$$\begin{aligned}
b(G) &= -\frac{1}{12}(\tilde{c}_1(0)-c_3(0)) \\
&= -60 \qquad s=0 \\
&= +84 \qquad s=8
\end{aligned} \tag{4.19}$$

In general the coefficients $c_1(n)$ and $c_3(n)$ depend both on the choice of gauge bundle and on which low-energy gauge group is being studied.

4.3. Formulae for the Integrals

The integrals $\mathcal{I}, \tilde{\mathcal{I}}$ are evaluated in appendix A. The integral $\mathcal{I}$ is given by the expression:

$$\begin{aligned}\mathcal{I}_{s+2,2}(y) &= -2\log\Big|\Phi(y)\Big|^2 + c_3(0)\Big(-\log[-(\Re y)^2] - \mathcal{K}\Big)\\ \Phi(y) &= e^{-2\pi\rho\cdot y}\prod_{r>0}\Big(1-e^{-2\pi r\cdot y}\Big)^{c_3(-r^2/2)}\end{aligned} \tag{4.20}$$

In the above $\mathcal{K}$ is a constant defined in the appendix. The product over $r > 0$ means the following. We consider the even-self-dual Lorentzian lattice $\Pi^{s+1,1}$ for $s = 0, 8$ and write lattice vectors as $r = (\vec{b}, -\ell, -k)$ with $\vec{b} \in \Pi^{s,0}$. For $s = 8$, $\Pi^{8,0}$ is the root lattice of E_8 and we choose a set of positive roots for this lattice. With this understood, $r > 0$ means:

1. $k > 0$ or,
2. $k = 0$, $\ell > 0$, or,
3. $k = \ell = 0$, $\vec{b} > 0$.

For $s = 8$ we show in section seven below that this is the positive root condition for E_{10}. For $s = 0$ the coefficient $c_3(0)$ is not determined purely by modular invariance. After explicitly dividing out the terms involving $c_3(0)$ the remaining product is over the positive roots of the Monster Lie algebra [34][35].

The vector ρ is:

$$\begin{aligned}\rho = &\rho_{E_{10}} = -(\vec{\rho}; 31, 30) \qquad s = 8\\ \rho = &-\frac{c_3(0)}{24}(1,1) + (0,1) \qquad s = 0.\end{aligned} \tag{4.21}$$

where $\vec{\rho}$ is the Weyl vector of E_8. For $s = 8$, $\rho_{E_{10}}$ is the Weyl vector for E_{10}. For $s = 0$ (4.21) gives a lattice Weyl vector for the $\Pi^{1,1}$ lattice but only gives the Weyl vector for the Monster Lie algebra after subtraction of the $c_3(0)$ term.

The second integral we need is[9]:

$$\begin{aligned}\tilde{\mathcal{I}}_{s+2,2}(y) = &4\Re\Bigg\{\sum_{r>0}\Big[\tilde{c}_1(-\frac{r^2}{2})Li_1(e^{-2\pi r\cdot y}) + \frac{6}{\pi(y_1)^2}c_1(-\frac{r^2}{2})\mathcal{P}(ir\cdot y)\Big]\Bigg\}\\ &+\tilde{c}_1(0)\Big(-\log[-(y_1)^2] - \mathcal{K}\Big) + \frac{1}{(y_1)^2}[\tilde{d}^{s+2,2}_{ABC}y_1^A y_1^B y_1^C + \delta]\end{aligned} \tag{4.22}$$

---

[9] Integrals of this type are also evaluated in [69] although there are important differences in our results.

where

$$\delta = \frac{6}{\pi^2} c_1(0)\zeta(3). \tag{4.23}$$

Here $Li_1(x) = -\log(1-x)$ and the function $\mathcal{P}$ involves the polylogarithms Li_2 and Li_3 and is defined in the appendix. As explained in section 5.1, $\mathcal{H}^{s+1,1}$ is tessellated by a system of Weyl chambers, and the symmetric tensor $\tilde{d}^{s+2,2}$ is piecewise constant in $\mathcal{H}^{s+1,1}$, taking different values in different Weyl chambers. Explicit formulae for it are given in appendix A.

4.4. Answer for the prepotential

Equating (4.16) with (4.5) and using (4.4) and (4.7) we obtain a differential equation for $h^{(1)}$:

$$\begin{aligned} &\Re\Big[\frac{1}{s+4}\eta^{ab}\frac{\partial}{\partial y^a}\frac{\partial}{\partial y^b}h^{(1)}\Big] + \frac{1}{(\Re y)^2}\Re\Big[h^{(1)} - y_1^a\frac{\partial}{\partial y^a}h^{(1)}\Big] \\ &\qquad = -\frac{1}{12}\frac{1}{16\pi^2}\Big(\tilde{\mathcal{I}}_{s+2,2} - \mathcal{I}_{s+2,2}\Big) + \frac{1}{(s+4)\pi^2}\Re\big[\log\Psi\big] + \frac{b(G)}{16\pi^2}\log(-y_1^2). \end{aligned} \tag{4.24}$$

A particular solution of the differential equation (4.24), *in the fundamental Weyl chamber*, [10] is given by

$$h^{(1)} = \frac{1}{384\pi^2}\tilde{d}^{s+2,2}_{ABC}y^A y^B y^C - \frac{1}{2(2\pi)^4}c_1(0)\zeta(3) - \frac{1}{(2\pi)^4}\sum_{r>0} c_1(-r^2/2)Li_3(e^{-2\pi r\cdot y}) \tag{4.25}$$

Substitution into (4.24) leads to a solution with

$$\log\Psi(y) = \tfrac{1}{2}\log[J(iT) - J(iU)] + b(E_8)\log[\eta(iT)\eta(iU)] \qquad s = 0 \tag{4.26}$$

and

$$\Psi(y) = \Phi(y) = e^{-2\pi\rho\cdot y}\prod_{r>0}\Big(1 - e^{-2\pi r\cdot y}\Big)^{c_3(-r^2/2)} \qquad s = 8. \tag{4.27}$$

Proof. We substitute directly the ansatz for $h^{(1)}$. The universal term is given by

$$\frac{1}{16\pi^2}\Delta^{\text{univ}} = \frac{1}{y_1^2}\frac{1}{(2\pi)^3}\Re\Big[\sum_{r>0} c_1(-r^2/2)\mathcal{P}(ir\cdot y)\Big] + \frac{1}{192\pi^2(y_1)^2}[\tilde{d}^{s+2,2}_{ABC}y_1^A y_1^B y_1^C + \delta] \tag{4.28}$$

---

[10] See section 5.1

In order to cancel the other terms we must use the identity:

$$
\begin{aligned}
\sum n c_1(n) q^n &= -\frac{1}{2}\frac{E_2E_6+E_4^2}{\eta^{24}} \qquad\qquad s=8 \\
\sum n c_1(n) q^n &= -\frac{1}{6}\frac{E_2E_4E_6+2E_6^2+3E_4^3}{\eta^{24}} \qquad s=0
\end{aligned}
\tag{4.29}
$$

One can check the rational terms directly, but a more elegant method relates the trace of $\tilde{d}_{ABC}$ to the Weyl vector. For example, in the case $s=8$ we proceed as follows. The Laplacian for the Kahler metric on $\mathcal{N}^{s+2,2}$ is given by

$$
\nabla^2 = -2y_1^2\Big(\eta^{ab} - \frac{2}{y_1^2}y_1^a y_1^b\Big)\partial_a\bar{\partial}_{\bar{b}} \tag{4.30}
$$

By straightforward computation one finds:

$$
\begin{aligned}
(\nabla^2-24)\tilde{\mathcal{I}}_{10,2} + 280\tilde{c}_1(0) = 24\Big[&-2\log|\Phi(y)|^2 \\
&- c_3(0)(\log(-y_1^2)+\mathcal{K}) + (8\pi\rho_b - \frac{1}{4}\tilde{d}^a{}_{ab})y_1^b\Big]
\end{aligned}
\tag{4.31}
$$

since both sides of the equation must be invariant under the duality group we have after comparing to (4.20):

$$
\tilde{d}^a{}_{ab} = -32\pi\rho_b \tag{4.32}
$$

Similarly one finds

$$
\begin{aligned}
(\nabla^2-4)\tilde{\mathcal{I}}_{2,2} &= 4\tilde{c}(0)\big(\log\big[2T_1U_1|\eta(iT)^4\eta(iU)^4|\big] + \mathcal{K} - \tfrac{1}{2}\big) \\
&\quad - 80\log|J(iT)-J(iU)|
\end{aligned}
\tag{4.33}
$$

Using this equation one can check that the rational terms in (4.25) solve the equation required for equality of (4.1) and (4.5).

Above we have exhibited a particular solution of the second order differential equation. Two solutions to this equation must differ by a solution of the homogeneous equation. It is straightforward to show that the only solutions of the homogeneous equation which are analytic around zero are of the form:

$$
\delta h^{(1)} = \sum_{0\le m+n\le 2} a_{IJ,mn}(\hat{X}^I)^m(\hat{X}^J)^n \tag{4.34}
$$

where the coefficients $a_{IJ,mn}$ are pure imaginary and [11]

$$\hat{X}^I = (1, -y^2, iy^a). \tag{4.35}$$

Two prepotentials differing by such an expression are physically equivalent. We may use this result, together with the automorphic properties discussed in section six to argue that the prepotential given above is the unique answer.

It is worthwhile to make several checks on the above answer. First, the physical coupling must be a nonsingular function on moduli space. We can check this since the singularities of $\log \Psi$ are identical to $\frac{1}{s+4}\left(\frac{\partial}{\partial y}\right)^2 h^{(1)}$. Second, the physical coupling must be duality invariant. This is a consequence of the automorphic properties proved in the next two sections. Third, in the case $s = 0$, a differential equation for the quantity $S^{\rm inv} = S - \frac{1}{16\pi^2}\Delta^{\rm univ}$ was derived in [48,38]. [12] It is straightforward to show that the above formula for $h^{(1)}$ satisfies this constraint. As a fourth check we may compare the "Yukawa couplings" [13] following from (4.25) with those derived in [38][39]. For example, one finds, in the $s = 0$ case:

$$\partial_U^3 h^{(1)} = -\frac{1}{2\pi}\left[1 - \sum_{r>0} c_1(k\ell)\ell^3 \frac{e^{-2\pi(kT+\ell U)}}{1 - e^{-2\pi(kT+\ell U)}}\right] \tag{4.36}$$

According to [38,39] (4.36) must coincide with

$$-\frac{1}{2\pi}\frac{E_4(iU)E_4(iT)E_6(iT)}{(J(iT) - J(iU))\eta^{24}(iT)} \quad . \tag{4.37}$$

Comparing the $T \to \infty$ and $U \to \infty$ limits of the expressions one finds perfect agreement. Expanding in power series and comparing terms we find agreement to 10^{th} order.

4.5. Gravitational Corrections

There are other terms in the effective supergravity action which involve chiral densities and are therefore computable to all orders of perturbation theory. The first of these is the gravitational coupling F_1 given by

$$F_1 = \frac{-i}{192\pi^2}\int_{\mathcal{F}} \frac{d^2\tau}{\tau_2}\left[\frac{1}{\eta^2}{\rm Tr}_{\rm R} {\rm J}_0 (-1)^{{\rm J}_0} {\rm q}^{{\rm L}_0 - 22/24}\bar{\rm q}^{\tilde{\rm L}_0 - 9/24}\left[{\rm E}_2 - \frac{3}{\pi\tau_2}\right] - {\rm b}_{\rm grav}\right] \tag{4.38}$$

---

[11] in a gauge where $X^0 = 1$

[12] See, for example, equation 4.46 in [38].

[13] Actually, magnetic moments, [60].

where the E_2 factor arises from the $Q^2_{grav} = -2\partial_\tau \log \eta$ term in [43]. In heterotic string theory F_1 and its generalizations F_g can be computed at one-loop order and the comparison between these calculations and genus g computations in dual twisted Calabi-Yau theories provide strong evidence for $N=2$ string duality [58,56]. Again it is clear from the previous discussion that these quantities in heterotic string theory receive contributions only from BPS states. There are also potential ambiguities in these amplitudes which require a careful treatment of infrared divergences, perhaps along the lines presented in [69] [14].

5. Comment on relation to work of Borcherds

In this section we will discuss the automorphic properties of the threshold corrections we have computed and compare our results to work of Borcherds. We will work in "automorphic" conventions for the moduli as described in footnote 4 of the previous section.

First we explain the relation between Borcherds' "rational quadratic divisors" (RQD) and enhanced symmetry points (ESP) in Narain compactifications. Let $L \cong \Pi^{s+1,1}$ be an even unimodular lattice, and consider the $\Pi^{s+2,2}$ lattice $M \cong L \oplus \Pi^{1,1}$. We represent an element of M by $v = (r; a_+, a_-)$ with $r \in L$ and $a_\pm$ integer. In [29] Borcherds defines rational quadratic divisors to be the locus $\mathcal{D}(v) \subset \mathcal{H}^{s+1,1}$ of

$$\langle (r; -a_+, a_-), (y; 1, -\tfrac{1}{2}(y,y)) \rangle = 0 \tag{5.1}$$

for

$$\langle (r; -a_+, a_-), (r; -a_+, a_-) \rangle = r^2 - 2a_+a_- > 0 \tag{5.2}$$

From the discussion in sec. 3.1 we know that BPS states are parametrized by vectors $v = (r; a_+, a_-) \in \Pi^{s+2,2} \cong \Pi^{s+1,1} \oplus \Pi^{1,1}$ The central charge of a BPS state with quantum numbers $(r; a_+, a_-) \in \Pi^{s+1,1} \oplus \Pi^{1,1}$ is just the inner product [37]

$$\mathcal{Z}(v, y) = (r, y) + a_- - \tfrac{1}{2} a_+ y^2 = \langle (r; a_+, a_-), (y; 1, -\tfrac{1}{2} y^2) \rangle \tag{5.3}$$

Moreover, for such a state

$$p_L^2 - p_R^2 = r^2 + 2a_+a_- \tag{5.4}$$

---

[14] We thank J. Louis for pointing this out to us.

Thus in string theory only the divisors with $\langle (r;-a_+,a_-),(r;-a_+,a_-)\rangle = 2$ are of importance and these correspond to enhanced symmetry points in the Narain moduli space.

In [29][30] Borcherds has proved the following theorem:

Theorem. Let $f(\tau)=\sum c(n)q^n$ be a meromorphic modular form with all poles at cusps. Suppose that f is of weight $-s/2$ for $SL(2,\mathbb{Z})$ and has integer coefficients, with $24|c(0)$ if $s=0$. Then there is a unique vector $\rho\in L$ such that

$$\Phi(y)=e^{2\pi i\rho\cdot y}\prod_{r>0,r\in\Pi^{s+1,1}}(1-e^{2\pi i r\cdot y})^{c(-r.r/2)} \tag{5.5}$$

can be analytically continued to define a meromorphic automorphic form of weight $c(0)/2$ for $O(s+2,2;\mathbb{Z})^+$. All the zeroes and poles of Φ lie on rational quadratic divisors, and the multiplicity of the zero of Φ at the rational quadratic divisor of the triple $(b;a_1,a_2)$ is

$$\sum_{n>0}c(n^2(a_1a_2-(b,b)/2)) \tag{5.6}$$

In (5.5) $r>0$ means that r has positive inner product with a chosen negative norm vector in L. In some cases the product (5.5) is known to be the denominator formula for a generalized Kac-Moody algebra.

We have seen that products of precisely this type arise in the analysis of threshold corrections in $N=2$ heterotic string compactifications. Indeed, by studying the properties of the integrals $\mathcal{I}_{s+2,2}(y)$ of appendix A we can easily rederive many of the results discovered by Borcherds.

To do this we must explain the holomorphic factorization of the product arising in the expression for $\mathcal{I}$ in equation $(A.29)$ of appendix A. In the previous section we presented the results only in a particular Weyl chamber (defined below). However the integrals as evaluated in the appendix depend on the "hatted" dot product $r\hat{\cdot}y$ rather than the dot product $r\cdot y$. The quantity $r\hat{\cdot}y$ is defined by:

$$r\,\hat{\cdot}\,y\equiv\Re\Big[(\vec{b}\cdot\vec{y}+\ell y_-+ky_+)\Big]+i\Big|\Im\Big[(\vec{b}\cdot\vec{y}+\ell y_-+ky_+)\Big]\Big| \tag{5.7}$$

when $k>0$, and, when $k=0$:

$$r\,\hat{\cdot}\,y\equiv r\cdot y-N(r,y)y_- \tag{5.8}$$

where

$$N(r,y)=\mathrm{sgn}(\vec{b})\left[\mathrm{sgn}(\vec{b})\frac{\vec{b}\cdot\Im\vec{y}}{y_{-,2}}\right] \tag{5.9}$$

is an integer ($[\cdot]$ is the greatest integer function.) In order to understand the holomorphic factorization we must introduce Weyl chambers.

5.1. Weyl chambers

We can tessellate the forward lightcone $C_{+}^{s+1,1} \subset \mathcal{H}^{s+1,1}$ into convex polyhedra whose walls are defined by the *real* codimension one subvarieties

$$\Im(r \cdot y) = 0 \tag{5.10}$$

for $r^2 = 2, r \in \Pi^{s+1,1}$. These are the "surfaces of marginal stability" and must be crossed when circling the divisors of vanishing BPS central charges.

Given a choice of simple roots r_μ for the lattice $\Pi^{s+1,1}$ we can define a *fundamental Weyl chamber* by the equation

$$\mathcal{CW}_0 \equiv \{y : r_\mu \cdot \Im y > 0\} \tag{5.11}$$

Explicit choices of simple roots are described in section seven. For $s = 0$ there are two Weyl chambers and we take the fundamental Weyl chamber to be simply $y_{+,2} > y_{-,2}$. For $s = 8$ we choose a set of positive roots $\vec{b} > 0$, $\vec{b}^2 = 2$ for E_8. Using the simple roots in the next section we get the conditions:

$$\begin{aligned} 0 < & \frac{\vec{b} \cdot \Im \vec{y}}{y_{-,2}} < 1 \\ y_{-,2} & < y_{+,2} \end{aligned} \tag{5.12}$$

5.2. Holomorphic factorization and $\mathcal{I}_{s+2,2}(y)$

By definition of the fundamental Weyl chamber we know that $r \hat{\cdot} y = r \cdot y$ for the positive roots. Thus, the products $(A.31), (A.37)$ factorize straightforwardly in the fundamental chamber. The question arises as to the other chambers.

Contributions from $c(n)$ for $n > 0$ always holomorphically factorize. To see this note that $\Im y$ is in the forward light cone so

$$\begin{aligned} \Im y_+ &> 0 \\ \Im y_- &> 0 \\ 2 \Im y_+ \Im y_- &> (\Im \vec{y})^2 \end{aligned} \tag{5.13}$$

Since we are studying coefficients $c(n)$ for $n > 0$ in the product we have $2k\ell > (\vec{b})^2$. It follows that

$$(k \Im y_+ + \ell \Im y_-)^2 > 4(k \Im y_+)(\ell \Im y_-) > |\vec{b} \cdot \Im \vec{y}|^2 \tag{5.14}$$

so the imaginary part of $r \cdot y$ is always positive and the product is a holomorphic square. Similarly, the coefficient $c(0)$ enters for roots $k = 0, \ell > 0, \vec{b} = 0$ and for roots $k\ell = \frac{1}{2}\vec{b}^2 > 0$. For these roots we can again drop the hat. All of this is quite simply understood from the physical point of view: only states with $v^2 = 2$ can become massless and lead to nonanalytic behavior.

The real source of nontrivial holomorphic factorization is entirely in the coefficients of $c(-1)$ which are connected to RQD's or ESP's. For example, the peculiar shift in (5.9) affects these terms. The key observation is that these changes can be absorbed in a change of the linear term $\rho \cdot y \to \rho_\alpha \cdot y$ in the RHS of $(A.29)$ in each Weyl chamber $\mathcal{C}_\alpha$. Consider for example, the holomorphic factorization for roots with $r^2 = +2$ and $k > 0$. Then:

$$\log\left|1 - e^{2\pi i \widehat{r \cdot y}}\right|^2 = \begin{cases} \log\left|1 - e^{2\pi i r \cdot y}\right|^2 & \text{for } \Im r \cdot y > 0 \\ \log\left|e^{-2\pi i r \cdot y}(1 - e^{2\pi i r \cdot y})\right|^2 & \text{for } \Im r \cdot y < 0 \end{cases} \tag{5.15}$$

For example, consider the case $s = 0$. There is only one positive root with $r^2 = 2$, namely $r = (\ell, k) = (-1, 1)$. The wall is just

$$\Im y_+ = \Im y_- \tag{5.16}$$

i.e. $T_2 = U_2$. Consequently the product in (4.20) becomes

$$-2 \log\left| e^{-2\pi i T c(-1)} \prod_{r>0} \left(1 - e^{2\pi i (kT + \ell U)}\right)^{c(k\ell)} \right|^2 \tag{5.17}$$

for $T_2 > U_2$ and

$$-2 \log\left| e^{-2\pi i U c(-1)} \prod_{r>0} \left(1 - e^{2\pi i (kU + \ell T)}\right)^{c(k\ell)} \right|^2 \tag{5.18}$$

for $U_2 > T_2$.

5.3. Automorphic properties of Φ

We will now use invariance of the integral under the group generated by

1. $y \to y + \lambda \ , \ \lambda \in \Pi^{s+1,1}$
2. $y \to w(y)$, $w \in O(s+1, 1; \mathbb{Z})^+$
3. $y \to y' = 2y/(y, y)$

to deduce some automorphic properties of the "holomorphic square root" $\Phi(y)$. It is evident that the first two transformations act on $\mathcal{H}^{s+1,1}$. The third is surprising, but note that under this transformation:

$$(\Im y', \Im y') = +\frac{4}{|(y,y)|^2}(\Im y, \Im y) \tag{5.19}$$

and so preserves the "upper half plane." In fact, the transformations 1.,2. and 3. only generate an index 2 subgroup of the duality group, and Φ is automorphic for the entire group $O(s+2,2;\mathbb{Z})$.

Invariance under $y \to y + \lambda$ is trivial. To verify $y \to w(y)$ invariance we use (5.15) which says that in a Weyl chamber $\mathcal{C}_\alpha$ we have

$$\mathcal{I} = -2\log|e^{(\rho_\alpha - \rho)\cdot y}\Phi(y)|^2 + c(0)\Big(-\log[-(\Im y)^2] - \mathcal{K}\Big) \tag{5.20}$$

Now we note that

$$(\rho_\alpha - \rho) = w(\rho) - \rho \tag{5.21}$$

To prove this note that it is true for chambers related to the fundamental chamber by a reflection in a simple root r_i. Then proceed from there by induction.

The transformation of Φ under the third generator is the most difficult to prove by straightforward methods. We may note that if $\Re y = 0$ then the transformation is a rescaling of $\Im y$ by a positive coefficient. Therefore, an open set of the fundamental Weyl chamber is mapped to itself. From the invariance of the integral $\mathcal{I}_{s+2,2}$ and its holomorphic factorization we then find the modular transformation law:

$$\Phi(y') = \Big[\frac{(y,y)}{2}\Big]^{c(0)/2}\Phi(y) \tag{5.22}$$

5.4. Zeroes and Poles of Φ

Finally, we come to the last part of Borcherds' theorem which is concerned with the zeros and poles of Φ. Unlike the walls of the Weyl chambers, which are determined by $r \in \Pi^{s+1,1}$, the RQD's are determined by vectors $v \in \Pi^{s+2,2}$ with $v^2 = 2$. As $y \to \mathcal{D}(v)$ for some vectors in the Narain lattice $\Gamma^{s+2,2}(y)$, $p_R \to 0$, $p_L^2 \to 2$. Each such vector contributes a logarithmic divergence to $\mathcal{I}_{r+2,2}(y)$:

$$\int^{\infty} \frac{d\tau_2}{\tau_2} e^{-4\pi\tau_2 \frac{1}{2}p_R^2} \to -\log|\mathcal{Z}(v,y)|^2 \tag{5.23}$$

Analysis of RQD's: (2,2) case

The RQD's in $\mathcal{H}^{1,1}$ are given by the divisor $T = U$ and modular transformations of it. These have a double intersection at the points $T = U = i$ and a triple intersection at $T = U = \rho$ (and their modular images). This is in accord with standard analysis of the enhanced symmetry points.

One proof of the above statements proceeds by writing:

$$\mathcal{Z} = \begin{pmatrix} y_+ & 1 \end{pmatrix} \begin{pmatrix} n_0 & n_- \\ m_+ & m_0 \end{pmatrix} \begin{pmatrix} y_- \\ 1 \end{pmatrix} \tag{5.24}$$

where $r^2 = 2$ implies $m_0 n_0 - m_+ n_- = 1$. Note that $SL(2,Z) \times SL(2,Z)$ acts on the sets of divisors. By acting on y_- we can transform the matrix to the unit matrix, so the divisor equation becomes $1 + y_+ y_- = 0$ or, by a further $SL(2,\mathbb{Z})$ transformation $y_+ = y_-$. We obtain the set of all divisors in $\mathcal{H} \times \mathcal{H}$ by taking $SL(2,Z) \times SL(2,Z)$ images of this divisor. Note that divisors can only intersect when both y_+ and y_- are fixed by some element of $SL(2,\mathbb{Z})$. In particular, the divisor $y_+ = y_-$ has a double intersection at i and a triple intersection at ρ.

Analysis of RQD's: (10,2) case

It would be interesting to give a classification of the RQD's in $\mathcal{H}^{9,1}$ analogous to that above. An important class of RQD's are defined by the simple roots of E_8. For example, define the hyperplane

$$\mathcal{H}_i = \{y : \vec{y} \cdot \vec{\alpha}_i = 0\} \tag{5.25}$$

Along this hyperplane Φ has a simple zero

$$\Phi(y) \rightarrow -2\pi i \vec{\alpha}_i \cdot \vec{y} \Phi'(y') \tag{5.26}$$

where, for $y' \in \mathcal{H}_i$ we have

$$\Phi'(y') = e^{2\pi i \rho' \cdot y'} \prod_{r' > 0}{}' (1 - e^{2\pi i r' \cdot y'})^{c_3'(-r^2/2)} \tag{5.27}$$

where $r' \sim r$ if $r - r' \propto \alpha_i$ and $c_3'(-r^2/2) = \sum_{r' \sim r} c_3(-(r')^2/2)$. Restricting to successive intersections of divisors we get a series of automorphic forms beginning with the E_{10} form Φ of (4.20) and ending with $J(T) - J(U)$.

6. Quantum Monodromy

6.1. General Remarks

The nature of the semiclassical monodromy of $N=2$ heterotic string compactifications has been thoroughly analyzed in references [38,39]. Using the above explicit expressions we can compute the monodromy directly.

As discussed in [60,38,39] the best basis of special coordinates for questions of monodromy is the basis $\hat{X}^I$ related to the basis S, y^a with prepotential $\mathcal{F}=(X^0)^2 S(y,y)$ by a duality transformation $\hat{X}^1 = F_1, \hat{F}_1 = -X^1$. Explicitly we have:

$$\begin{aligned}\hat{X}^1 &= X^0 (y,y)^2 \\ \hat{X}^a &= X^0 y^a \qquad a = 2, \dots s+3\end{aligned} \tag{6.1}$$

In this basis the general transformation rule for the one-loop prepotential, in automorphic conventions is:

$$h^{(1)}(\tilde{y}) = \left(\frac{\tilde{X}^0}{X^0}\right)^{-2} \left[h^{(1)}(y) - i\Lambda_{IJ}\frac{\hat{X}^I}{X^0}\frac{\hat{X}^J}{X^0}\right] \tag{6.2}$$

where Λ_{IJ} is a real symmetric matrix. Thus, the prepotential is an automorphic form of weight -2 transforming with shifts.

In discussing monodromy one should always bear in mind that the prepotential is ambiguous by an addition of a term of the form (4.34).

6.2. Monodromies for $s=0$

It is convenient to introduce the function

$$\begin{aligned}\mathcal{L}(T,U) &\equiv \sum_{r>0} c(-r^2/2) Li_3(e^{2\pi i(kT+\ell U)}) \\ &= Li_3(e^{2\pi i(T-U)}) + \sum_{k,\ell\geq 0} c(k\ell) Li_3(e^{2\pi i(kT+\ell U)})\end{aligned} \tag{6.3}$$

where

$$F(q) = \sum_{n=-1}^{\infty} c(n) q^n = \frac{E_4 E_6}{\eta^{24}} \quad . \tag{6.4}$$

This function has a branch locus at $T=U$ and can be defined by power series for $T_2 > U_2$, i.e., in the fundamental Weyl chamber.

The function Li_3 can be analytically continued outside the unit circle and satisfies the connection formula [70]:

$$Li_3(e^x) = Li_3(e^{-x}) + \frac{\pi^2}{3}x - \frac{i\pi}{2}x^2 - \frac{1}{6}x^3 \tag{6.5}$$

Thus, under analytic continuation into the other Weyl chamber with $U_2 > T_2$ we have:

$$\mathcal{L}(T,U) = \mathcal{L}(U,T) - (2\pi)^4 \frac{i}{24\pi}\left[2U^3 - 2T^3 - 3(T-U)^2 + (T-U)(6TU-1)\right] \tag{6.6}$$

Under the generators $T \to T+1$ and $U \to U+1$ of the duality group the function $\mathcal{L}(T,U)$ is invariant in its region of convergence. Finally, to compute the monodromy under $T \to -1/T$ (and similarly for $U \to -1/U$) we rewrite the integral $\tilde{\mathcal{I}}_{2,2}$ as:

$$\begin{aligned} \tilde{\mathcal{I}}_{2,2} = -\frac{6}{U_2 T_2 \pi^2}\Re\left[\left(1 - iU_2\frac{\partial}{\partial U}\right)\left(1 - iT_2\frac{\partial}{\partial T}\right)\mathcal{L}(T,U)\right] \\ +20\log|J(T)-J(U)| + 264[\log[2T_2U_2|\eta(T)\eta(U)|^4] - \mathcal{K}] - \frac{\delta}{2T_2U_2} \\ +16\pi\frac{U_2^2}{T_2} \qquad T_2 \geq U_2 \\ +16\pi\frac{T_2^2}{U_2} \qquad U_2 \geq T_2 \end{aligned} \tag{6.7}$$

We know the integral $\tilde{\mathcal{I}}_{2,2}$ is invariant under $T \to T' = -1/T, U \to U$ and from this is it straightforward to derive the transformation law:

$$\begin{aligned} \mathcal{L}(T',U) &= T^{-2}\Big[\mathcal{L}(T,U) + \mathcal{R}(T,U)\Big] \\ \mathcal{R}(T,U) &= \frac{\pi^2}{12}\delta(1-T^2) - \frac{4\pi^3 i}{3}U^3(T^2-1) \qquad T_2' > U_2 \\ &= \frac{\pi^2}{12}\delta(1-T^2) - \frac{4\pi^3 i}{3}\left(\frac{1-T^4}{T}\right) + \frac{4\pi^3 i}{3}U^3 \qquad T_2' < U_2 \end{aligned} \tag{6.8}$$

In the 2,2 case there are two Weyl chambers, and accordingly we have the two expressions for the prepotential (in automorphic conventions):

$$\begin{aligned} h^{(1)} &= -\frac{1}{(2\pi)^4}\mathcal{L}(T,U) - \frac{\delta}{192\pi^2} - i\frac{U^3}{12\pi} + \delta h_+^{(1)} \qquad T_2 > U_2 \\ &= -\frac{1}{(2\pi)^4}\mathcal{L}(U,T) - \frac{\delta}{192\pi^2} - i\frac{T^3}{12\pi} + \delta h_-^{(1)} \qquad T_2 < U_2 \end{aligned} \tag{6.9}$$

where $\delta h_\pm^{(1)}$ correspond to the ambiguity (4.34).

Using these expressions and the above transformation rules for $\mathcal{L}(T,U)$ it is straightforward to compute the monodromy of $h^{(1)}$.

6.3. Remarks on the $s = 8$ case

In principle the above discussion generalizes in a fairly straightforward way to the computation of the monodromy on $\mathcal{N}^{10,2}$. The Weyl reflections σ_i in the E_{10} roots no longer square to zero because of the monodromy associated with the Li_3 terms around enhanced symmetry varieties. The transformation of $\mathcal{L}(y)$ under the inversion $y \to 2y/(y,y)$ can be deduced from an analog of (6.7) for $\tilde{\mathcal{I}}_{10,2}$. We hope to return to a detailed discussion of this monodromy representation, which gives an interesting representation of the E_{10} braid group, in the future.

7. GKM algebras and denominator formulae

In this section we will provide a very brief summary of some of the properties of GKM algebras and the hyperbolic Kac-Moody algebra E_{10} which enter into the interpretation of the product formulae for threshold corrections found in the previous section. For further details on Kac-Moody algebras and GKM algebras the reader can consult [34,71,72,73,25]. E_{10} is discussed in [74,75,26,76,28]

We first give the formal definition in terms of Cartan matrices, generators and relations. Recall the usual definition of a finite-dimensional simple Lie algebra. One starts with a symmetric $r \times r$ Cartan matrix $A = (a_{ij})$ with $i, j = 1, 2, \cdots r$ satisfying

$$\begin{aligned} &a_{ii} = 2, \\ &a_{ij} \le 0 \quad \text{for} \quad i \ne j, \\ &a_{ij} \in Z, \end{aligned} \tag{7.1}$$

and $\det A > 0$. The Lie algebra is then defined in terms of generators (e_i, f_i, h_i) obeying the relations

$$\begin{aligned} [h_i, h_j] &= 0, \\ [h_i, e_j] &= a_{ji} e_j, \\ [h_i, f_j] &= -a_{ji} f_j, \\ [e_i, f_j] &= \delta_{ij} h_j \\ (\mathrm{ad}_{e_i})^{1-a_{ji}} e_j &= 0, \\ (\mathrm{ad}_{f_i})^{1-a_{ji}} f_j &= 0. \end{aligned} \tag{7.2}$$

A formal construction of Kac-Moody Lie algebras is obtained by weakening the condition that $\det A > 0$. In particular one obtains affine Lie algebras by allowing A to have a zero eigenvalue and hyperbolic Kac-Moody algebras by allowing a single negative eigenvalue. For Kac-Moody algebras one has the usual notion of root spaces, positive roots, simple roots, and the Weyl group generated by reflections in the real simple roots. Furthermore there is a denominator formula

$$e^{\rho}\prod_{r>0}(1-e^{r})^{\mathrm{mult}(r)}=\sum_{\sigma\in W}(\mathrm{sgn}(\sigma))e^{\sigma(\rho)} \tag{7.3}$$

where ρ is the Weyl vector, the product on the left hand side runs over all positive roots and each term is weighted by the root multiplicity $\mathrm{mult}(r)$, and on the right hand side the sum is over all elements of the Weyl group W. For example for the $su(2)$ level one affine Lie algebra (7.3) is just the Jacobi triple product identity.

Generalized Kac-Moody algebras have a great deal in common with Kac-Moody algebras of hyperbolic type but differ from them in that simple roots r with $r^2 \leq 0$ are allowed. The formal definition follows from a slight generalization of the conditions (7.1). One again starts with a symmetric Cartan matrix $A=(a_{ij})$ which is allowed to have infinite rank in general. Then one demands the conditions

$$\begin{aligned} a_{ii}&=2 \quad \text{or} \quad a_{ii}\leq 0,\\ a_{ij}&\leq 0 \quad \text{for} \quad i\neq j,\\ a_{ij}&\in Z \quad \text{if} \quad a_{ii}=2, \end{aligned} \tag{7.4}$$

and defines the algebra by generators (h_{ij}, e_i, f_i) and relations

$$\begin{aligned} [h_{ij},e_k]&=\delta_{ij}a_{jk}e_k,\\ [h_{ij},f_k]&=-\delta_{ij}a_{jk}f_k,\\ [e_i,f_j]&=h_{ij}\\ (\mathrm{ad}_{e_i})^{1-a_{ji}}e^{j}&=0, \quad (\mathrm{ad}_{f_i})^{1-a_{ji}}f^{j}=0, \quad a_{ii}=2, i\neq j,\\ [e_i,e_j]&=0, \quad [f_i,f_j]=0, \quad a_{ii}\leq 0, a_{jj}<0, a_{ij}=0. \end{aligned} \tag{7.5}$$

The fact that $a_{ii}\leq 0$ is allowed shows that imaginary simple roots ($r^2 \leq 0$) appear in contrast to Kac-Moody algebras. There is again a denominator formula for GKM algebras which reads

$$e^{\rho}\prod_{r>0}(1-e^{r})^{\mathrm{mult}(r)}=\sum_{\sigma\in W}(\mathrm{sgn}(\sigma))\sigma(e^{\rho}\sum_{r}\epsilon(r)e^{r}) \tag{7.6}$$

where the correction factor on the right involves $\epsilon(r)$ which is $(-1)^n$ if r is the sum of n distinct pairwise orthogonal imaginary roots and zero otherwise.

As with hyperbolic Kac-Moody algebras, these formal definitions are of little practical utility without some method of determining the root multiplicities. For a few special GKM algebras it is possible in some cases to determine root multiplicities through the use of product formulae.

A more useful construction of a GKM algebra arises as the vertex operator algebra of physical string states in compactifications of string theory based on Lorentzian lattices, for example in toroidal compactifications of all string coordinates including time [20,77,23,25]. In our application the metric is the Narain metric rather than the spacetime metric but similar mathematical considerations apply.

We now discuss two specific examples related to the product representation of threshold corrections obtained in the previous section.

7.1. $\Pi^{1,1}$

We will first consider a GKM algebra with root lattice $\Pi^{1,1}$. Lattice vectors are labelled by a pair of integers (m,n) and the inner product of two lattice vectors is $(m,n)\cdot(m',n') = -(m'n+n'm)$. There is a single real simple root of length squared two which can be chosen to be $r_{-1}=(1,-1)$.

The Weyl group is generated by reflections in the real simple roots and so here is just the Z_2 transformation acting as

$$\sigma_{-1}(r) = r - (r\cdot r_{-1})r_{-1} \tag{7.7}$$

and thus takes $(m,n)\to(n,m)$.

A lattice Weyl vector is defined to be a lattice vector ρ which satisfies [78]

$$\rho\cdot r = -r^2/2 \tag{7.8}$$

for any simple real root. Applying this to $r=(1,-1)$ shows that lattice Weyl vectors must have the form $\rho=(m,m+1)$ for some integer m.

We now compare this to the Weyl vector ρ appearing in (4.21)

$$\rho = c(-1)(0,1) - \frac{c(0)}{24}(1,1) \tag{7.9}$$

where by the conditions given $F(q)=\sum_{n=-1}^{\infty} c(n)q^n$ is a modular function (that is weight zero). Thus $F(q)=(j(q)-744)+c(0)$. Taking $c(-1)=1$ and using in addition the condition that $24|c(0)$ we see that (7.9) gives a lattice Weyl vector.

Borcherds has investigated two different GKM algebras related to the $\Pi^{1,1}$ lattice. The first is the "fake" monster Lie algebra based on the Lie algebra of physical states on the lattice $\Pi^{25,1} = \Lambda_{\rm Leech} \oplus \Pi^{1,1}$. This algebra is just the algebra of physical string states in a covariant theory with the transverse degrees of freedom of the string compactified on the Leech lattice and the remaining space and time dimensions on the $\Pi^{1,1}$ lattice. The second theory is the monster Lie algebra based roughly speaking on the Lie algebra of physical states associated with the tensor product of the the $\Pi^{1,1}$ system with the monster vertex algebra of FLM based on a Z_2 orbifold of the Leech lattice [79]. In this case $c(0) = 0$ since all the massless transverse states are projected out and the Weyl vector is $\rho = (0, 1)$. In (4.20) we have a product over roots $r = (-\ell, -k)$ satisfying the conditions $k > 0$, $\ell \in Z$ or $k = 0$, $\ell > 0$. Since $c(0) = 0$ the only roots of the algebra (as compared to the lattice) appearing in this product are those with $k > 0$, $\ell \in Z$ (and with $\ell \geq -1$).

We will now show that the condition $r > 0$ encountered in the threshold corrections is the positive root condition for a GKM algebra with Weyl vector $\rho = (0, 1)$. According to a theorem in [71] if r is a positive root then $r^2 \leq -2\rho \cdot r$ with equality if and only if r is simple. With $r = (-\ell, -k)$ and $\rho = (0, 1)$ as above this gives the inequality

$$-2\ell k \leq -2\ell \tag{7.10}$$

which is satisfied for the roots $r = (-\ell, -k)$ with $k > 0$, $\ell \in Z$ and furthermore this shows that the simple roots are the real root $(1, -1)$ and the imaginary roots $(-\ell, -1)$ for $\ell > 0$.

Using the facts that the unique real simple root has multiplicity one and that there are no pairwise orthogonal simple roots the denominator formula (7.6) gives

$$p^{-1} \prod_{\ell \in Z, k > 0} (1 - p^k q^\ell)^{\mathrm{mult}(-\ell, -k)} = \sum_{\ell \geq -1, n \neq 0} \mathrm{mult}(-\ell, -1)(p^\ell - q^\ell) \tag{7.11}$$

with $p = e^{-(0,1)}$ and $q = e^{-(1,0)}$. As was shown by Borcherds [35] the undetermined root multiplicities can be determined indirectly based on the denominator formula (1.2). For Borcherds this root multiplicity arises in the construction of the monster Lie algebra. This leads to root multiplicities of $\mathrm{mult}(-\ell, -k) = c(k\ell)$ in (7.11) where the coefficients $c(n)$ appear in the expansion of the modular j function with constant term set equal to zero, $j(q) - 744 = \sum c(n) q^n$. Here we obtain similar products but the root multiplicity is now interpreted as the (Z_2 graded) multiplicity of BPS states. The formula (7.11) is precisely that appearing in (4.20) up to the $c_3(0)$ term after substituting the characters $p = e^{2\pi i T}$ and $q = e^{2\pi i U}$.

For the compactification constructed previously we have $c(0) = -984$ which leads to the Weyl vector $\rho = (41, 42)$. This does not seem to lead to a simple positive root condition for a GKM algebra. However the $\Pi^{1,1}$ case is rather exceptional in that the coefficient $c(0)$ is not determined by the conditions on $F(q)$. There is therefore some ambiguity in the precise interpretation of the product formula we have obtained related to the treatment of the $c(0)$ terms. If we explicitly evaluate these terms in the product then the remaining product is as described above a product over the positive roots of the monster Lie algebra. This ambiguity does not arise for lattices $\Pi^{s+1,1}$ with $s > 0$. We now turn to such an example.

7.2. $\Pi^{9,1}$

In this subsection we show that the condition $r > 0$ appearing in the threshold corrections is identical to the positive root condition for E_{10}. Recall that the condition $r > 0$ for $r = (\vec{b};, -\ell, -k)$ with $s = 8$ means:

$$\begin{aligned} k\ell - \tfrac{1}{2}\vec{b}^2 \geq -1 \quad & \text{and,} && (7.12a)\\ k > 0 \quad & \text{or,} && (7.12b)\\ k = 0, \quad \ell > 0 \quad & \text{or,} && (7.12c)\\ k = \ell = 0, \quad \vec{b} > 0 \quad & . && (7.12d) \end{aligned}$$

where we have taken into account that the multiplicities $c(-r^2/2)$ vanish for $r^2 > 2$ in (7.12*a*).

On the other hand, a choice of simple roots for the E_{10} lattice is given by taking:

$$r_i = (\vec{b}; 0, 0) = (\vec{\alpha}^{(i)}; 0, 0) \qquad i = 1, 8 \tag{7.13}$$

where $\vec{\alpha}^{(i)}$ is a set of simple roots of E_8, together with the extra root of E_9,

$$r_0 = (-\vec{\theta}; -1, 0), \tag{7.14}$$

($\vec{\theta}$ is the highest root of E_8), and

$$r_{-1} = (\vec{0}; 1, -1). \tag{7.15}$$

Given a set of simple roots r_μ the positive roots of E_{10} are simply

$$r = a_{-1}r_{-1} + a_0 r_0 + a_i r_i \tag{7.16}$$

with positive a_μ. We claim this set coincides with the set $r > 0$ above.

Several cases need to be checked. The only one that causes any difficulty is the case $k > 0, \ell > 0$. To check this suppose

$$k\ell \geq \tfrac{1}{2}\vec{b}^2 - 1. \tag{7.17}$$

Let

$$a_i \vec{\alpha}_i = \vec{b} + (k+\ell)\vec{\theta} \tag{7.18}$$

We then want to show that $a_i > 0$.

Proof: Let λ_i be the fundamental weights dual to α_i. Then

$$a_i = \vec{\lambda}_i \cdot \vec{b} + (k+\ell)\vec{\lambda}_i \cdot \vec{\theta}. \tag{7.19}$$

Now, by the Schwarz inequality and (7.17) we have

$$|\vec{\lambda}_i \cdot \vec{b}| \leq \sqrt{2k\ell + 2}|\lambda_i| \tag{7.20}$$

so

$$a_i \geq -\sqrt{2k\ell + 2}|\lambda_i| + (k+\ell)\vec{\lambda}_i \cdot \vec{\theta} \tag{7.21}$$

Now $\vec{\lambda}_i \cdot \vec{\theta} > 0$, and for $k > 0, \ell > 0$ we have:

$$(k+\ell)\vec{\lambda}_i \cdot \vec{\theta} \geq \sqrt{2k\ell + 2}|\lambda_i| \tag{7.22}$$

if we satisfy

$$(\vec{\lambda}_i \cdot \vec{\theta})^2 \geq \vec{\lambda}_i^2 \tag{7.23}$$

which is equivalent to

$$n_i^2 \geq G_{ii} \tag{7.24}$$

with G_{ii} the diagonal elements of the quadratic form of E_8 and n_i the numerical marks (or Coxeter labels) of E_8. This is true by inspection.

Moreover, the Weyl vector $\rho = (-\vec{\rho}, -31, -30)$ can be identified with the E_{10} lattice Weyl vector. To show this it suffices to check

$$\rho \cdot r_\mu = -\tfrac{1}{2}r_\mu^2 \qquad \mu = -1, 0, 1, \ldots 8 \tag{7.25}$$

As a nontrivial check on the above statements one can prove that the vectors which satisfy the inequality:

$$(r,r) \leq -2(\rho,r) \tag{7.26}$$

for all positive roots of a GKM algebra mentioned above are precisely the vectors satisfying (7.12a,b,c,d) above.

We thus conclude that the product formula we obtain through fundamental domain integrals which in turn determine the threshold corrections can be written in terms of a product over the positive roots of E_{10}. Furthermore, the product formula determines a (graded) multiplicity associated to the roots of E_{10}. The precise relation between these multiplicities and the root multiplicities of the E_{10} hyperbolic Kac-Moody algebra is not evident to us.

8. Some Limiting Cases

Further insight into the meaning of the formula for the prepotential can be gleaned from examining some limiting cases.

8.1. $M_{\rm string} \to \infty$

In this limit we expect to recover the standard formulae of global N=2 supersymmetry. On the moduli space $\mathcal{N}^{10,2}$ we consider a generic point $y_0 = (\vec{0}; y_+, y_-)$ on the embedded $\mathcal{N}^{2,2}$ submanifold. In the limit $M_{\rm string} \to \infty$ a fiber of the normal bundle of this submanifold is identified with the vectormultiplet moduli space of the global E_8 theory. Working near $\mathcal{H}^{1,1} \subset \mathcal{H}^{9,1}$ we let

$$y = y_0 + (\delta\vec{y}; 0, 0) \tag{8.1}$$

and in terms of dimensionful fields we let

$$\delta\vec{y} = \frac{\vec{a}}{M_{\rm string}} \tag{8.2}$$

In the global limit the constraint $2y_{+,2}y_{-,2} > (\delta\vec{y}_2)^2$ is trivially satisfied for fixed $\vec{a}$ and hence, after modding out by the duality group we have a coordinate $[\vec{a}] \in \underline{\mathbf{t}}(E_8) \otimes \mathbb{C}/W$, as expected.

Restoring string units, using (4.25), and the $N=2$ nonrenormalization theorems, the prepotential to all orders of perturbation theory is given by:

$$\mathcal{F} = M_{\rm string}^2\Big[-Sy^2 - \frac{1}{(2\pi)^4}\sum_{r>0} c_1(-r^2/2) Li_3(e^{2\pi i r\cdot y}) + \mathcal{A}(y)\Big] \tag{8.3}$$

where $\mathcal{A}(y)$ is a cubic polynomial. Now, in taking the $M_{\rm string}\to\infty$ limit (with $\vec{a}$ held fixed) we may extract the global prepotential from

$$\mathcal{F} \to M_{\rm string}^2 S y_0^2 + i\mathcal{F}^{\rm global} + \mathcal{O}(\frac{|\vec{a}|}{M_{\rm string}}) \tag{8.4}$$

In order to take the limit we note that the positive roots $r=(\vec{r};-\ell,-k)>0$ with $k\neq 0$ or $\ell\neq 0$ come in pairs with $\pm\vec{r}$. Using this and the limiting formula

$$Li_3(1-x) \to -\tfrac{1}{2}x^2\log x + \mathcal{O}(x^3\log x) \tag{8.5}$$

for the $k=\ell=0$ roots we obtain a sum only over the positive roots of E_8:

$$i\mathcal{F}^{\rm global} = \tilde{S}\vec{a}^2 - \frac{1}{8\pi^2}\sum_{\vec{\alpha}>0}(\vec{\alpha}\cdot\vec{a})^2\log\big[\frac{2\pi i\vec{\alpha}\cdot\vec{a}}{M_{\rm string}}\big] \tag{8.6}$$

in agreement with the standard one-loop prepotential of the global theory, where, for any group G we have the one-loop expressions [7,8]

$$\begin{aligned}\mathcal{F} &= \frac{i}{4\pi}\sum_{\vec{\alpha}>0}(\alpha\cdot A)^2\log\frac{(\alpha\cdot A)^2}{\Lambda^2}\\ K &= 2\Re\Big[i\mathcal{F}_i\overline{A^i}\Big]\\ &= -\frac{1}{\pi}\Re\Big[\sum_{\vec{\alpha}>0}|\alpha\cdot A|^2(\log\frac{(\alpha\cdot A)^2}{\Lambda^2}+1)\Big]\end{aligned} \tag{8.7}$$

In (8.6) the renormalized "classical" coupling is

$$\begin{aligned}\tilde{S} =& S + \frac{1}{8\pi^2}\sum_{r>0}c_1(-r^2/2)d(\vec{r}^2)\\ &\big[e^{2\pi i r\cdot y_0}Li_2(e^{2\pi i r\cdot y_0}) + e^{4\pi i r\cdot y_0}Li_1(e^{2\pi i r\cdot y_0})\big]\end{aligned} \tag{8.8}$$

the quantity $d(n)$ is defined by

$$\sum_{\vec{r}^2=n}(\vec{r}\cdot\vec{a})^2 = d(n)\vec{a}^2. \tag{8.9}$$

Finally, the cubic terms in $\mathcal{A}(y)$ vanish. The ambiguous quadratic terms with imaginary coefficients correspond to a change in scale of $M_{\rm string}$.

8.2. $M_{\rm string} \to 0$

One could also try taking the opposite, $M_{\rm string} \to 0$ limit. This raises many new conceptual questions [15] but, through the analogy with spontaneously broken gauge theory, might be expected to reveal fundamental underlying symmetries in string theory [80,23,24].

We must now introduce normalized fields for the other two moduli

$$y_\pm = \frac{a_\pm}{M_{\rm string}} \tag{8.10}$$

In the low energy theory the fields $a_\pm$ may be viewed as Higgs fields in the Cartan subalgebra of the enhanced $SU(2)\times SU(2)$ or $SU(3)$ gauge symmetry. Thus $M_{\rm string} \to 0$ holding a fixed is equivalent to $y \to \infty$. More fundamentally $a_\pm$ may be viewed as geometrical data on T^2. Consider the two-torus with vanishing B field and a diagonal metric $G_{11} = R_1^2$ and $G_{22} = R_2^2$. Then $T = 2iR_1R_2$ and $U = iR_2/R_1$. Thus the $y \to \infty$ limit is equivalent to a decompactification to *five* dimensions. In this limit the dominant terms in $\mathcal{F}$ are the cubic terms in $\mathcal{A}(y)$ [16].

By the automorphic properties of $\mathcal{F}$ the limit $y \to \infty$ is equivalent to a limit with $y \to 0$. Taking a formal $y \to 0$ limit leads us to the following suggestive formulae. We formally take the $y \to 0$ limit term-by-term using (8.5) and

$$\mathcal{P}(x) \to \pi x\bar{x}\log x + \mathcal{O}(x^3\log x). \tag{8.11}$$

Applying this to the formulae for the prepotential (8.3) we get:

$$f^{\rm perturbative} \to -S(a)^2 - \frac{1}{8\pi^2}\sum_{r>0} c(-r^2/2)(r\cdot a)^2 \log[\frac{2\pi i r\cdot a}{M_{\rm string}}] \tag{8.12}$$

and the Kahler potential becomes, in the $y \to 0$ limit:

$$K \to -\log\left[(\Im S)(-\Im a)^2 - \frac{1}{16\pi^2}\Re\left[\sum_{r>0} c(-r^2/2)|r\cdot a|^2 \log[\frac{2\pi i r\cdot a}{M_{\rm string}}]^2\right]\right] \tag{8.13}$$

If we furthermore take a special weak-coupling limit with $(\Im S)(-\Im a)^2 \to \infty$ then we recover the form of the global answer (8.7) but with the sum running over the positive roots of E_{10}.

---

[15] and perhaps should not be attempted without the full nonperturbative answer

[16] This cubic polynomial is probably related to the very special geometry of $D = 5, N = 2$ supergravity [81]

The limits (8.12)(8.13) are formal since the sums do not converge. Nevertheless comparison with the formulae for the global case suggests that the weak coupling 5-dimensional theory may be viewed, from the four-dimensional theory as an $N=2$ gauge theory for a generalized Kac-Moody algebra - most of which is spontaneously broken- with the full, infinite, spectrum of BPS states playing the role of a tower of gauge bosons. From the above formulae we see that the true root multiplicities are given by the coefficients $c(k\ell-\frac{1}{2}\vec{b}^2)$.

9. An algebra associated to BPS states

The results of sections 4-8 suggest that there is a GKM Lie algebra associated to the BPS states in D=4,N=2 heterotic compactifications. In this section we will construct a GKM Lie super-algebra with even elements associated to BPS vectormultiplets and the odd elements associated to BPS hypermultiplets. For the specific compactifications discussed previously this algebra has root lattice $\Pi^{1,1}$ or $\Pi^{9,1}$ and has root multiplicities related to those of the BPS states.

There are two obvious puzzles in trying to construct an algebra of BPS states. First, if we try to define an algebra by looking at the OPE of BPS vertex operators then it is clear that in general the OPE will contain operators for non-BPS states. In particular we will find operators with right-moving conformal dimension $\bar{h}>1/2$. Second, the physical BPS states are connected to a lattice of the form $\Pi^{s+2,2}$ while the products involved in threshold corrections involve only the lattice $\Pi^{s+1,1}$. We will see that the resolution to the first puzzle also provides the resolution to the second.

Consider the first point. In the Neveu-Schwarz sector a vertex operator which creates a BPS state is of the form:

$$V(z,\bar{z})=e^{ip_L X_L(z)+ip_R\tilde{X}_R(\bar{z})}\Phi_i(z,\bar{z}) \tag{9.1}$$

where X_R is the bosonic component of the free superfield in the internal $c=3$, $N=2$ theory, Φ is an operator of conformal dimensions $(h,\bar{h}=1/2)$ and

$$\tfrac{1}{2}p_L^2+h-1=\tfrac{1}{2}p_R^2 \qquad . \tag{9.2}$$

Note that Φ is chiral or anti-chiral primary with respect to the the total right-moving $N=2$ SCA with $U(1)$ charge ± 1. [17]

Using the decomposition (3.10) we can assign to each BPS vectormultiplet two distinguished vertex operators whose right-moving chiral primary field in the full internal $N=2$ theory is just the unit operator. In the lightcone gauge this vertex operator looks like:

$$V^A_{vm}(z) = e^{ip_L X_L(z) + ip_R \tilde{X}_R(\bar{z})} \Phi^A(z) \tilde{\psi}^\mu(\bar{z}) \tag{9.3}$$

where the index A runs over an infinite range and $\tilde{\psi}^\mu(\bar{z})$ is the right-moving transverse spacetime fermion field, i.e., $\mu = 2,3$. Now in the OPE of two such operators with opposite p_R we will find terms of the form $\prod \partial^n_{\bar{z}} X_R$. These operators create states with right-moving oscillators in the $c=3$ theory excited, that is states which are not BPS saturated. At this point we exploit the fact that the $c=3$ system is a free system. In (9.3) we can unambiguously drop the right-moving spacetime part of the vertex operator and change the right-moving free fields $X_R(\bar{z})$ to left-moving free fields which we will denote by $X_R(z)$ while at the same time retaining the Narain metric on (p_L, p_R). Technically, we have defined a mapping from the BPS states in the original light-cone gauge CFT of the heterotic string: [18]

$$\mathcal{C}^{2,0}_{\text{transverse}} \otimes \mathcal{C}^{0,3}_{\text{transverse}} \otimes \mathcal{C}^{0,3}_{\text{free N=(0,2)}} \otimes \mathcal{C}^{22,6}_{\text{N=(0,4)}} \tag{9.4}$$

to new leftmoving vertex operators of the form

$$V^A_{vm}(z,\bar{z}) \to \hat{V}^A_{vm}(z) \equiv e^{ip_L X_L(z) + ip_R X_R(z)} \Phi^A(z) \tag{9.5}$$

which live in the CFT:

$$\mathcal{C}^{2,0}_{\text{transverse}} \otimes \mathcal{C}^{22,6}_{\text{N=(0,4)}} \otimes \mathcal{C}^{2,0}_{\text{gaussian}} \tag{9.6}$$

Note that the physical state condition means that the left-moving conformal dimension of these vertex operators is

$$h + \tfrac{1}{2} p_L^2 - \tfrac{1}{2} p_R^2 = 1 \tag{9.7}$$

---

[17] In the examples we consider explicitly X_L is either the left-moving partner of X_R and $(p_L, p_R) \in \Pi^{2,2}$ or we extend X_L to include the lattice of the unbroken E_8 and $(p_L, p_R) \in \Pi^{10,2}$. In fact our considerations are more general and apply to any theory which has dimension one currents on the left, whether or not they arise from a free field construction, but for simplicity we will restrict ourselves to that case in what follows. We will also ignore cocycle factors in the vertex operators which are necessary to obtain a consistent operator algebra.

[18] Superscripts denote left and right conformal charges.

and hence these operators generate a current algebra based on the lattice $\Pi^{s+2,2}$. In terms of CFT correlators the structure constants for three vectormultiplets are

$$\left\langle \hat{V}^1_{vm}(1)\hat{V}^2_{vm}(2)\hat{V}^3_{vm}(3) \right\rangle \qquad . \tag{9.8}$$

We have now introduced two negative signature fields into our system and the techniques of BRST cohomology are the most appropriate to use when defining an algebra. We also need a mechanism to kill two sets of oscillator states and at the same time reduce the the $\Pi^{s+2,2}$ lattice to a $\Pi^{s+1,1}$ lattice. Such a mechanism is provided by string theory with local $N_{\rm ws}=2$ world-sheet supersymmetry, particularly in the heterotic version [82]. In heterotic $N_{\rm ws}=2$ string theory the leftmoving gauge algebra is a product $Vir \ltimes U(1)$. The gauged $U(1)$ current is of the form $J = v\cdot\partial X$ with $v \in \Pi^{s+2,2}$ where v is null. (For $\Pi^{2,2}$ and $\Pi^{10,2}$ there is a unique such null vector up to lattice automorphism.)

In the present context we do not have local $N_{\rm ws}=2$ world-sheet supersymmetry but we may nonetheless borrow these ideas to define a Lie algebra based on a $\Pi^{s+1,1}$ lattice which acts in a positive definite Hilbert space. We let L_n be the left-moving Virasoro operators constructed from the $c=(26,6)$ CFT defined by (9.6) and J_n the modes of the current defined in the previous paragraph. We then define the physical subspace of states as those annihilated by the L_n and J_n for $n\geq 0$. The J_0 constraint implies that physical states lie on a $\Pi^{s+1,1}$ sublattice of the $\Pi^{s+2,2}$ lattice parametrizing BPS states and the L_n and J_n constraints act to remove the negative norm states associated with the two timelike oscillators.

More formally, we enlarge the CFT to the BRST complex

$$\mathcal{C}^{2,0}_{\rm transverse}\otimes\mathcal{C}^{22,6}_{\rm N=(0,4)}\otimes\mathcal{C}^{2,0}_{\rm gaussian}\otimes\mathcal{C}^{-2,0}_{\xi\eta}\otimes\mathcal{C}^{-26,0}_{\rm b,c}\otimes\mathcal{C}^{2,0}_{x} \tag{9.9}$$

where the (ξ,η) system of $c=-2$ are the $U(1)$ ghosts. The last factor is a $c=2$ pair of free bosonic fields which is needed to ensure we are in the critical dimension. Now we may take the cohomology with respect to Q_{vir} and $Q_{U(1)}$ which are defined by:

$$\begin{aligned} Q_{vir} &= \oint\left[c\Big(T_L(z)+\tfrac{1}{2}(\partial x)^2-\tfrac{1}{2}(\partial X_R)^2+\eta\partial\xi\Big)-c\partial cb\right] \\ Q_{U(1)} &= \oint \xi v\cdot\partial X = \sum \xi_n v\cdot\alpha_{-n} \end{aligned} \tag{9.10}$$

where $T_L(z)$ is the leftmoving stress tensor of the $\mathcal{C}^{2,0}_{\rm transverse}\otimes\mathcal{C}^{22,6}_{\rm N=(0,4)}$ system. It is important to work in the "little Hilbert space" of the complex [83]. Thus we should also take cohomology with respect to $\oint \eta$. One important effect of this cohomology is on the allowed momentum. Since

$$\{\oint \eta, \oint \xi v \cdot \partial X\} = \oint v \cdot \partial X \qquad , \tag{9.11}$$

momenta must satisfy $p \cdot v = 0$ and are identified mod $p \sim p + \lambda v$. This removes momentum dependence in one $\Pi^{1,1}$ factor of the lattice. The cohomology with respect to the non-zero modes of J then kills two of the oscillators as desired. We can now define the vectormultiplet Lie algebra to be the algebra of physical states formed from the cohomology classes of vertex operators $\hat{V}^A_{vm}(z)$ with respect to the above cohomologies. By the no-ghost theorem the Virasoro cohomology has a positive definite contravariant form and thus the vectormultiplet Lie algebra is a generalized Kac-Moody Lie algebra (or Borcherds algebra) [35].

As we saw previously, threshold corrections depend on the difference between vectormultiplets and hypermultiplets. This suggests that we can extend this algebra to a Z_2 graded superalgebra with even elements corresponding to BPS vectormultiplets under the map (9.5) and the odd elements corresponding to hypermultiplets. Threshold corrections would then be interpreted in terms of a supertrace over the states of this superalgebra.

This extension can be accomplished as follows. From (3.10) we see that to each BPS hypermultiplet we can assign two distinguished vertex operators whose right-moving chiral primary field is a highest weight state for the $\mathcal{A}^{c=6}_{N=4}$ algebra and the unit operator for the $\mathcal{A}^{c=3}_{N=2}$ algebra.

$$V^{A,i}_{hm}(z,\bar{z}) = e^{ip_L X_L(z) + ip_R \tilde{X}_R(\bar{z})} \Phi^{A,i}(z,\bar{z}) \tag{9.12}$$

where A runs over an infinite range and i over a finite range (labelling the degeneracy of the $(\frac{1}{2},\frac{1}{2})$ representation of the $N=4, c=6$ theory.) We again construct a new vertex operator by making X_R left-moving and dropping the unit operator in the $c=3$ theory:

$$V^{A,i}_{hm}(z,\bar{z}) \to \hat{V}^{A,i}_{hm}(z,\bar{z}) \equiv e^{ip_L X_L(z) + ip_R X_R(z)} \Phi^{A,i}(z,\bar{z}) \tag{9.13}$$

This gives a vertex operator which is a holomorphic vertex operator multiplied by an antiholomorphic operator which is a primary chiral operator in the $\mathcal{A}^{c=6}_{N=4}$ algebra. To define a closed algebra we need to combine the left-moving current algebra with the graded commutative associative chiral algebra on the right. Since the $N=2$ chiral algebra splits according to (2.1), the bosonized $U(1)$ current also splits:

$$\sqrt{3} H^{tot} = H + \sqrt{2} H^{N=4} \tag{9.14}$$

so that the $N=4$ current is bosonized by: [19]

$$-2J_{+-} = -i\sqrt{2}\partial H^{N=4} \tag{9.15}$$

Since the $U(1)$ charge violation of the $N=4$ system is 2 the chiral ring of the $N=4$ theory gives us a map from $\hat{V}^{A,i}_{hm} \times \hat{V}^{B,j}_{hm} \to V^{C}_{vm}$, thus giving a $\mathbb{Z}_2$ grading of the desired type. Explicitly, the structure constants between two hypermultiplets and one vectormultiplet are:

$$\left\langle \hat{V}^1_{hm}(1)\hat{V}^2_{hm}(2)\hat{V}^3_{vm}(3)e^{-i\sqrt{2}H^{N=4}}(\bar{z}_4)\xi(z_0)\right\rangle \tag{9.16}$$

where z_0, z_4 can be inserted at any point $\neq z_1, z_2, z_3$.

More formally, we can take a twisted $N=4$ cohomology [84,85,86] on the right in addition to the Virasoro and $U(1)$ cohomologies on the left. From the (small) $N=4$ superconformal algebra, we have four odd supercurrents G_{AB}, $A, B = +, -$. Now we consider a twisting so that $T' = T - \partial J_{+-}$. Then G_{+A} has $h' = 1$ and G_{-A} has $h' = 2$. Thus, there are two BRST currents. In defining the topological states we should take *both* cohomologies

$$\tilde{Q}_A = \oint G_{+A} \tag{9.17}$$

The resulting cohomology states are chiral primary (not antichiral primary) with respect to all embedded N=2 algebras. On the resulting cohomology we can combine the leftmoving "Gerstenhaber bracket" with the rightmoving "Gerstenhaber product," [87][88], that is, we can take the product:

$$(V^1, V^2)(w,\bar{w}) \to \oint_w dz \lim_{\bar{z}\to\bar{w}} b_{-1}V^1(z,\bar{z}) \cdot V^2(w,\bar{w}) \tag{9.18}$$

Under this product the right-moving piece of two hypermultiplets maps to a right-moving chiral primary with charge +2. This does not correspond to a BPS vertex operator, but we can conjugate, or, equivalently, use the topological metric as in (9.16) above.

The vertex operators $\hat{V}$ associated to BPS states then form a graded Lie algebra of the generalized Kac-Moody type. If we introduce vectormultiplets with a multiplicity two then the root supermultiplicities of this algebra coincide with the degeneracies $c(-r^2/2)$ occurring in the product formula.

---

[19] In terms of the $N=2$ $U(1)$ current, $J^{(2)} = 2J_{+-}$.

10. Application to $N=2$ String Duality

There is now some evidence that $N=2$ heterotic string theories are dual to Type IIA or IIB string theory on special Calabi-Yau spaces [9,10]. These Calabi-Yau spaces have, roughly speaking, the structure of $K3$ surfaces fibered over rational curves [89][57]. The results presented here should allow for detailed tests of this duality in a broader class of models than has been considered so far. We hope to return to this issue in more detail elsewhere [90] but will make a few preliminary remarks here.

The heterotic theory we have considered arises from the symmetric embedding of the spin connection in the gauge group. In the Z_2 orbifold limit that we have used for explicit computations the massless spectrum consists of vector multiplets transforming in the adjoint representation of $E_8 \times E_7 \times SU(2) \times U(1)^4$ with a total of 388 states (including the graviphoton) and hypermultiplets transforming as

$$4(1,1,1)+8(1,56,1)+(1,56,2)+32(1,1,2). \tag{10.1}$$

with a total of 628 states. Note that $388-628=-240$ which matches the coefficient $c_1(0)$ in the $s=0$ case with unbroken E_8 gauge group. In order to compare with the spectrum of a possible dual Calabi-Yau space we can completely Higgs the $E_7 \times SU(2)$ gauge group (which does not change the difference between the number of vector and hypermultiplets) and break E_8 to $U(1)^8$ by turning on Wilson lines. This leaves us with gauge group $U(1)^{12}$ and 492 gauge neutral hypermultiplet fields [9,91]. The difference between the number of massless vector and hypermultiplets is then $12-492=-480$ which agrees with the coefficient $c_1(0)$ for $s=8$.

This massless spectrum would arise in Type II string theory on a Calabi-Yau space with $b_{11}=11$ and $b_{21}=491$ and hence with Euler number $\chi=-960$. Precisely such a Calabi-Yau family, denoted $X_{84}^{1,1,12,28,42}$ appears in the list of $K3$ fibrations given in [57]and is distinguished by having the maximal value of $|\chi|$ known for Calabi-Yau spaces.[20] These Calabi-Yau's are resolutions of degree 84 hypersurfaces in $\mathbb{P}_4^{1,1,12,28,42}$. A typical defining polynomial would be:

$$x_1^{84}+x_2^{84}+x_3^7+x_4^3+x_5^2=0. \tag{10.2}$$

Following the procedure in [89] we obtain a K3 fibration in the sense that there is a complete linear system $|L|$ whose divisors are K3 surfaces. In the present example we set

---

[20] We are grateful to D. Morrison for some very helpful remarks concerning these spaces.

$x_2 = \lambda x_1$ and define $y_1 = x_1^2$ to get a family $X_{42}^{1,6,14,21}$ of K3 surfaces realized as degree 42 polynomials in $\mathbb{P}_3^{1,6,14,21}$. For example (10.2) gives:

$$(1+\lambda^{84})y_1^{42} + x_3^7 + x_4^3 + x_5^2 = 0 \tag{10.3}$$

The K3 family $X_{42}^{1,6,14,21}$ possesses many beautiful and special properties, and has arisen before in the physics literature [92][93]. According to [93] the family is self-mirror with complexified Kahler cone $\cong \mathcal{H}^{9,1}$.

The formulae we have derived for the heterotic prepotential fit in well with the predictions of heterotic/type II duality. According to [9][57] the cohomology class in $H^2(X;Z)$ dual to a divisor L in the linear system defines the heterotic coordinate S. The remaining generators of the Kähler cone define coordinates $y \in \mathcal{H}^{9,1}$ and may be identified with the Kähler classes of $X_{42}^{1,6,14,21}$. The form of the S-dependence, Sy^2 of the classical prepotential follows from the structure of the $K3$-fibration, therefore, let us consider the third derivatives with respect to the y^A. The third derivative of the perturbative prepotential following from (4.25) is

$$\frac{\partial}{\partial y^A}\frac{\partial}{\partial y^B}\frac{\partial}{\partial y^C}\mathcal{F}^{\rm pert} = \frac{\tilde{d}^{10,2}_{ABC}}{64\pi^2} + \frac{1}{2\pi}\sum_{r>0} c_1(-r^2/2) r_A r_B r_C \frac{e^{-2\pi r\cdot y}}{1-e^{-2\pi r\cdot y}} \tag{10.4}$$

Note this is in precisely the right form expected for the counting of rational curves on a Calabi-Yau. Substituting the values of $\tilde{d}^{10,2}_{ABC}$ from the appendix we see that the third derivatives of $\mathcal{F}$ are indeed integers if we multiply $\mathcal{F}$ by $2\pi t$ where t is an integer. [21] Moreover, since $c_1(0) = \frac{1}{2}\chi$ we now recognize the constant term in (4.25):

$$-\frac{2\delta}{384\pi^2} = -\frac{c_1(0)\zeta(3)}{2(2\pi)^4}, \tag{10.5}$$

as the famous $\zeta(3)$ term appearing in the Calabi-Yau prepotential of [94] which is related to the four-loop renormalization of the Calabi-Yau sigma-model [95]. Comparing with the normalization of [94] we see that the properly normalized prepotential must be $4\pi\mathcal{F}$.

In view of this heterotic/type II duality makes some curious predictions for algebraic geometry, namely:

The cubic intersection product on $H^{1,1}$ for the family $X_{84}^{1,1,12,28,42}$ is governed by the structure of E_8 and may be computed from the expressions in $(A.51)$ and $(A.52)$

---

[21] In verifying this it is important to bear in mind the freedom to redefine $\mathcal{F}$ by (4.34). We hope to further investigate this chamber-dependence in the future [90].

by differentiation. Moreover, the rational curves in the family $X_{84}^{1,1,12,28,42}$ which are orthogonal to $c_1(L) \in H^2(X;\mathbb{Z})$ are parametrized by the positive roots $r > 0$ of E_{10} and appear with multiplicity $2c_1(-r^2/2)$ where $c_1(n)$ are the coefficients of the modular form $F(q) = E_6/\eta^{24}$.

If the rational curves are not isolated the integers must be interpreted as integrals over the moduli space, as is standard in topological field theory. These integers should be related to the numbers of rational curves on $K3$ surfaces in $X_{42}^{1,6,14,21}$.

Remarks entirely analogous to the above apply to the relation between the family of $K3$ fibrations $X_{24}^{1,1,2,8,12}$ discussed in [9][57] and the formula (4.36).

11. Concluding Speculations

We have shown that threshold corrections in $N = 2$ heterotic string theories are determined by the spectrum of BPS states and have provided evidence that there is a generalized Kac-Moody algebra associated with these states which governs the form of the threshold corrections. Various extensions of these results should prove very interesting.

It would be interesting to generalize the computations here to other backgrounds and more general dependence on the moduli. In particular, the computations done here involved the standard embedding of the spin connection on $K3$ in the gauge group. By repeating these calculations for different ranks of gauge group and for different topologies of gauge bundle it should be possible to recover interesting product formulae associated with a large number of hyperbolic and generalized Kac-Moody algebras. As examples, we expect to get an interesting algebra associated with $\Pi^{17,1}$ even with the symmetric embedding, and moreover we expect to recover the products occurring in the work of Feingold and Frenkel [96]. Indeed, the relevant products have already been suggested in [59].

Other embeddings and other choices of moduli dependence will also lead to modular integrals for congruence subgroups of $SL(2,\mathbb{Z})$. Given the presence (for the standard embedding) of the Monster Lie algebra and the j function, which is the Thompson series for the identity element of the Monster, it seems likely that these other embeddings will involve some of the other Thompson series for the Monster. It might be that the Monster provides a general classification of $N = 2$ heterotic string vacua.

The formula we have given for the perturbative heterotic prepotential fits in well with the proposed heterotic/type II string duality and therefore admits a natural extension to a full nonperturbative answer. In this paper we have shown that the special Kahler geometry of the $N = 2$ heterotic compactification is summarized by the prepotential:

$$\begin{aligned}\mathcal{F} = & - S(y, y) + \frac{1}{384\pi^2} i\tilde{d}^{s+2,2}_{ABC} y^A y^B y^C - \frac{\zeta(3)}{2(2\pi)^4} c_1(0) \\ & - \frac{1}{(2\pi)^4} \sum_{r>0} c_1(-r^2/2) Li_3(e^{2\pi i r\cdot y}) + \mathcal{F}^{\rm nonpert}(y, e^{2\pi i S})\end{aligned} \tag{11.1}$$

where $\mathcal{F}^{\rm nonpert}(y, e^{2\pi i S})$ has an analytic power series expansion in its second argument. As noted in the previous section, the formula for the prepotential as a sum of trilogarithms is *dictated* by the curve-counting formulae given a dual type II background. Thus, for backgrounds admitting a dual pair, the full nonperturbative prepotential will again be a sum of trilogarithms, with the replacement

$$e^{2\pi i r\cdot y} \rightarrow e^{2\pi i r\cdot y + 2\pi i n S}$$

in the argument of the trilogarithms. The sum will run over the full positive Kahler cone of the dual Calabi-Yau variety. In view of our results it is natural to speculate that this sum will again be a sum over positive roots of some interesting algebra.

The results of this paper should have two interesting mathematical applications in the context of heterotic/type II string duality. First, given an $N = 2$ dual string pair the results presented here combined with those of [97] suggest that special combinations of Ray-Singer torsions on dual Calabi-Yau spaces should admit infinite product representations. These considerations are undoubtedly related to the recent work of Jorgenson and Todorov [98]. Second, interesting recent work of Lian and Yau [99], has shown that certain mirror maps associated to one-parameter families of algebraic K3 surfaces are related to Thompson series. Since the heterotic string is a more natural home for the Monster it is tempting to speculate that the algebraic structure of BPS states together with string duality might provide a way to understand the observations of [99].

The algebraic structures we have begun to uncover should also shed new light on string duality. For example, it is tempting to speculate that different dual theories are simply different representations of an underlying algebraic structure much as in the different realizations of affine Kac-Moody algebras. It would be very interesting to try to identify generalized Kac-Moody algebras in Type II string theories on Calabi-Yau spaces arising as $K3$ fibrations. In addition to the applications to $N = 2$ string duality outlined in the previous section our work might also have relations to the conjectured duality between heterotic and Type I theories [14]. The exchange of $\bar{z}$ and z dependence needed to define the vertex algebra is reminiscent of world-sheet orbifolds considered in [100,101,102] and recently applied to Type I -heterotic duality in [103]. There is possibly an alternative point of view on our construction which might be interesting to pursue. In closed string theory there is a Virasoro algebra which generates transformations on the spatial string coordinate σ with generators $\hat{L}_n = L_n - \bar{L}_{-n}$. If we take the $\bar{L}_{-n}$ to be those of the free right-moving bosons and the L_n those of the left-moving degrees of freedom then the vertex operators we have defined are dimension one as a result of the condition (9.7). If we were then to complexify σ we would obtain a holomorphic vertex operator algebra. This suggests a complexification of the string world-sheet, something that has also been suggested in other contexts [104].

Finally, if the GKM algebra associated to BPS states that we have found is a gauge algebra, as it appears, then in analogy to the structure of $N = 2$ Yang-Mills theory the full nonperturbative prepotential should be governed by "monopoles" of this algebra and the monodromies given by an algebraic variety whose monodromy group is the Weyl group of this algebra. There is a natural candidate for these monopoles. Recall that the gauge structure became clearest in the $M_{\text{string}} \to 0$ limit, which coincides with a decompactification to 5 dimensions. We propose that the states being counted by the product representation of threshold corrections are five-branes wrapped around the remaining $K3 \times S^1$ internal space.

Appendix A. Fundamental Domain Integrals

In this appendix we evaluate the following two integrals:

$$\mathcal{I}_{s+2,2}(y) \equiv \int_{\mathcal{F}} \frac{d^2\tau}{\tau_2} \left[\left(\sum_{p \in \Gamma^{s+2,2}} q^{\frac{1}{2}p_L^2} \bar{q}^{\frac{1}{2}p_R^2} \right) F(q) - c(0) \right] \tag{A.1}$$

and

$$\tilde{\mathcal{I}}_{s+2,2}(y) \equiv \int_{\mathcal{F}} \frac{d^2\tau}{\tau_2}\left[\Bigl(\sum_{p\in\Gamma^{s+2,2}} q^{\frac{1}{2}p_L^2}\bar{q}^{\frac{1}{2}p_R^2}\Bigr)F(q)(E_2-\frac{3}{\pi\tau_2})-\tilde{c}(0)\right] \tag{A.2}$$

These integrals are absolutely convergent for $y \in \mathcal{H}^{s+1,1}$ where y is not on the RQD's. They have logarithmic singularities on the RQD's and moreover, are $O(s+2,2;\mathbb{Z})$ invariant.

The notation is as follows: $\mathcal{F}$ is the fundamental domain for $SL(2,\mathbb{Z})$. $F(q)$ is a $SL(2,\mathbb{Z})$ modular function of weight $-s/2$ for $\mathcal{I}$ or of weight $-s/2-2$ for $\tilde{\mathcal{I}}$ which is holomorphic except at infinity where it has a first order pole. That is, we assume F has a Fourier expansion in terms of $q=e^{2\pi i\tau}$:

$$F(q)=\sum_{n=-1}^{\infty} c(n)q^n = c(-1)q^{-1}+c(0)+\cdots \tag{A.3}$$

and define $c(n)\equiv 0$, $n<-1$. We also define coefficients $\tilde{c}(n)$ through the expansion:

$$F(q)E_2(q)\equiv \sum_{n=-1}^{\infty}\tilde{c}(n)q^n \tag{A.4}$$

where $E_2(q)$ is the first of the series of Eisenstein functions:

$$E_2(q)=1-24\sum_{n=1}^{\infty}\frac{nq^n}{1-q^n}=1-24\sum_{n=1}^{\infty}\sigma_1(n)q^n\ , \tag{A.5}$$

$$E_4(q)=1+240\sum_{n=1}^{\infty}\frac{n^3q^n}{1-q^n}=1+240\sum_{n=1}^{\infty}\sigma_3(n)q^n\ , \tag{A.6}$$

$$E_6(q)=1-504\sum_{n=1}^{\infty}\frac{n^5q^n}{1-q^n}=1-504\sum_{n=1}^{\infty}\sigma_5(n)q^n\ , \tag{A.7}$$

where

$$\sigma_k(n)=\sum_{d|n}d^k \tag{A.8}$$

is the sum of the kth powers of the divisors of n.

$E_2(\tau)$ is not modular covariant since it transforms with a shift. The combination

$$E_2(\tau)-\frac{3}{\pi\tau_2} \tag{A.9}$$

appearing in (A.2) on the other hand is not holomorphic but transforms covariantly.

The sums in (A.1) and (A.2)run over an even self-dual lattice $\Gamma^{s+2,2}(y) \cong \Pi^{s+2,2}$, and thus $s = 8t$ with t integer. As discussed in the text we write $\Pi^{8t+2,2} \cong \Pi^{8t,0} \oplus \Pi^{2,2}$ and write lattice vectors as

$$(\vec{b}; m_+, n_-; m_0, n_0) \tag{A.10}$$

with metric

$$(\vec{b}; m_+, n_-; m_0, n_0)^2 = \vec{b}^2 - 2m_+n_- + 2m_0n_0 \tag{A.11}$$

Also, for Narain compactifications we have

$$\begin{aligned} \tfrac{1}{2}(\vec{p}_L^2 - \vec{p}_R^2) &= \tfrac{1}{2}\vec{b}^2 - m_+n_- + m_0n_0 \\ \tfrac{1}{2}p_R^2 &= \frac{1}{-2(\Im y)^2}\left|\vec{b}\cdot\vec{y} - m_+y_- - n_-y_+ + m_0 - \tfrac{1}{2}n_0y^2\right|^2 \end{aligned} \tag{A.12}$$

Our conventions for the complex coordinates on the homogeneous space $SO(8t+2,2)/SO(8t+2)\times SO(2)$ are as in sec. 2.

A.1. Evaluation of $\mathcal{I}_{s+2,2}$

We will follow quite closely the calculation in the appendix of [42]. The general strategy for the evaluation of (A.1) and (A.2) is to perform first a Poisson resummation on the "momenta" m_+ and m_0 which leads to a sum over matrices A which are general two by two matrices with integer elements. The contributions of two matrices A, A' related by an element $V$of $SL(2,\mathbb{Z})$are related by modular transformation of τ by V which allows one to sum instead over orbits of $SL(2,\mathbb{Z})$and integrate over the images of the fundamental domain under the elements V that yield distinct matrices A when acting on a representative element of the orbit.

We now consider (A.1). Performing a Poisson resummation on m_+, m_0 gives

$$\tau_2 Z_\Gamma = \tau_2 \sum_{p\in\Gamma^{s+2,2}} q^{\frac{1}{2}p_L^2}\bar{q}^{\frac{1}{2}p_R^2} = \sum_{A\in Mat_{2\times 2}} T_\Gamma[A] \tag{A.13}$$

where

$$T_\Gamma[A] = \frac{-(\Im y)^2}{2y_{-,2}} \sum_{\vec{b}\in\Gamma^{8s,0}} q^{\frac{1}{2}\vec{b}^2} \exp\mathcal{G}, \tag{A.14}$$

$$\begin{aligned} \mathcal{G} = \Bigg[&\frac{\pi(\Im y)^2}{2y_{-,2}^2\tau_2}|\mathcal{A}|^2 - 2\pi i y_+ \det A + \frac{\pi}{y_{-,2}}\vec{b}\cdot(\vec{y}\tilde{\mathcal{A}} - \vec{y}^*\mathcal{A}) \\ &- \frac{\pi}{2y_{-,2}}n_0(\vec{y}^2\tilde{\mathcal{A}} - (\vec{y}^*)^2\mathcal{A}) + \frac{i\pi}{y_{-,2}^2}(\Im\vec{y})^2\ (n_- + n_0y_-^*)\mathcal{A}\Bigg] \end{aligned} \tag{A.15}$$

and

$$\begin{aligned}\mathcal{A} &= (\,1 \quad y_-\,)\begin{pmatrix} n_- & k_1 \\ n_0 & -k_2 \end{pmatrix}\begin{pmatrix} \tau \\ 1 \end{pmatrix} = (\,1 \quad y_-\,)\, A \begin{pmatrix} \tau \\ 1 \end{pmatrix} \\ \tilde{\mathcal{A}} &= (\,1 \quad y_-^*\,)\begin{pmatrix} n_- & k_1 \\ n_0 & -k_2 \end{pmatrix}\begin{pmatrix} \tau \\ 1 \end{pmatrix}\end{aligned} \tag{A.16}$$

Under modular transformations we have

$$\begin{aligned} A &\to A\begin{pmatrix} a & b \\ c & d \end{pmatrix} \\ \mathcal{A} &\to \frac{1}{c\tau+d}\mathcal{A}\end{aligned} \tag{A.17}$$

Unlike the simpler integral analyzed in [42], it is no longer obvious that the contribution from two matrices A related by the modular transformation (A.17) is given by the modular transformation $\tau' = \frac{a\tau+b}{c\tau+d}$. However for $s = 8t$ it is still true as can be seen by Poisson resummation on the $\Pi^{8t,0}$ lattice sum and using the fact that $\Pi^{8t,0}$ is even self-dual. Note that one could equally well have used a Poisson resummation on n_-, m_0 leading to the same expression with y_+ exchanged for y_-.

Following [42] we can split the sum on A into three orbits and correspondingly write the integrals as a sum of three integrals:

$$\begin{aligned}\mathcal{I}_{s+2,2} &= \mathcal{I}^0_{s+2,2} + \mathcal{I}^{nd}_{s+2,2} + \mathcal{I}^{dg}_{s+2,2} \\ \mathcal{I}^0_{s+2,2} &= \int_{\mathcal{F}} \frac{d^2\tau}{\tau_2^2} T_\Pi[A=0]F(q) \\ \mathcal{I}^{nd}_{s+2,2} &= 2\int_{\mathcal{H}} \frac{d^2\tau}{\tau_2^2} \sum_{0\le j<k, p\neq 0} T_\Pi[A = \begin{pmatrix} k & j \\ 0 & p \end{pmatrix}]F(q) \\ \mathcal{I}^{dg}_{s+2,2} &= \int_{\mathcal{S}} \frac{d^2\tau}{\tau_2^2}\left[\sum_{j,p}{}' T_\Pi[A = \begin{pmatrix} 0 & j \\ 0 & p \end{pmatrix}]F(q) - \tau_2 c(0)\theta(\tau\in\mathcal{F})\right]\end{aligned} \tag{A.18}$$

where $\mathcal{H}$ is the upper half plane and $\mathcal{S}$ is the strip $\{\tau \in \mathcal{H}, |\tau_1| < 1/2\}$. These three terms correspond to the zero orbit $A = 0$, the non-degenerate orbit with $detA \neq 0$ and the degenerate orbit with $detA = 0$ and a particular choice of representative matrices from each orbit.

In deriving (A.18) we have made an important exchange of summation and integration. Because of the tachyon divergences $\sim q^{-1}$ which exist before the $L_0 = \bar{L}_0$ projection this exchange can be invalid. Indeed, it is clear that if $y_{+,2} > 2y_{-,2}$ then one must use the expressions (A.13),(A.14)(A.15). On the other hand, if $y_{-,2} > 2y_{+,2}$, one must use the other Poisson summation with $y_+ \leftrightarrow y_-$. In fact, we know that the expressions must change as we cross the wall of the Weyl chamber $y_{-,2} = y_{+,2}$. [22]

The $A = 0$ orbit may be evaluated using [105] [23] .

$$\frac{-(\Im y)^2}{2y_{-,2}} \int_{\mathcal{F}} \frac{d^2\tau}{\tau_2^2} \vartheta_{\Pi^{8t,0}} F(q) = \frac{-(\Im y)^2}{2y_{-,2}} \frac{1}{\pi} [G_2(q)\vartheta_{\Pi^{8t,0}} F(q)]_{q^0} \tag{A.19}$$

For $t = 1$ which will be of most relevance for our discussion we have

$$\frac{1}{\pi}[G_2(q)\vartheta_{\Pi^{8,0}} F(q)]_{q^0} = \frac{\pi}{3}(c(0) + 216c(-1)) \tag{A.20}$$

The non-degenerate orbit is evaluated using the representative matrix

$$A_0 = \begin{pmatrix} k & j \\ 0 & p \end{pmatrix} \tag{A.21}$$

with $0 \le j < k$ and $p \neq 0$. The τ_1 integral is gaussian and the sum on j is then trivial. The integral over τ_2 gives a representation of the Bessel function $K_{1/2}$ which is elementary. The sum on p yields a logarithm so that the contribution from the non-degenerate orbit is given by

$$-2\log\left|\prod_{\vec{b}\in\Pi^{8t,0}}\ \prod_{k>0,\ell\in\mathbb{Z}}\left(1 - e^{2\pi i r\hat{\cdot}y}\right)^{c(k\ell - \frac{1}{2}\vec{b}^2)}\right|^2 \tag{A.22}$$

where we have introduced a “hatted dot product ” defined by

$$r\hat{\cdot}y \equiv \Re\left[(\vec{b}\cdot\vec{y} + \ell y_- + k y_+)\right] + i\left|\Im\left[(\vec{b}\cdot\vec{y} + \ell y_- + k y_+)\right]\right| \tag{A.23}$$

when $k > 0$, and, when $k = 0$:

$$\begin{aligned} r\hat{\cdot}y &\equiv r\cdot y - N(r,y)y_- \\ N(r,y) &= \operatorname{sgn}(\vec{b})\left[\operatorname{sgn}(\vec{b})\frac{\vec{b}\cdot\Im\vec{y}}{y_{-,2}}\right] \end{aligned} \tag{A.24}$$

where $[\cdot]$ is the greatest integer function.

To evaluate the contribution from the degenerate orbit we take

$$A_0 = \begin{pmatrix} 0 & j \\ 0 & p \end{pmatrix} \tag{A.25}$$

---

[22] Hence there is a puzzle about why the exchange of sum and integral is not valid for one Poisson summation in the range $2 > y_{+,2}/y_{-,2} > 1$. We have not resolved this point.

[23] After correcting a factor two error in eqn. 9.38 of [105].

with j, p not both zero. After evaluating the τ_1 integral the sum on j may be performed using a Sommerfeld-Watson transformation:

$$\begin{aligned}\sum_{j=-\infty}^{\infty} \frac{e^{i\theta j}}{(j+B)^2+C^2} &= \frac{\pi}{C} e^{-i\theta(B-iC)} \frac{1}{1-e^{-2\pi i(B-iC)}} \\ &\quad + \frac{\pi}{C} e^{-i\theta(B+iC)} \frac{e^{2\pi i(B+iC)}}{1-e^{2\pi i(B+iC)}} \\ &\quad C > 0, \qquad 0 \le \theta \le 2\pi\end{aligned} \tag{A.26}$$

A special case is

$$\sum_{j=1}^{\infty} \frac{\cos\theta j}{j^2} = \frac{\theta(\theta-2\pi)}{4} + \frac{\pi^2}{6} \tag{A.27}$$

for $0 \le \theta \le 2\pi$.

To write the final answer it is useful to introduce the polylogarithm functions:

$$\begin{aligned} Li_1(x) &= \sum_{j=1}^{\infty} \frac{x^j}{j} = -\log(1-x) \\ Li_2(x) &= \sum_{j=1}^{\infty} \frac{x^j}{j^2} = \int_0^1 \frac{dt}{t} \frac{1}{(1-xt)} \\ Li_3(x) &= \sum_{j=1}^{\infty} \frac{x^j}{j^3} = -\int_0^1 \frac{dt}{t} \int_0^1 \frac{ds}{s} \log(1-xts) \end{aligned} \tag{A.28}$$

The general answer for the integral (A.1) is then

$$\begin{aligned}\mathcal{I}_{8t+2,2}(y) &= \frac{-(\Im y)^2}{2y_{-,2}} \frac{\pi}{3} [E_2(q)\vartheta_{\Pi^{8t,0}} F(q)]_{q^0} \\ &\quad + c(0)\left(-\log[-(\Im y)^2] + \frac{\pi}{3} y_{-,2} - \mathcal{K}\right) \\ &\quad + c(-1) \frac{2y_{-,2}}{\pi} \sum_{\vec{b}^2=2} \Re\left[Li_2\big(e^{2\pi i \frac{\vec{b}\cdot\Im\vec{y}}{y_{-,2}}}\big)\right] \\ &\quad + 4\Re\left\{\sum_{r>0}\left[c(kl-\tfrac{1}{2}\vec{b}^2) Li_1(e^{2\pi i r\hat{\cdot} y})\right]\right\}\end{aligned} \tag{A.29}$$

Here $r > 0$ means:

1. $k > 0$ or,
2. $k = 0$, $\ell > 0$ or,

3. $k = \ell = 0$, $\vec{b} > 0$.

The first line of (A.29) comes from $A = 0$. The second and third lines come from the degenerate orbit, and the last line comes from the nondegenerate and degenerate orbits. The constant $\mathcal{K}$ is

$$\mathcal{K} = \log[\frac{4\pi}{\sqrt{27}} e^{1-\gamma_E}] \tag{A.30}$$

where γ_E is the Euler-Mascheroni constant.

We now consider two special cases.

$\underline{s = 0}$: In this case it is customary to denote $y_+ = T, y_- = U$. The general formula (A.29) then gives

$$\begin{aligned}\mathcal{I}_{2,2}(T,U) &= c(0)[-\log[2T_2U_2] - \mathcal{K}] + c(0)\frac{\pi}{3}(T_2 + U_2) \\ &\quad - 2\log\left| e^{-2\pi i T c(-1)} \prod_{r>0} \left(1 - e^{2\pi i (kT+\ell U)}\right)^{c(k\ell)} \right|^2\end{aligned} \tag{A.31}$$

Here $r > 0$ means $k > 0, \ell \in \mathbb{Z}$, or $k = 0, \ell > 0$. We have also assumed that $T_2 > U_2$. In this case one may replace $r \hat{\cdot} y$ with $r \cdot y$ since they only differ for $k = 1, \ell = -1$ and in this case $r \hat{\cdot} y = (T_1 - U_1) + i|T_2 - U_2|$ which equals $r \cdot y$ for $T_2 > U_2$. For $U_2 > T_2$ one should interchange U and T in (A.31).

The last two terms in (A.31) may be written as

$$-2\log|j(T) - j(U)|^2 - 2\log|\eta(T)\eta(U)|^{2c(0)} \tag{A.32}$$

using the product formula (1.2).

$\underline{s = 8}$: In this case we have, without loss of generality,

$$F(q) = \frac{E_4^2}{\eta^{24}} \tag{A.33}$$

The finite sums over simple roots of $\Pi^{8,0}$ can be simplified. In (A.29) we have a term

$$\Re\Big[Li_2(e^{i\theta})\Big] = \sum_{j=1}^{\infty} \frac{\cos\theta j}{j^2} = \frac{\theta(\theta - 2\pi)}{4} + \frac{\pi^2}{6} \qquad 0 \le \theta \le 2\pi \tag{A.34}$$

In order to apply this to the third line of (A.29) we need to be careful to take care of the range of the angle $\frac{\vec{b}\cdot\Im\vec{y}}{y_{-,2}}$. Since, by assumption, y is not at an enhanced symmetry point this quantity is not integral. If we further take y to be in the fundamental Weyl chamber (5.12) we get:

$$2c(-1)\frac{2y_{-,2}}{\pi} \sum_{\vec{b}^2=2,\vec{b}>0} \left[\frac{\pi^2}{3} - 2\pi^2\frac{\vec{b}\cdot\Im\vec{y}}{y_{-,2}} + 2\pi^2(\frac{\vec{b}\cdot\Im\vec{y}}{y_{-,2}})^2\right] \tag{A.35}$$

We can evaluate the sum over E_8 root vectors. The Weyl vector of E_8 is $\vec{\rho} \equiv \frac{1}{2}\sum_{\vec{b}^2=2,\vec{b}>0}\vec{b}$ and the quadratic sum can be evaluated [106] to give

$$\sum_{\vec{b}^2=2}(\vec{b}\cdot\vec{v})^2 = 60\vec{v}^2 \tag{A.36}$$

To summarize, under the assumption (5.12) we get the product:

$$\begin{aligned}
\mathcal{I}_{10,2}(y) &= -2\log\left|\Phi(y)\right|^2 + c(0)\left(-\log[-(\Im y)^2] - \mathcal{K}\right)\\
\Phi(y) &= e^{2\pi i\rho\cdot y}\prod_{r>0}\left(1-e^{2\pi i r\hat{\cdot} y}\right)^{c(k\ell-\frac{1}{2}\vec{b}^2)}\\
\rho &= -(\vec{\rho};31,30)
\end{aligned} \tag{A.37}$$

In general the integral $\mathcal{I}_{s+2,2}(y)$ has a Weyl vector. This means that the cubic terms cancel, as can be derived using theorems 6.2 and 10.3 of Borcherds [29]. Moreover, the Weyl vector ρ appearing in the product formulae of [29] can be extracted from the terms linear in y. Abstractly we have - for all $t \geq 1$:

$$y_{+,2}\frac{\pi}{3}[E_2\vartheta_{\Pi^{8t,0}}F(\tau)]_{q^0} + y_{-,2}\frac{\pi}{3}[\vartheta_{\Pi^{8t,0}}F(\tau)]_{q^0} - 4\pi\sum_{\vec{b}>0}c(-\vec{b}^2/2)\vec{b}\cdot\Im\vec{y}. \tag{A.38}$$

This agrees exactly with the expression in theorem 10.4 of [29].

A.2. Evaluation of $\tilde{\mathcal{I}}$

We now turn to an evaluation of (A.2). We again decompose the sum over A into a sum over orbits of $SL(2,\mathbb{Z})$. The $A=0$ orbit is done using [105]

$$\int_{\mathcal{F}}\frac{d^2\tau}{\tau_2^2}(\hat{G}_2(\tau))^k F(q) = \frac{1}{\pi(k+1)}\left[(G_2(\tau))^{k+1}F(q)\right]_{q^0} \tag{A.39}$$

The evaluation of the non-degenerate orbit proceeds as before except that the τ_2 integral now gives a representation of $K_{3/2}$ and in the sum over p one makes the replacement

$$\frac{1}{|p|} \to \frac{\left|\Im\left[(\vec{b}\cdot\vec{y}+\ell y_- + k y_+)\right]\right|}{p^2} + \frac{1}{2\pi|p|^3} \tag{A.40}$$

Thus, instead of logarithms we get $Li_2(x)$ and $Li_3(x)$. The evaluation of the degenerate orbit also proceeds as before except that the sum on j now involves

$$\sum_{j=-\infty}^{\infty} \frac{e^{i\theta j}}{((j+B)^2+C^2)^2} = -\frac{1}{2C}\frac{\partial}{\partial C}\sum_{j=-\infty}^{\infty} \frac{e^{i\theta j}}{((j+B)^2+C^2)} \tag{A.41}$$

which thus reduces to (A.26). The result is

$$\begin{aligned}
\tilde{\mathcal{I}}_{8t+2,2}(y) =& \frac{-(\Im y)^2}{2y_{-,2}}\frac{\pi}{6}[E_2^2(q)\vartheta_{\Pi^{8t,0}}F(q)]_{q^0} + \tilde{c}(0)(-\log[-(\Im y)^2] + \frac{\pi}{3}y_{-,2} - \mathcal{K}) \\
&+c(0)\frac{2\pi}{15}\frac{y_{-,2}^3}{(\Im y)^2} + \frac{6}{\pi^2}\frac{c(0)}{(\Im y)^2}\zeta(3) \\
&+\sum_{\vec{b}^2=2}\Re\left[\tilde{c}(-1)\frac{2y_{-,2}}{\pi}Li_2\big(e^{2\pi i\frac{\vec{b}\cdot\Im\vec{y}}{y_{-,2}}}\big) + c(-1)\frac{12y_{-,2}^3}{\pi^3(\Im y)^2}Li_4\big(e^{2\pi i\frac{\vec{b}\cdot\Im\vec{y}}{y_{-,2}}}\big)\right] \\
&+4\Re\left\{\sum_{r>0}\left[\tilde{c}(kl-\tfrac{1}{2}\vec{b}^2)Li_1(e^{2\pi i r\hat{\cdot} y}) + \frac{6}{\pi(\Im y)^2}c(kl-\tfrac{1}{2}\vec{b}^2)\mathcal{P}(r\hat{\cdot} y)\right]\right\}
\end{aligned} \tag{A.42}$$

where we have also introduced the function

$$\mathcal{P}(x) = \Im(x)Li_2(e^{2\pi i x}) + \frac{1}{2\pi}Li_3(e^{2\pi i x}). \tag{A.43}$$

In fact, this integral can be written in the form:

$$\begin{aligned}
\tilde{\mathcal{I}}_{8t+2,2}(y) =& 4\Re\left\{\sum_{r>0}\left[\tilde{c}(kl-\tfrac{1}{2}\vec{b}^2)Li_1(e^{2\pi i r\hat{\cdot} y}) + \frac{6}{\pi(\Im y)^2}c(kl-\tfrac{1}{2}\vec{b}^2)\mathcal{P}(r\hat{\cdot} y)\right]\right\} \\
&+\tilde{c}(0)\bigg(-\log[-y_2)^2] - \mathcal{K}\bigg) + \frac{1}{(y_2)^2}[\tilde{d}_{ABC}^{8t+2,2}y_2^A y_2^B y_2^C + \delta]
\end{aligned} \tag{A.44}$$

where the constant is

$$\delta = \frac{6}{\pi^2}c(0)\zeta(3) \tag{A.45}$$

and $\tilde{d}$ is a real symmetric tensor, which depends on the Weyl chamber.

We now consider the two special cases $s=0$ and $s=8$. For the case $s=0$ without loss of generality we have

$$F = \frac{E_4E_6}{\eta^{24}} \tag{A.46}$$

With $y_+ = T, y_- = U$ as before we have

$$\begin{aligned}\tilde{\mathcal{I}}_{2,2}(y) =&4\Re\Bigg\{\sum_{r>0}\bigg[\tilde{c}(kl)Li_1(e^{2\pi i r\hat{\cdot}y}) - \frac{3}{\pi T_2 U_2}c(kl)\mathcal{P}(r\,\hat{\cdot}\,y)\bigg]\Bigg\}\\ -\frac{\delta}{2T_2U_2}&-264[-\log[2y_{+,2}y_{-,2}]-\mathcal{K}]\\ &-48\pi T_2 - 88\pi U_2 + 16\pi\frac{U_2^2}{T_2} \qquad T_2 > U_2\\ &-48\pi U_2 - 88\pi T_2 + 16\pi\frac{T_2^2}{U_2} \qquad U_2 > T_2\end{aligned} \tag{A.47}$$

As discussed above $r\,\hat{\cdot}\,y$ is only different from $r\cdot y$ for $k=1, \ell=-1$ and in this case it is $(T_1 - U_1) + i|T_2 - U_2|$.

When $s = 8$, we have

$$F = \frac{E_6}{\eta^{24}} \tag{A.48}$$

To calculate $\tilde{\mathcal{I}}$ we need

$$\Re\Big[Li_4(e^{i\theta})\Big] = \sum_{j=1}^{\infty}\frac{\cos\theta j}{j^4} = \frac{\pi^4}{90} - \frac{1}{48}\theta^2(2\pi-\theta)^2 \tag{A.49}$$

valid for $0 \le \theta \le 2\pi$. We also need the E_8 root sum

$$\sum_{\vec{b}^2=2,\vec{b}>0}(\vec{b}\cdot\vec{v})^4 = 18(\vec{v}^2)^2 \tag{A.50}$$

where the quartic sum can be evaluated using formulae in [106]. Again specializing to the Weyl chamber (5.12) we can write the answer as in (A.44) with the symmetric tensor $\tilde{d}$ is determined by:

$$\begin{aligned}\tilde{d}^{10,2}_{ABC}y_2^A y_2^B y_2^C =&-8\pi\Big[(\vec{\rho}\cdot\vec{y}_2 + 41y_{-,2} + 42y_{+,2})(y_2)^2\\ -2\sum_{\vec{b}^2=2,\vec{b}>0}&(\vec{b}\cdot\vec{y}_2)^3 + 60y_{-,2}^2 y_{+,2} + 72y_{+,2}^2 y_{-,2} + 4(y_{-,2})^3\Big]\end{aligned} \tag{A.51}$$

Finally, we need an explicit formula for the cubic sum over E_8 roots. This is given by

$$\begin{aligned}\sum_{\vec{b}^2=2,\vec{b}>0}(\vec{b}\cdot\vec{v})^3 =&6\,v(1)^2\,v(2)+2\,v(2)^3+6\,v(1)^2\,v(3)+6\,v(2)^2\,v(3)\\&+4\,v(3)^3+6\,v(1)^2\,v(4)+6\,v(2)^2\,v(4)+6\,v(3)^2\,v(4)\\&+6\,v(4)^3+6\,v(1)^2\,v(5)+6\,v(2)^2\,v(5)+6\,v(3)^2\,v(5)\\&+6\,v(4)^2\,v(5)+8\,v(5)^3+6\,v(1)^2\,v(6)+6\,v(2)^2\,v(6)\\&+6\,v(3)^2\,v(6)+6\,v(4)^2\,v(6)+6\,v(5)^2\,v(6)+10\,v(6)^3\\&+6\,v(1)^2\,v(7)+6\,v(2)^2\,v(7)+6\,v(3)^2\,v(7)+6\,v(4)^2\,v(7)\\&+6\,v(5)^2\,v(7)+6\,v(6)^2\,v(7)+12\,v(7)^3+30\,v(1)^2\,v(8)\\&+30\,v(2)^2\,v(8)+30\,v(3)^2\,v(8)+30\,v(4)^2\,v(8)+30\,v(5)^2\,v(8)\\&+30\,v(6)^2\,v(8)+30\,v(7)^2\,v(8)+22\,v(8)^3\end{aligned}\tag{A.52}$$

where $v(i)$ is the i^{th} component of v in the usual Cartesian basis for E_8 roots.

A Monster Lie Algebra?

Chapter 30 of “Sphere packing, lattices and groups” by Conway and Sloane, and Adv. in Math. 53 (1984), no. 1, 75–79.

R. E. Borcherds, J. H. Conway, L. Queen and N. J. A. Sloane

We define a remarkable Lie algebra of infinite dimension, and conjecture that it may be related to the Fischer-Griess Monster group.

The idea was mooted in [C-N] that there might be an infinite-dimensional Lie algebra (or superalgebra) L that in some sense “explains” the Fischer-Griess ‘Monster” group M. In this chapter we produce some candidates for L based on properties of the Leech lattice described in [C-S]. These candidates are described in terms of a particular Lie algebra L_∞ of infinite rank.

We first review some of our present knowledge about these matters. It was proved by character calculations in [C-N, p. 317] the centralizer C of an involution of class 2A in the Monster group has a natural sequence of modules affording the head characters (restricted to C). In [K], V. Kac has explicitly constructed these as C-modules. Now that Atkin, Fong and Smith [F], [S] have verified the relevant numerical conjectures of [C-N] for M, we know that these modules can be given the structure of M-modules. More recently, Frenkel, Lepowsky, and Meurman [F-L-M] have given a simple construction for the monster along these lines, but this sheds little light on the conjectures.

Some of the conjectures of [C-N] have analogs in which M is replaced by a compact simple Lie group, and in particular by the Lie group E_8. Most of the resulting statements have now been established by Kac and others. However, it seems that this analogy with Lie groups may not be as close as one would wish, since two of the four conjugacy classes of elements of order 3 in E_8 were shown in [Q] to yield examples of modular functions neither of which are the Hauptmodul for any modular group. This disproves the conjecture made on p. 267 of [K], and is particularly distressing since it was the Hauptmodul property that prompted the discovery of the conjectures in [C-N], and it is this property that gives those conjectures almost all their predictive power.

The properties of the Leech lattice that we shall use stem mostly from the facts about “deep holes” in that lattice reported in [C-S Chapter 23]. Let $w = (0, 1, 2, 3, \ldots, 24 \mid 70)$. The main result of [C-S Chapter 26] is that the subset of vectors r in $II_{25,1}$ for which $r \cdot r = 2$, $r \cdot w = -1$ (the “Leech roots’) is isometric to the Leech lattice, under the metric defined by $d(r, s)^2 = \text{norm}(r - s)$. The main result of [C-S Chapter 27] is that $\text{Aut}(\text{II}_{25,1})$ is obtained by extending the Coxeter subgroup generated by the reflections in these Leech roots by its group of graph automorphisms together with the central inversion -1. It is remarkable that the walls of the fundamental region for this Coxeter group (which correspond one-for-one with the Leech roots) are transitively permuted by the graph automorphisms, which form an infinite group abstractly isomorphic to the group of all automorphisms of the Leech lattice, including translations.

Vinberg [V] shows that for the earlier analogs $II_{9,1}$ and $II_{17,1}$ of $II_{25,1}$ the fundamental regions for the reflection subgroups have respectively 10 and 19 walls, and the graph automorphism groups have orders 1 and 2. For the later analogs $II_{33,1}, \ldots$, there is no “Weyl vector” like w, so it appears that $II_{25,1}$ is very much a unique object.

We can use the vector w to define a root system in $II_{25,1}$. If $v \in II_{25,1}$ then we define the height of v by $-v \cdot w$, and we say that v is positive or negative according as its height is positive or negative. We now define a Kac-Moody Lie algebra L_∞, of infinite dimension and rank, as follows: L_∞ has three generators $e(r)$, $f(r)$, $h(r)$ for each Leech root r, and is presented by the following relations:

$$\begin{aligned}
[e(r), h(s)] &= r \cdot s\ e(r)\ , \\
[f(r), h(s)] &= -r \cdot s\ f(r), \\
[e(r), f(r)] &= h(r), \\
[e(r), f(s)] &= 0, \\
[h(r), h(r)] &= 0 = [h(r), h(s)], \\
e(r)\ \{\mathrm{ad}\ e(s)\}^{1-r\cdot s} &= 0 = f(r)\ \{\mathrm{ad}\ f(s)\}^{1-r\cdot s},
\end{aligned}$$

where r and s are distinct Leech roots. (We have quoted these relations from Moody's excellent survey article [M]. Moody supposes that the number of fundamental roots is finite, but since no argument ever refers to infinitely many fundamental roots at once, this clearly does not matter. See also [K89].)

Then we conjecture that L_∞ provides a natural setting for the Monster, and more specifically that the Monster can be regarded as a subquotient of the automorphism group of some naturally determined subquotient algebra of L_∞.

The main problem is to "cut L_∞ down to size'. Here are some suggestions. A rather trivial remark is that we can replace the Cartan subalgebra H of L_∞ by the homomorphic image obtained by adding the relations

$$c_1\ h(r_1)\ +\ c_2\ h(r_2)\ +\ \ldots\ =\ 0$$

for Leech roots $r_1, r_2, \ldots$, whenever $c_1, c_2, \ldots$ are integers for which

$$c_1 r_1\ +\ c_2 r_2\ +\ \ldots\ =\ 0\ .$$

A more significant idea is to replace L_∞ by some kind of completion allowing us to form infinite linear combinations of the generators, and then restrict to the subalgebra fixed by all the graph automorphisms. The resulting algebra, supposing it can be defined, would almost certainly not have any notion of root system.

Other subalgebras of L_∞ are associated with the holes in the Leech lattice, which are either "deep" holes or "shallow" holes (see [C-S Chapter 23]).

(i) By [C-S Chapter 23], any deep hole corresponds to a Niemeier lattice N, which has a Witt part which is a direct sum of root lattices chosen from the list A_n $(n = 1, 2, \ldots)$, D_n $(n = 4, 5, \ldots)$, E_6, E_7 and E_8. Only 23 particular combinations arise, and we shall take $A_{11} D_7 E_6$ as our standard example. The graph of Leech roots contains a finite subgraph which is the disjoint union of extended Dynkin diagrams corresponding to these Witt components W of N, and so our algebra L_∞ has a subalgebra $L[N]$ which is a direct sum of the Euclidean Lie algebras $E(W)$ corresponding to those components (see [K89]). For example, L_∞ has a subalgebra

$$E(A_{11}) \ + \ E(D_7) \ + \ E(E_6) \ .$$

Each such subalgebra of L_∞ can be extended to a larger subalgebra $L^*(N)$ having one more fundamental root, corresponding to a "glue vector' of the appropriate hole (see [C-S Chapter 25]). In the corresponding graph, the new node is joined to a single special node in each component. The graph for $L^*[A_{11}D_7E_6]$ is shown in Figure 30.1 of [C-S]. (A special node of a connected extended Dynkin diagram is one whose deletion would result in the corresponding ordinary diagram.) These hyperbolic algebras $L^*[N]$, having finite rank, are certainly more manageable than L_∞ itself. Since the 23 Niemeier lattices yield 23 constructions for the Leech lattice ([C-S Chapter 25]), it is natural to ask if we can obtain 23 different constructions for the Monster using the Lie algebras $L[N]$ or $L^*[N]$.

(ii) Each shallow hole in the Leech lattice (see [C-S Chapter 24]) corresponds to a maximal subalgebra of L_∞ of finite rank.

We are making various calculations concerning L_∞ (finding the multiplicities of certain roots via the Weyl-MacDonald-Kac formula, etc.). It is worth noting that these calculations are facilitated by the remarkable recent discovery that the Mathieu group M_{12} is generated by the two permutations

$$t \ \mapsto \ |2t| \ , \qquad t \ \mapsto \ 11 - t \ (\text{mod } 23) \ ,$$

of the set $\{0,1,2,3,4,5,6,7,8,9,10,11\}$, where $|x|$ denotes the unique y in this set for which $y \ \equiv \ \pm x$ (mod 23). (See [C-S Chapter 11]. This discovery arose from the study of properties of various standard playing-card shuffles. We have noticed that there are many other elements of M_{12} which have simple formulae in this "card numbering", for example $t \ \mapsto \ | \ t^3 \ |$.) The simplest transformation (see [C-S Chapter 28]) between the usual Euclidean coordinates for the Leech lattice and its Lorentzian coordinates uses this description of M_{12}.

Remark added 1998: The Lie algebra of this paper is indeed closely related to the monster simple group. In order to get a well behaved Lie algebra it turns out to be necessary to add some imaginary simple roots to the "Leech roots". This gives the *fake* monster Lie algebra, which contains the Lie algebra of this paper as a large subalgebra. See "The monster Lie algebra", Adv. Math. Vol. 83, No. 1, Sept. 1990, for details (but note that the fake monster Lie algebra is called the monster Lie algebra in this paper). The term "monster Lie algebra" is now used to refer to a certain "$Z/2Z$-twisted" version of the fake monster Lie algebra. The monster Lie algebra is acted on by the monster simple group, and can be used to show that the monster module constructed by Frenkel, Lepowsky, and Meurman satisfies the moonshine conjectures; see "Monstrous moonshine and monstrous Lie superalgebras", Invent. Math. 109, 405-444 (1992).

Abstract: We show that the meromorphic Jacobi form that counts the quarter-BPS states in $\mathcal{N} = 4$ string theories can be canonically decomposed as a sum of a *mock Jacobi form* and an *Appell-Lerch sum.* The quantum degeneracies of single-centered black holes are Fourier coefficients of this mock Jacobi form, while the Appell-Lerch sum captures the degeneracies of multi-centered black holes which decay upon wall-crossing. The *completion* of the mock Jacobi form restores the modular symmetries expected from AdS_3/CFT_2 holography but has a holomorphic anomaly reflecting the non-compactness of the microscopic CFT. For every positive integral value m of the magnetic charge invariant of the black hole, our analysis leads to a special mock Jacobi form of weight two and index m, which we characterize uniquely up to a Jacobi cusp form. This family of special forms and another closely related family of weight-one forms contain almost all the known mock modular forms including the mock theta functions of Ramanujan, the generating function of Hurwitz-Kronecker class numbers, the mock modular forms appearing in the Mathieu and Umbral moonshine, as well as an infinite number of new examples.

Keywords: black holes, mock modular forms, superstrings, wall-crossing.

"My dream is that I will live to see the day when our young physicists, struggling to bring the predictions of superstring theory into correspondence with the facts of nature, will be led to enlarge their analytic machinery to include not only theta-functions but mock theta-functions . . . But before this can happen, the purely mathematical exploration of the mock-modular forms and their mock-symmetries must be carried a great deal further."

Freeman Dyson (1987 Ramanujan Centenary Conference)

1. Introduction

The quantum degeneracies associated with a black hole horizon are of central importance in quantum gravity. The counting function for these degeneracies for a large class of black holes in string theory is expected to be modular from the perspective of holography. However, in situations with wall-crossing, there is an apparent loss of modularity and it is far from clear if and how such a counting function can be modular. In the context of quarter-BPS black holes in $\mathcal{N} = 4$ supersymmetric theories, we develop the required analytic machinery that provides a complete answer to this question which leads naturally to the mathematics of mock modular forms. We present a number of new mathematical results motivated by but independent of these physical considerations.

Since this paper is of possible interest to both theoretical physicists (especially string theorists) and theoretical mathematicians (especially number theorists), we give two introductions in their respective dialects.

1.1 Introduction for mathematicians

In the quantum theory of black holes in the context of string theory, the physical problem of counting the dimensions of certain eigenspaces ("the number of quarter-BPS dyonic states of a given charge") has led to the study of Fourier coefficients of certain *meromorphic* Siegel modular forms and to the question of the modular nature of the corresponding generating functions. Using and refining results of S. Zwegers [130], we show that these generating functions belong to the recently discovered class of functions called *mock modular forms*.

Since this notion is still not widely known, it will be reviewed in some detail (in §7.1). Very roughly, a mock modular form of weight k (more precisely, "pure" mock modular forms; we will also introduce a somewhat more general notion of "mixed" mock modular forms in §7.3) is a holomorphic function f in the upper half plane to which is associated a holomorphic modular form g of weight $2-k$, called the "shadow" of f, such that the sum of f and a suitable non-holomorphic integral of g transforms like a holomorphic modular form of weight k. Functions of this type occur in several contexts in mathematics and mathematical physics: as certain q-hypergeometric series (like Ramanujan's original mock theta functions), as generating functions of class numbers of imaginary quadratic fields [126], or as characters of extended superconformal algebras [99], with special cases of the last class being conjecturally related to the Mathieu group M_{24} [52]. They also arise, as was shown by Zwegers in his thesis [130], as the Fourier coefficients of meromorphic Jacobi forms. It is this last occurrence which is at the origin of the connection to black hole physics, because the Fourier coefficients of meromorphic Jacobi forms have the same wall-crossing behavior as that exhibited by the degeneracies of BPS states.

The specific meromorphic Jacobi forms that are of interest for the black hole counting problem are the Fourier-Jacobi coefficients $\psi_m(\tau, z)$ of the meromorphic Siegel modular form

$$\frac{1}{\Phi_{10}(\Omega)} \;=\; \sum_{m=-1}^{\infty} \psi_m(\tau, z)\, p^m\,, \qquad \left(\Omega = \begin{pmatrix} \tau & z \\ z & \sigma \end{pmatrix},\ p = e^{2\pi i \sigma}\right), \tag{1.1}$$

the reciprocal of the Igusa cusp form of weight 10, which arises as the partition function of quarter-BPS dyons in the type II compactification on the product of a $K3$ surface and an elliptic curve [51, 109, 42]. These coefficients, after multiplication by the discriminant function $\Delta(\tau)$, are meromorphic Jacobi forms of weight 2 with a double pole at $z = 0$ and no others (up to translation by the period lattice).

The new mathematical results of the paper are contained in Sections 8, 9 and 10. In §8, extending the results of [130], we show that any meromorphic Jacobi form $\varphi(\tau, z)$ having poles only at torsion points $z = \alpha\tau + \beta$ ($\alpha,\, \beta \in \mathbb{Q}$) has a canonical decomposition into two pieces $\varphi^{\mathrm{F}}(\tau, z)$ and $\varphi^{\mathrm{P}}(\tau, z)$, called its "finite" part and "polar" part, respectively, of which the first is a finite linear combination of classical theta series with mock modular forms as coefficients, and the second is an elementary expression that is determined completely by the poles of φ. Again using the results of Zwegers, we give explicit formulas for the polar part φ^P for all φ having only simple or double poles. In the particular case of ψ_m, the polar part is given by the formula

$$\psi_m^{\mathrm{P}}(\tau, z) \;=\; \frac{p_{24}(m+1)}{\Delta(\tau)}\, \mathcal{A}_{2,m}(\tau, z) \qquad \left(q = e^{2\pi i \tau}\,,\ y = e^{2\pi i z}\right), \tag{1.2}$$

where $\Delta(\tau)$ is the Ramanujan discriminant function, $p_{24}(m+1)$ the coefficient of q^m in $\Delta(\tau)^{-1}$, and $\mathcal{A}_{2,m}(\tau, z)$ the elementary function (Appell-Lerch sum)

$$\mathcal{A}_{2,m}(\tau, z) \;=\; \sum_{s \in \mathbb{Z}} \frac{q^{ms^2+s} y^{2ms+1}}{(1 - q^s y)^2}\,. \tag{1.3}$$

Note that $\mathcal{A}_{2,m}$ exhibits wall-crossing: for $0 < \mathrm{Im}(z) < \mathrm{Im}(\tau)$ it has the Fourier expansion

$$\mathcal{A}_{2,m}(\tau, z) \;=\; \sum_{\substack{r \geq \ell > 0 \\ r \equiv \ell \pmod{2m}}} \ell\, q^{\frac{r^2 - \ell^2}{4m}}\, y^r\,, \tag{1.4}$$

but the Fourier expansions are different in other strips $n < \mathrm{Im}(z)/\mathrm{Im}(\tau) < n + 1$. This wall-crossing is at the heart of both the mathematical and the physical theories. On the mathematical side it explains the "mockness" of the finite part ψ_m^{F} of ψ_m. On the physical side it has an interpretation in terms of counting two-centered black holes, with the integer ℓ in (1.4) being the dimension of the $SU(2)$ multiplet with angular momentum $(\ell - 1)/2$ contained in the electromagnetic field produced by the two centers.

Starting in §9 we focus attention on two particular classes of functions $\{\varphi_{1,m}\}$ and $\{\varphi_{2,m}\}$, where $\varphi_{k,m}$ is a meromorphic Jacobi form of weight $k \in \{1, 2\}$ and index $m \in \mathbb{N}$ having singular part $(2\pi iz)^{-k} + \mathrm{O}(1)$ as $z \to 0$ and no other poles except the translates of this one by the period lattice. These functions in the case $k = 2$ are related to the Fourier coefficients ψ_m defined in (1.1) by

$$\psi_m(\tau, z) \;=\; \frac{p_{24}(m+1)}{\Delta(\tau)}\,\varphi_{2,m}(\tau, z) \,+\, (\text{weakly holomorphic Jacobi form}). \tag{1.5}$$

The polar part of $\varphi_{2,m}$ is the function $\mathcal{A}_{2,m}$ defined above, and that of $\varphi_{1,m}$ an Appell-Lerch sum $\mathcal{A}_{1,m}$ with a similar definition (eq. (9.6)), but the functions themselves are not unique, since we can add to them any (weak) Jacobi forms of weight k and index m without changing the defining property. This will change the mock Jacobi form $\Phi_{k,m} = \varphi^{\mathrm{F}}_{k,m}$ in the corresponding way. Much of our analysis concerns finding "optimal" choices, meaning choices for which the functions $\Phi_{k,m}$ have poles of as small an order as possible at infinity and consequently Fourier coefficients whose asymptotic growth is as small as possible. Our main results concern the case $k = 2$, and are as follows:

1. If m is a prime power, then the functions $\Phi_{2,m}$ can be chosen to be strongly holomorphic (i.e., with Fourier expansions containing only monomials $q^n y^r$ with $4nm - r^2 \geq 0$). Their Fourier coefficients then have polynomial growth and are given by explicit linear combinations of class numbers of imaginary quadratic fields.
2. More generally, for arbitrary m, the function $\Phi_{2,m}$ can be chosen to be the sum of the images under appropriate "Hecke-like operators" of special mock Jacobi forms $\mathcal{Q}_M$, where M ranges over all divisors of m having an even number of distinct prime factors. These summands are the eigencomponents of $\Phi_{2,m}$ with respect to the Atkin-Lehner-like operators W_{m_1} $(m_1|m,\ (m_1, m/m_1) = 1)$ acting on the space of mock Jacobi forms of index m.
3. The mock Jacobi form $\mathcal{Q}_1$ is the generating function of class numbers of imaginary quadratic fields, and is strongly holomorphic. The other special mock Jacobi forms $\mathcal{Q}_M$ $(M = 6, 10, 14, \ldots)$ can be chosen to have "optimal growth" (meaning that their Fourier expansions contain only monomials $q^n y^r$ with $4nm - r^2 \geq -1$). Their Fourier coefficients then grow like $e^{\pi\sqrt{\Delta}/m}$ as $\Delta := 4nm - r^2$ tends to infinity.
4. One can also choose $\Phi_{2,m}(\tau, z)$ for arbitrary $m \geq 1$ to be of the form $\sum \Phi^0_{2,m/d^2}(\tau, dz)$, where d ranges over positive integers with $d^2|m$ and each $\Phi^0_{2,m/d^2}$ has optimal growth.
5. There are explicit formulas for the polar coefficients (those with $\Delta < 0$) of $\Phi^0_{2,m}$ and $\mathcal{Q}_M$. In particular, the coefficient of $q^n y^r$ in $\mathcal{Q}_M$ vanishes if $4nM - r^2 = 0$ and equals $\pm\varphi(M)/12$ if $4nM - r^2 = -1$, where $\varphi(M) = \prod_{p|M}(p-1)$ is the Euler φ-function of M.

The proofs of these properties are contained in §10, which gives a detailed description (based on difficult results on Jacobi forms proved in [114, 115]) of the way that the space of holomorphic

Jacobi forms is contained in the spaces of weak or of weakly holomorphic Jacobi forms. This analysis contains several surprises, such as the result (Theorem 9.4) that for all $m \geq 1$ the space of holomorphic Jacobi forms of index m has codimension exactly 1 in the space of Jacobi forms of index m with optimal growth.

For $\varphi_{1,m}$ the description is much less complete. There is still a result like 2., with M now ranging over the divisors of m with an *odd* number of distinct prime factors, but it is no longer possible in general to choose the $\mathcal{Q}_M$ to have optimal growth. The few cases where this is possible turn out to be related to mock theta functions that have played a prominent role in the past. Thus $\mathcal{Q}_{30}$ and $\mathcal{Q}_{42}$ are essentially equal to the mock theta functions of "order 5" and "order 7" in Ramanujan's original letter to Hardy, and $\mathcal{Q}_2$ and several of the other $\mathcal{Q}_M$ are related to the "Mathieu moonshine" and "Umbral moonshine" story [52, 25]. The mock Jacobi forms $\mathcal{Q}_M$ for the $k = 2$ case are also related to special mock theta functions, now of weight 3/2, e.g. $\mathcal{Q}_6$ is the mock theta function with shadow $\eta(\tau)$ given in [129].

The applications of the results (for the $k = 2$ case, via the fact that ψ_m is the sum of $p_{24}(m+1)\varphi_{2,m}/\Delta$ and a weakly holomorphic Jacobi form of weight -10 and index m) to the original physics problem are explained in §11 and in the following "second introduction."

1.2 Introduction for physicists

The microscopic quantum description of supersymmetric black holes in string theory usually starts with a brane configuration of given charges and mass at weak coupling, which is localized at a single point in the noncompact spacetime. One then computes an appropriate indexed partition function in the world-volume theory of the branes, which from the perspective of enumerative geometry computes topological invariants such as the Donaldson-Thomas invariants. At strong coupling, the brane configuration gravitates and the indexed partition function is expected to count the microstates of the corresponding macroscopic gravitational configurations. Assuming that the gravitational configuration is a single-centered black hole then gives a way to obtain a statistical understanding of the entropy of the black hole in terms of its microstates, in accordance with the Boltzmann relation[1].

One problem that one often encounters is that the macroscopic configurations are no longer localized at a point and include not only a single-centered black hole of interest but also several multi-centered ones [46, 47, 11, 48]. Moreover, the indexed degeneracy of the multi-centered configurations typically jumps upon crossing walls of marginal stability in the moduli space where the multi-centered configuration breaks up into its single-centered constituents. These jumps are referred to as the 'wall-crossing phenomenon'.

If one is interested in the physics of the horizon or the microstates of a single black hole, the multi-centered configurations and the associated wall-crossings are thus something of a nuisance.

---

[1] Under certain conditions the index equals the absolute number [106, 107, 37].

It is desirable to have a mathematical characterization that isolates the single-centered black holes directly at the microscopic level. One distinguishing feature of single-centered black holes is that they are '*immortal*' in that they exist as stable quantum states for all values of the moduli and hence their degeneracy does not exhibit the wall-crossing phenomenon. We will use this property later to define the counting function for the immortal black holes.

The wall-crossing phenomenon raises important conceptual questions regarding the proper holographic formulation in this context. In many cases, the black hole can be viewed as an excitation of a black string. The near horizon geometry of a black string is AdS_3 which is expected to be holographically dual to a two-dimensional conformal field theory CFT_2. The conformal boundary of Euclidean AdS_3 is a 2-torus with a complex structure parameter τ, and the physical partition function of AdS_3 and of the boundary CFT_2 is a function of τ. The $SL(2,\mathbb{Z})$ transformations of τ can be identified geometrically with global diffeomorphisms of the boundary of AdS_3 space. The partition function is expected to have good modular properties under this geometric symmetry. This symmetry is crucial for the Rademacher-type expansions of the black hole degeneracies for understanding the quantum entropy of these black holes via holography [106, 107, 35, 49, 44, 89, 117, 95, 90, 36]. Implementing the modular symmetries presents several subtleties in situations when there is wall-crossing.

The wall-crossing phenomenon has another important physical implication for the invariance of the spectrum under large gauge transformations of the antisymmetric tensor field. Large gauge transformations lead to the 'spectral flow symmetry' of the partition function of the black string [44]. Since these transformations act both on the charges and the moduli, degeneracies of states with a charge vector Γ at some point ϕ in the moduli space get mapped to the degeneracies of states with charge vector Γ' at some other point ϕ' in the moduli space. Typically, there are many walls separating the point ϕ' and the original point ϕ. As a result, the degeneracies extracted from the black string at a *given* point ϕ in the moduli space do not exhibit the spectral-flow symmetry. On the other hand, the spectrum of immortal black holes is independent of asymptotic moduli and hence must exhibit the spectral-flow symmetry. This raises the question as to how to make the spectral-flow symmetry manifest for the degeneracies of immortal black holes in the generic situation when there is wall-crossing.

With these motivations, our objective will be to isolate the partition functions of the black string associated with immortal black holes and investigate their transformation properties under the boundary modular group and large gauge transformations. More precisely, we would like to investigate the following four questions.

1. Can one define a *microscopic* counting function that cleanly isolates the microstates of immortal black holes from those of the multi-centered black configurations?
2. What are the modular properties of the counting function of immortal black holes when the asymptotic spectrum exhibits the wall-crossing phenomenon?

3. Can this counting function be related to a quantity that is properly modular as might be expected from the perspective of near-horizon AdS_3/CFT_2 holography?
4. Can one define a partition function of the immortal black holes that manifestly exhibits the spectral-flow symmetry resulting from large gauge transformations?

The main difficulties in answering these questions stem from the complicated moduli dependence of the black hole spectrum which is often extremely hard to compute. To address the central conceptual issues in a tractable context, we consider the compactification of Type-II on $K3 \times T^2$ with $\mathcal{N} = 4$ supersymmetry in four dimensions. The spectrum of quarter-BPS dyonic states in this model is exactly computable [51, 60, 109, 110, 85, 42] and by now is well understood at *all* points in the moduli space [105, 31, 26] and for *all* possible duality orbits [31, 7, 8, 6, 33]. Moreover, as we will see, this particular model exhibits almost all of the essential issues that we wish to address. The $\mathcal{N} = 4$ black holes have the remarkable property that even though their spectrum is moduli-dependent, the partition function itself is moduli-independent. The entire moduli dependence of the black hole degeneracy is captured by the moduli dependence of the choice of the Fourier contour [105, 31, 26]. Moreover, the only multi-centered configurations that contribute to the supersymmetric index of quarter-BPS states are the ones with only two centers, each of which is half-BPS [38]. Consequently, the only way the index can jump at a wall is by the decay of a two-centered configuration into its half-BPS constituents [105, 31, 26]; this is a considerable simplification compared to the general $\mathcal{N} = 2$ case where more complicated multi-centered decays are possible. These features make the $\mathcal{N} = 4$ case much more tractable.

The number of microstates of quarter-BPS dyonic states for the above-mentioned compactification is given by a Fourier coefficient of a meromorphic Jacobi form $\psi_m(\tau, z)$ with a moduli-dependent contour. The partition function (1.1) referred to earlier is the generating function for these meromorphic Jacobi forms. Using this simplicity of the moduli dependence and the knowledge of the exact spectrum, it is possible to give very precise answers to the above questions in the $\mathcal{N} = 4$ framework, which turn out to naturally involve mock modular forms.

1. One can define a holomorphic function for counting the microstates of immortal black holes[2] as a Fourier coefficient of the partition function of the black string for a specific choice of the Fourier contour [105, 31, 26]. The contour corresponds to choosing the asymptotic moduli of the theory in the attractor region of the single-centered black hole.
2. Because the asymptotic counting function is a *meromorphic* Jacobi form, the near horizon counting function of immortal black holes is a *mock* modular form in that it fails to be

---

[2] We will use the terms 'immortal' and 'single-centered' interchangeably. In general, the moduli-independent 'immortal' degeneracies can receive contributions not only from single black holes but also from scaling solutions [48]. They are not expected to contribute to the $\mathcal{N} = 4$ index that we consider [38]. In addition, there can be 'hair' degrees of freedom [10, 75], which are degrees of freedom localized outside the black hole horizon that carry part of the charge of the black hole. In frames where the black hole is represented entirely in terms of D-branes, such hair modes are expected to be absent.

modular but in a very specific way. The failure of modularity is governed by a *shadow*, which is given in terms of another holomorphic modular form.

3. Given a mock modular form and its shadow, one can define its *completion* which is a nonholomorphic modular form. The failure of holomorphy can be viewed as a 'holomorphic anomaly' which is also governed by the shadow.
4. The partition function of immortal black holes with manifest spectral-flow invariance is a mock Jacobi form – a new mathematical object defined and elaborated upon in §7.2.

The main physical payoff of the mathematics of mock modular forms in this context is the guarantee that one can still define a completion as in (3) which *is* modular albeit nonholomorphic. As mentioned earlier, the modular transformations on the τ parameter can be identified with global diffeomorphisms of the boundary of the near horizon AdS_3. This connection makes the mathematics of mock modular forms physically very relevant for AdS_3/CFT_2 holography in the presence of wall-crossing and holomorphic anomalies. The required mathematical results concerning mock modular forms are developed in sections §7, §8, §9, and §10.

To orient the physics reader, we summarize the essential conclusions of this mathematical investigation from the perspective of the questions posed above.

1. **Decomposition**: Given an asymptotic counting function, the degeneracies of single-centered black holes can be isolated using the results in §8. Applying Theorem 8.3 to the meromorphic Jacobi form $\psi_m(\tau, z)$ gives a unique decomposition

   $$\psi_m(\tau, z) = \psi_m^{\mathrm{F}}(\tau, z) \, + \, \psi_m^{\mathrm{P}}(\tau, z) \, , \tag{1.6}$$

   such that $\psi_m^{\mathrm{P}}(\tau, z)$ is a simple function (1.2) with the same pole structure in z as $\psi_m(\tau, z)$ and $\psi_m^{\mathrm{F}}(\tau, z)$ has no poles. The elegant decomposition (1.6) is motivated partly by the choice of 'attractor contour' for single-centered black holes and and has a direct physical interpretation: $\psi_m(\tau, z)$ is the counting function of all asymptotic states including both single and multi-centered configurations, $\psi_m^{\mathrm{F}}(\tau, z)$ is the counting function of immortal black holes, whereas $\psi_m^{\mathrm{P}}(\tau, z)$ is the counting function of multi-centered black holes.

   Since both $\psi_m(\tau, z)$ and $\psi_m^{\mathrm{P}}(\tau, z)$ have poles in z, their Fourier coefficients depend on the choice of the contour which in turn depends on the moduli. On the other hand, the Fourier coefficients of $\psi_m^{\mathrm{F}}(\tau, z)$ are unambiguously defined without any contour or moduli dependence. This is what is expected for immortal black holes.

2. **Modular Completion**: The immortal counting function $\psi_m^{\mathrm{F}}(\tau, z)$ defined by the decomposition (1.6) is not modular. However, theorem 8.3 ensures that by adding a specific nonholomorphic function to $\psi_m^{\mathrm{F}}(\tau, z)$, one can obtain its nonholomorphic completion

$\widehat{\psi}^{\mathrm{F}}_m(\tau,z)$ which *is* modular and transforms as a Jabobi form. The failure of holomorphy of the completion $\widehat{\psi}^{\mathrm{F}}_m(\tau,z)$ is given by the equation

$$\tau_2^{3/2}\,\frac{\partial}{\partial\overline{\tau}}\,\widehat{\psi}^{\mathrm{F}}_m(\tau,z) \;=\; \sqrt{\frac{m}{8\pi i}}\,\frac{p_{24}(m+1)}{\Delta(\tau)}\sum_{\ell\,\mathrm{mod}\,(2m)}\overline{\vartheta_{m,\ell}(\tau,0)}\,\vartheta_{m,\ell}(\tau,z)\,. \tag{1.7}$$

Hence the counting function of immortal black holes has a hidden modular symmetry and more specifically is a mock Jacobi form as defined in §7.2. This is one of our main physics results and is described in more detail in §11.

3. **Holomorphic anomaly**: The completion is a natural object to be identified with the indexed partition function of the superconformal field theory $SCFT_2$ dual to a single-centered AdS_3, which is expected to be modular.

   From this perspective, the equation (1.7) can be viewed as a holomorphic anomaly and can in fact be taken as a defining property of a mock Jacobi form for physics applications. Naively, an indexed partition function is expected to be holomorphic because of a cancellation between right-moving bosons and fermions as for the elliptic genus [123]. However, if the $SCFT_2$ is noncompact, then the spectrum is continuous and this naive reasoning may fail leading to an ‘anomaly’. The holomorphic anomaly can then arise as a consequence of the fact that for the right-movers in a noncompact $SCFT$, the density of states of bosons and fermions may be slightly different [119, 4] and may not precisely cancel. The detailed connection between the holomorphic anomaly and the noncompactness of the $SCFT_2$ in this context needs to be understood better from a path-integral perspective.

4. **Optimality**: The Fourier coefficients of $\psi^{\mathrm{F}}_m(\tau,z)$ grow exponentially rapidly as expected for a counting function of black hole degeneracies. It is clear from the anomaly equation (1.7) that if we add a holomorphic true Jacobi form to $\psi^{\mathrm{F}}_m(\tau,z)$ with the same weight and index, it will still admit a modular completion satisfying the same anomaly equation. This raises the question whether for a given holomorphic anomaly there is an ‘optimal’ mock Jacobi form whose Fourier coefficients grow as slowly as possible. The answer to this question (for the functions $\varphi_{2,m}$ related to ψ_m by (1.5)) is in the affirmative but is subtle and requires several new results in the theory of Jacobi forms developed in §10, motivated by and explaining the numerical experiments and observations described in §9.

   A practical implication of such an optimal choice is that the leading contribution to the black hole entropy is then determined essentially by a Fourier coefficient of a true Jacobi form. One can thus apply the familiar Cardy formula and the Rademacher expansion of the Fourier coefficients of true modular forms for the leading answer. There will be exponentially subleading corrections to this leading answer coming from the optimal mock Jacobi form. A Rademacher expansion for these corrections requires a generalization [13, 16] applicable for mock rather than true modular forms.

5. **Examples**: Modular forms with slowly growing Fourier coefficients are mathematically particularly interesting and many of the best-known examples of mock modular forms share this property. An 'optimal' choice thus enables us in many cases to obtain a very explicit expression for the immortal counting function $\psi_m^{\mathrm{F}}(\tau, z)$ in terms of these known mock modular forms. For example, for all m prime, the optimal mock part of $\psi_m^{\mathrm{F}}(\tau, z)$ can be expressed in terms of the generating function of Hurwitz-Kronecker class numbers (see §9.2). On the other hand, for a nonprime m our analysis leads to new mock modular forms with very slowly growing Fourier coefficients.

   The functions $\psi_m(\tau, z)$ that arise in the black hole problem have a double pole at $z = 0$ and its translates, but our methods can also be applied to a related class of functions with just a single pole at $z = 0$. This leads to a second infinite family of mock modular forms, this time of weight 1/2. (In the double pole case, the mock Jacobi forms had weight 2 and their coefficients were mock modular forms of weight 3/2. In both cases, the coefficients are in fact mock theta functions, i.e., mock modular forms whose shadows are unary theta series.) Unlike the first case, where we found that the mock modular forms occurring can always be chosen to have at most simple poles at the cusps, the pole order here is much greater in general, and there are only a handful of examples having only simple poles. It is remarkable that these include essentially all the most prominent examples of mock theta functions, including the original ones of Ramanujan, the mock theta function conjecturally related to the Mathieu group M_{24} [52] and the functions arising in the umbral moonshine conjecture [24].

Modular symmetries are very powerful in physics applications because they relate strong coupling to weak coupling, or high temperature to low temperature. The hidden modular symmetry of mock modular forms is therefore expected to be useful in diverse physics contexts. As mentioned above, mock modularity of the counting function in the present context of black holes is a consequence of meromorphy of the asymptotic counting function which in turn is a consequence of noncompactness of the target space of the microscopic SCFT. Now, conformal field theories with a noncompact target space occur naturally in several physics contexts. For example, a general class of four-dimensional BPS black holes is obtained as a supersymmetric D-brane configuration in Type-II compactification on a Calabi-Yau three-fold X_6. In the M-theory limit, these black holes can be viewed as excitations of the MSW black string [87, 92]. The microscopic theory describing the low energy excitations of the MSW string is the $(0, 4)$ MSW SCFT. The target space of this SCFT does not necessarily have to be compact in which case the considerations of this paper will apply. Very similar objects [126, 73] have already made their appearance in the context of topological supersymmetric Yang-Mills theory on $\mathbb{CP}^2$ [120]. Other examples include the theory of multiple M5-branes [2] quantum Liouville theory and E-strings [91], and the $SL(2,\mathbb{R})/U(1)$ SCFT [54, 119, 4] where the CFT is noncompact. The appearance of a holomorphic anomaly in the regularized Poincaré series for the elliptic genus of CFT_2 was noted in [89] in the context of the $\mathrm{AdS}_3/\mathrm{CFT}_2$ correspondence.

We expect that the general framework of mock modular forms and Jacobi forms developed in this paper is likely to have varied physical applications in the context of non-compact conformal field theories, wall-crossings in enumerative geometry, and recently formulated Mathieu and umbral moonshine conjectures [52, 24].

1.3 Organization of the paper

In §2, we review the physics background concerning the string compactification on $K3 \times T^2$ and the classification of BPS states corresponding to the supersymmetric black holes in this theory. In sections §3, §4, and §5, we review the basic mathematical definitions of various types of classical modular forms (elliptic, Jacobi, Siegel) and illustrate an application to the physics of quantum black holes in each case by means of an example. In §6, we review the moduli dependence of the Fourier contour prescription for extracting the degeneracies of quarter-BPS black holes in the $\mathcal{N} = 4$ theory from the partition function which is a meromorphic Siegel modular form. In §8, we refine results due to Zwegers to show that any meromorphic Jacobi form with poles only at the sub-multiples of the period lattice can be decomposed canonically into two pieces, one of which is a mock Jacobi form. We give explicit formulas for this decomposition in the case when the poles have at most order 2, and again give several examples. In §9 we give a detailed description of the experimental results for the Fourier coefficients of the two families of mock Jacobi forms $\{\Phi_{2,m}\}$ and $\{\Phi_{1,m}\}$, and formulate the main mathematical results concerning them. The proofs of these results are given in §10, after we have formulated and proved a number of structural results about holomorphic and weakly holomorphic Jacobi forms that are new and may be of independent interest. In §11, we apply these results in the physical context to determine the mock Jacobi form that counts the degeneracies of single-centered black holes and discuss the implications for AdS_2/CFT_1 and AdS_3/CFT_2 holography.

2. Review of Type-II superstring theory on $K3 \times T^2$

Superstring theories are naturally formulated in ten-dimensional Lorentzian spacetime $\mathcal{M}_{10}$. A 'compactification' to four-dimensions is obtained by taking $\mathcal{M}_{10}$ to be a product manifold $\mathbb{R}^{1,3} \times X_6$ where X_6 is a compact Calabi-Yau threefold and $\mathbb{R}^{1,3}$ is the noncompact Minkowski spacetime. We will focus in this paper on a compactification of Type-II superstring theory when X_6 is itself the product $X_6 = K3 \times T^2$. A highly nontrivial and surprising result from the 90s is the statement that this compactification is quantum equivalent or 'dual' to a compactification of heterotic string theory on $T^4 \times T^2$ where T^4 is a four-dimensional torus [74, 124]. One can thus describe the theory either in the Type-II frame or the heterotic frame.

The four-dimensional theory in $\mathbb{R}^{1,3}$ resulting from this compactification has $\mathcal{N} = 4$ supersymmetry[3]. The massless fields in the theory consist of 22 vector multiplets in addition to the supergravity multiplet. The massless moduli fields consist of the S-modulus λ taking values in the coset

$$SL(2,\mathbb{Z})\backslash SL(2,\mathbb{R})/O(2,\mathbb{R}), \tag{2.1}$$

and the T-moduli μ taking values in the coset

$$O(22,6,\mathbb{Z})\backslash O(22,6,\mathbb{R})/O(22,\mathbb{R}) \times O(6,\mathbb{R}). \tag{2.2}$$

The group of discrete identifications $SL(2,\mathbb{Z})$ is called the S-duality group. In the heterotic frame, it is the electro-magnetic duality group [101, 102], whereas in the type-II frame, it is simply the group of area-preserving global diffeomorphisms of the T^2 factor. The group of discrete identifications $O(22,6,\mathbb{Z})$ is called the T-duality group. Part of the T-duality group $O(19,3,\mathbb{Z})$ can be recognized as the group of geometric identifications on the moduli space of K3; the other elements are stringy in origin and have to do with mirror symmetry.

At each point in the moduli space of the internal manifold $K3 \times T^2$, one has a distinct four-dimensional theory. One would like to know the spectrum of particle states in this theory. Particle states are unitary irreducible representations, or supermultiplets, of the $\mathcal{N} = 4$ superalgebra. The supermultiplets are of three types which have different dimensions in the rest frame. A long multiplet is 256-dimensional, an intermediate multiplet is 64-dimensional, and a short multiplet is 16-dimensional. A short multiplet preserves half of the eight supersymmetries (*i.e.* it is annihilated by four supercharges) and is called a half-BPS state; an intermediate multiplet preserves one quarter of the supersymmetry (*i.e.* it is annihilated by two supercharges), and is called a quarter-BPS state; and a long multiplet does not preserve any supersymmetry and is called a non-BPS state. One consequence of the BPS property is that the spectrum of these states is 'topological' in that it does not change as the moduli are varied, except for jumps at certain walls in the moduli space [125].

An important property of a BPS states that follows from the superalgebra is that its mass is determined by its charges and the moduli [125]. Thus, to specify a BPS state at a given point in the moduli space, it suffices to specify its charges. The charge vector in this theory transforms in the vector representation of the T-duality group $O(22,6,\mathbb{Z})$ and in the fundamental representation of the S-duality group $SL(2,\mathbb{Z})$. It is thus given by a vector $\Gamma^{\alpha I}$ with integer entries

---

[3] This supersymmetry is a super Lie algebra containing $ISO(1,3) \times SU(4)$ as the even subalgebra where $ISO(1,3)$ is the Poincaré symmetry of the $\mathbb{R}^{1,3}$ spacetime and $SU(4)$ is an internal symmetry usually referred to as R-symmetry. The odd generators of the superalgebra are called supercharges. With $\mathcal{N} = 4$ supersymmetry, there are eight complex supercharges which transform as a spinor of $ISO(1,3)$ and a fundamental of $SU(4)$.

$$\Gamma^{\alpha I} \;=\; \begin{pmatrix} N^I \\ M^I \end{pmatrix} \qquad \text{where} \qquad \alpha = 1,2\,; \quad I = 1,2,\ldots 28 \tag{2.3}$$

transforming in the $(2,28)$ representation of $SL(2,\mathbb{Z}) \times O(22,6,\mathbb{Z})$. The vectors N and M can be regarded as the quantized electric and magnetic charge vectors of the state respectively. They both belong to an even, integral, self-dual lattice $\Pi^{22,6}$. We will assume in what follows that $\Gamma = (N,M)$ in (2.3) is primitive in that it cannot be written as an integer multiple of (N_0, M_0) for N_0 and M_0 belonging to $\Pi^{22,6}$. A state is called purely electric if only N is non-zero, purely magnetic if only M is non- zero, and dyonic if both M and N are non-zero.

To define S-duality transformations, it is convenient to represent the S-modulus as a complex field S taking values in the upper half plane. An S-duality transformation

$$\gamma \equiv \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in SL(2;\mathbb{Z}) \tag{2.4}$$

acts simultaneously on the charges and the S-modulus by

$$\begin{pmatrix} N \\ M \end{pmatrix} \to \begin{pmatrix} a & b \\ c & d \end{pmatrix} \begin{pmatrix} N \\ M \end{pmatrix}\,, \qquad S \to \frac{aS+b}{cS+d}\,. \tag{2.5}$$

To define T-duality transformations, it is convenient to represent the T-moduli by a 28×28 matrix μ_I^A satisfying

$$\mu^t\, L\, \mu = L \tag{2.6}$$

with the identification that $\mu \sim k\mu$ for every $k \in O(22;\mathbb{R}) \times O(6;\mathbb{R})$. Here L is the 28×28 matrix

$$L_{IJ} = \begin{pmatrix} -\mathbf{C}_{16} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathrm{I}_6 \\ \mathbf{0} & \mathrm{I}_6 & \mathbf{0} \end{pmatrix}, \tag{2.7}$$

with I_s the $s \times s$ identity matrix and $\mathbf{C}_{16}$ is the Cartan matrix of $E_8 \times E_8$. The T-moduli are then represented by the matrix

$$\mathcal{M} \;=\; \mu^t \mu \tag{2.8}$$

which satisifies

$$\mathcal{M}^t \;=\; \mathcal{M}\,, \qquad \mathcal{M}^t L \mathcal{M} = L\,. \tag{2.9}$$

In this basis, a T-duality transformation can then be represented by a 28×28 matrix R with integer entries satisfying

$$R^t L R \;=\; L\,, \tag{2.10}$$

which acts simultaneously on the charges and the T-moduli by

$$N \to RN; \quad M \to RM\,; \quad \mu \to \mu R^{-1} \tag{2.11}$$

Given the matrix μ_I^A, one obtains an embedding $\Lambda^{22,6} \subset \mathbb{R}^{22,6}$ of $\Pi^{22,6}$ which allows us to define the moduli-dependent charge vectors Q and P by

$$Q^A = \mu_I^A N_I\,, \qquad P^A = \mu_I^A M_I\,. \tag{2.12}$$

The matrix L has a 22-dimensional eigensubspace with eigenvalue -1 and a 6- dimensional eigensubspace with eigenvalue $+1$. Given Q and P, one can define the 'right-moving' and 'left-moving' charges[4] $Q_{R,L}$ and $P_{L,R}$ as the projections

$$Q_{R,L} \;=\; \frac{(1 \pm L)}{2} Q\,; \qquad P_{R,L} \;=\; \frac{(1 \pm L)}{2} P\,. \tag{2.13}$$

If the vectors N and M are nonparallel, then the state is quarter-BPS. On the other hand, if $N = pN_0$ and $M = qN_0$ for some $N_0 \in \Pi^{22,6}$ with p and q relatively prime integers, then the state is half-BPS.

An important piece of nonperturbative information about the dynamics of the theory is the exact spectrum of all possible dyonic BPS-states at all points in the moduli space. More specifically, one would like to compute the number $d(\Gamma)|_{S,\mu}$ of dyons of a given charge Γ at a specific point (S, μ) in the moduli space. Computation of these numbers is of course a very complicated dynamical problem. In fact, for a string compactification on a general Calabi-Yau threefold, the answer is not known. One main reason for focusing on this particular compactification on $K3 \times T^2$ is that in this case the dynamical problem has been essentially solved and the exact spectrum of dyons is now known. Furthermore, the results are easy to summarize and the numbers $d(\Gamma)|_{S,\mu}$ are given in terms of Fourier coefficients of various modular forms.

In view of the duality symmetries, it is useful to classify the inequivalent duality orbits labeled by various duality invariants. This leads to an interesting problem in number theory of classification of inequivalent duality orbits of various duality groups such as $SL(2,\mathbb{Z}) \times O(22,6;\mathbb{Z})$ in our case and more exotic groups like $E_{7,7}(\mathbb{Z})$ for other choices of compactification manifold X_6. It is important to remember though that a duality transformation acts simultaneously on charges and the moduli. Thus, it maps a state with charge Γ at a point in the moduli space (S, μ) to a state with charge Γ' but at some other point in the moduli space (S', μ'). In this respect, the half-BPS and quarter-BPS dyons behave differently.

---

[4] The right-moving charges couple to the graviphoton vector fields associated with the right-moving chiral currents in the conformal field theory of the dual heterotic string.

- For half-BPS states, the spectrum does not depend on the moduli. Hence $d(\Gamma)|_{S',\mu'} = d(\Gamma)|_{S,\mu}$. Furthermore, by an S-duality transformation one can choose a frame where the charges are purely electric with $M = 0$ and $N \neq 0$. Single-particle states have N primitive and the number of states depends only on the T-duality invariant integer $n \equiv N^2/2$. We can thus denote the degeneracy of half-BPS states $d(\Gamma)|_{S',\mu'}$ simply by $d(n)$.

- For quarter-BPS states, the spectrum does depend on the moduli, and $d(\Gamma)|_{S',\mu'} \neq d(\Gamma)|_{S,\mu}$. However, the partition function turns out to be independent of moduli and hence it is enough to classify the inequivalent duality orbits to label the partition functions. For the specific duality group $SL(2,\mathbb{Z}) \times O(22,6;\mathbb{Z})$ the partition functions are essentially labeled by a single discrete invariant [31, 5, 6].

  $$I \;=\; \gcd(N \wedge M)\,, \tag{2.14}$$

  The degeneracies themselves are Fourier coefficients of the partition function. For a given value of I, they depend only on[5] the moduli and the three T-duality invariants $(m, n, \ell) \equiv (M^2/2, N^2/2, N \cdot M)$. Integrality of (m, n, ℓ) follows from the fact that both N and M belong to $\Pi^{22,6}$. We can thus denote the degeneracy of these quarter-BPS states $d(\Gamma)|_{S,\mu}$ simply by $d(m, n, l)|_{S,\mu}$. For simplicity, we consider only $I = 1$ in this paper.

Given this classification, it is useful to choose a representative set of charges that can sample all possible values of the three T-duality invariants. For this purpose, we choose a point in the moduli space where the torus T^2 is a product of two circles $S^1 \times \tilde{S}^1$ and choose the following charges in a Type-IIB frame.

- For electric charges, we take n units of momentum along the circle S^1, and $\tilde{K}$ Kaluza-Klein monopoles associated with the circle $\tilde{S}^1$.
- For magnetic charges, we take Q_1 units of D1-brane charge wrapping S^1, Q_5 D5-brane wrapping $K3 \times S^1$ and l units of momentum along the $\tilde{S}^1$ circle.

We can thus write

$$\Gamma \;=\; \begin{bmatrix} N \\ M \end{bmatrix} \;=\; \begin{bmatrix} 0, & n; & 0, & \tilde{K} \\ Q_1, & \tilde{n}; & Q_5, & 0 \end{bmatrix}. \tag{2.15}$$

The T-duality quadratic invariants can be computed using a restriction of the matrix (2.7) to a $\Lambda^{(2,2)}$ Narain lattice of the form

$$L \;=\; \begin{pmatrix} \mathbf{0} & \mathrm{I}_2 \\ \mathrm{I}_2 & \mathbf{0} \end{pmatrix}, \tag{2.16}$$

---

[5] There is an additional dependence on arithmetic T-duality invariants but the degeneracies for states with nontrivial values of these T-duality invariants can be obtained from the degeneracies discussed here by demanding S-duality invariance [6].

to obtain

$$M^2/2 \; = \; Q_1 Q_5 \, , \quad N^2/2 \; = \; n\tilde{K} \, , \quad N \cdot M = \tilde{n}\tilde{K} \, . \tag{2.17}$$

We can simply the notation further by choosing $\tilde{K} = Q_5 = 1$, $Q_1 = m$, $\tilde{n} = l$ to obtain

$$M^2/2 \; = \; m, \quad N^2/2 \; = \; n, \quad N \cdot M = l \, . \tag{2.18}$$

For this set of charges, we can focus our attention on a subset of T-moduli associated with the torus T^2 parametrized by

$$\mathcal{M} \; = \; \begin{pmatrix} G^{-1} & G^{-1}B \\ -BG^{-1} & G - BG^{-1}B \end{pmatrix} \, , \tag{2.19}$$

where G_{ij} is the metric on the torus and B_{ij} is the antisymmetric tensor field. Let $U = U_1 + iU_2$ be the complex structure parameter, A be the area, and ϵ_{ij} be the Levi-Civita symbol with $\epsilon_{12} = -\epsilon_{21} = 1$, then

$$G_{ij} = \frac{A}{U_2} \begin{pmatrix} 1 & U_1 \\ U_1 & |U|^2 \end{pmatrix} \quad \text{and} \quad B_{ij} = AB\epsilon_{ij} \, , \tag{2.20}$$

and the complexified Kähler modulus $U = U_1 + iU_2$ is defined as $U := B + iA$. The S-modulus $S = S_1 + S_2$ is defined as

$$S := a + i \exp\left(-2\phi\right) \tag{2.21}$$

where a is the axion and ϕ is the dilaton field in the four dimensional heterotic frame. the relevant moduli can be parametrized by three complex scalars S, T, U which define the so-called 'STU' model in $\mathcal{N} = 2$ supergravity. Note that these moduli are labeled naturally in the heterotic frame which are related to the S_B, T_B, and U_B moduli in the Type-IIB frame by

$$S \; = \; U_B, \quad T = S_B, \quad U = T_B \, . \tag{2.22}$$

3. Modular forms in one variable

Before discussing mock modular forms, it is useful to recall the variety of modular objects that have already made their appearance in the context of counting black holes. In the following sections we give the basic definitions of modular forms, Jacobi forms, and Siegel forms, using the notations that are standard in the mathematics literature, and then in each case illustrate a physics application to counting quantum black holes by means of an example.

In the physics context, these modular forms arise as generating functions for counting various quantum black holes in string theory. The structure of poles of the counting function is of particular importance in physics, since it determines the asymptotic growth of the Fourier coefficients as well as the contour dependence of the Fourier coefficients which corresponds to the wall crossing phenomenon. These examples will also be relevant later in §11 in connection with mock modular forms. We suggest chapters I and III of [21] respectively as a good general reference for classical and Siegel modular forms and [57] for Jacobi modular forms.

3.1 Basic definitions and properties

Let $\mathbb{H}$ be the upper half plane, *i.e.*, the set of complex numbers τ whose imaginary part satisfies $\mathrm{Im}(\tau) > 0$. Let $SL(2,\mathbb{Z})$ be the group of matrices $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ with integer entries such that $ad - bc = 1$.

A *modular form* $f(\tau)$ of weight k on $SL(2,\mathbb{Z})$ is a holomorphic function on $\mathbb{H}$, that transforms as

$$f(\frac{a\tau + b}{c\tau + d}) = (c\tau + d)^k \, f(\tau) \qquad \forall \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in SL(2,\mathbb{Z}) \,, \tag{3.1}$$

for an integer k (necessarily even if $f(0) \neq 0$). It follows from the definition that $f(\tau)$ is periodic under $\tau \to \tau + 1$ and can be written as a Fourier series

$$f(\tau) \;=\; \sum_{n=-\infty}^{\infty} a(n)\, q^n \qquad \big(q := e^{2\pi i \tau}\big)\,, \tag{3.2}$$

and is bounded as $\mathrm{Im}(\tau) \to \infty$. If $a(0) = 0$, then the modular form vanishes at infinity and is called a *cusp form.* Conversely, one may weaken the growth condition at ∞ to $f(\tau) = \mathrm{O}(q^{-N})$ rather than $\mathrm{O}(1)$ for some $N \geq 0$; then the Fourier coefficients of f have the behavior $a(n) = 0$ for $n < -N$. Such a function is called a *weakly holomorphic modular form.*

The vector space over $\mathbb{C}$ of holomorphic modular forms of weight k is usually denoted by M_k. Similarly, the space of cusp forms of weight k and the space of weakly holomorphic modular forms of weight k are denoted by S_k and $M_k^!$ respectively. We thus have the inclusion

$$S_k \;\subset M_k \;\subset\; M_k^! \,. \tag{3.3}$$

The Fourier coefficients of the modular forms in these spaces have different growth properties:

1. $f \in S_k \;\Rightarrow\; a_n \;=\; \mathrm{O}(n^{k/2})$ as $n \to \infty$;
2. $f \in M_k \;\Rightarrow\; a_n \;=\; \mathrm{O}(n^{k-1})$ as $n \to \infty$;
3. $f \in M_k^! \;\Rightarrow\; a_n \;=\; \mathrm{O}(e^{C\sqrt{n}})$ as $n \to \infty$ for some $C > 0$.

Some important modular forms on $SL(2,\mathbb{Z})$ are:

1. The *Eisenstein series* $E_k \in M_k$ $(k \geq 4)$. The first two of these are

$$E_4(\tau) \;=\; 1 \;+\; 240 \sum_{n=1}^{\infty} \frac{n^3 q^n}{1 - q^n} \;=\; 1 + 240q + 2160q^2 + \cdots \,, \tag{3.4}$$

$$E_6(\tau) \;=\; 1 \;-\; 504 \sum_{n=1}^{\infty} \frac{n^5 q^n}{1 - q^n} \;=\; 1 - 504q - 16632q^2 - \cdots \,. \tag{3.5}$$

2. The *discriminant function* Δ. It is given by the product expansion

$$\Delta(\tau) \;=\; q\prod_{n=1}^{\infty}(1-q^n)^{24} \;=\; q-24q^2+252q^3+... \tag{3.6}$$

or by the formula $\Delta = (E_4^3 - E_6^2)/1728$. We mention for later use that the function $E_2(\tau) = \dfrac{1}{2\pi i}\dfrac{\Delta'(\tau)}{\Delta(\tau)} = 1-24\sum\limits_{n=1}^{\infty}\dfrac{nq^n}{1-q^n}$ is also an Eisenstein series, but is not modular. (It is a so-called *quasimodular form*, meaning in this case that the non-holomorphic function $\widehat{E}_2(\tau) = E_2(\tau) - \dfrac{3}{\pi\,\mathrm{Im}(\tau)}$ transforms like a modular form of weight 2.) This function can be used to form the *Ramanujan-Serre derivative*

$$\partial_k^{\mathrm{RS}} \,:\, M_k \to M_{k+2}\,, \qquad \partial_k^{\mathrm{RS}} f(\tau) \,:=\, \frac{1}{2\pi i}\,f'(\tau) \,-\, \frac{k}{12}\,E_2(\tau)\,f(\tau)\,. \tag{3.7}$$

The ring of modular forms on $SL(2,\mathbb{Z})$ is generated freely by E_4 and E_6, so any modular form of weight k can be written (uniquely) as a sum of monomials $E_4^\alpha E_6^\beta$ with $4\alpha+6\beta = k$. We also have $M_k = \mathbb{C}\cdot E_k \oplus S_k$ and $S_k = \Delta\cdot M_{k-12}$, so any $f \in M_k$ also has a unique expansion as $\sum_{n=0}^{[k/12]}\alpha_n\,E_{k-12n}\,\Delta^n$ (with $E_0 = 1$ and E_2 replaced by 0). From either representation, we see that a modular form is uniquely determined by its weight and first few Fourier coefficients.

Given two modular forms (f,g) of weight (k,l), one can produce a sequence of modular forms of weight $k+l+2n$, $n \geq 0$ using the *Rankin-Cohen bracket*

$$[f,g]_n \;=\; [f,g]_n^{(k,l)} \;=\; \sum_{r+s=n}(-1)^s\binom{k+n-1}{r}\binom{\ell+n-1}{s}f^{(s)}(\tau)g^{(r)}(\tau) \tag{3.8}$$

where $f^{(m)} := \left(\frac{1}{2\pi i}\frac{d}{d\tau}\right)^m f$. For $n = 0$, this is simply the product of the two forms, while for $n > 0$ we always have $[f,g]_n \in S_{k+l+2n}$. The first two non-trivial examples are

$$[E_4,E_6]_1 \;=\; -3456\,\Delta\;, \qquad [E_4,E_4]_2 = 4800\,\Delta\;. \tag{3.9}$$

As well as modular forms on the full modular group $SL(2,\mathbb{Z})$, one can also consider modular forms on subgroups of finite index, with the same transformation law (3.1) and suitable conditions on the Fourier coefficients to define the notions of holomorphic, weakly holomorphic and cusp forms. The weight k now need no longer be even, but can be odd or even half integral, the easiest way to state the transformation property when $k \in \mathbb{Z}+\frac{1}{2}$ being to say that $f(\tau)/\theta(\tau)^{2k}$ is invariant under some congruence subgroup of $SL(2,\mathbb{Z})$, where $\theta(\tau) = \sum_{n\in\mathbb{Z}} q^{n^2}$. The graded vector space of modular forms on a fixed subgroup $\Gamma \subset SL(2,\mathbb{Z})$ is finite dimensional in each weight, finitely generated as an algebra, and closed under Rankin-Cohen brackets. Important examples of modular forms of half-integral weight are the *unary theta series*, i.e., theta series associated to a quadratic form in one variable. They come in two types:

$$\sum_{n\in\mathbb{Z}} \varepsilon(n)\, q^{\lambda n^2} \qquad \text{for some } \lambda \in \mathbb{Q}_+ \text{ and some even periodic function } \varepsilon \tag{3.10}$$

and

$$\sum_{n\in\mathbb{Z}} n\,\varepsilon(n)\, q^{\lambda n^2} \qquad \text{for some } \lambda \in \mathbb{Q}_+ \text{ and some odd periodic function } \varepsilon\,, \tag{3.11}$$

the former being a modular form of weight 1/2 and the latter a cusp form of weight 3/2. A theorem of Serre and Stark says that in fact every modular form of weight 1/2 is a linear combination of form of the type (3.10), a simple example being the identity

$$\eta(\tau) \;:=\; q^{1/24}\prod_{n=1}^{\infty}(1-q^n) \;=\; \sum_{n=1}^{\infty}\chi_{12}(n)\, q^{n^2/24}\,, \tag{3.12}$$

proved by Euler for the so-called *Dedekind eta function* $\eta(t) = \Delta(\tau)^{1/24}$. Here χ_{12} is the function of period 12 defined by

$$\chi_{12}(n) \;=\; \begin{cases} +1 \text{ if } n \equiv \pm 1 \,(\mathrm{mod}\, 12) \\ -1 \text{ if } n \equiv \pm 5 \,(\mathrm{mod}\, 12) \\ 0 \quad \text{if } (n, 12) > 1\ . \end{cases} \tag{3.13}$$

Finally, we recall the definition of the Petersson scalar product. If $f(\tau)$ and $g(\tau)$ are two modular forms of the same weight k and the same "multiplier system" on some subgroup Γ of finite index of $SL_2(\mathbb{Z})$ (this means that the quotient f/g is invariant under Γ), and if either $k < 1$ or else at least one of f and g is a cusp form, then we can define the (normalized) *Petersson scalar product* of f and g by

$$\big(f, g\big) \;=\; \int_{\mathcal{F}_\Gamma} f(\tau)\,\overline{g(\tau)}\,\tau_2^k\, d\mu(\tau) \Big/ \int_{\mathcal{F}_\Gamma} d\mu(\tau) \qquad \Big(d\mu(\tau) \;:=\; \frac{d\tau_1 d\tau_2}{\tau_2^2}\Big)\,, \tag{3.14}$$

where $\mathcal{F}_\Gamma$ is a fundamental domain for Γ. This definition is independent of the choice of the subgroup Γ and the fundamental domain $\mathcal{F}_\Gamma$. By the Rankin-Selberg formula (see, for example, [127]), we have that if $f = \sum_\lambda a_\lambda q^\lambda$ and $g = \sum_\lambda b_\lambda q^\lambda$ (where $\lambda \geq 0$ may have a denominator), then

$$(f, g) \;=\; \frac{\Gamma(k)}{(4\pi)^k}\, \mathrm{Res}_{s=k}\Bigg(\sum_{\lambda>0}\frac{a_\lambda\,\overline{b_\lambda}}{\lambda^s}\Bigg)\,, \tag{3.15}$$

a formula that will be used later. For instance, for $f = g = \eta$ we have $k = 1/2$ and $\sum_\lambda a_\lambda b_\lambda \lambda^{-s} = 24^s(1-2^{-2s})(1-3^{-2s})\,\zeta(2s)$, and hence $(\eta, \eta) = 1/\sqrt{6}$.

3.2 Quantum black holes and modular forms

Modular forms occur naturally in the context of counting the Dabholkar-Harvey (DH) states [39, 32], which are states in the string Hilbert space that are dual to perturbative BPS states. The spacetime helicity supertrace counting the degeneracies reduces to the partition function of a chiral conformal field theory on a genus-one worldsheet. The τ parameter above becomes the modular parameter of the genus one Riemann surface. The degeneracies are given by the Fourier coefficients of the partition function.

A well-known simple example is the partition function $Z(\tau)$ which counts the half-BPS DH states for the Type-II compactification on $K3 \times T^2$ considered here. In the notation of (2.3) these states have zero magnetic charge $M = 0$, but nonzero electric charge N with the T-duality invariant $N^2 = 2n$, which can be realized for example by setting $Q_1 = Q_5 = l = 0$ in (2.15). They are thus purely electric and perturbative in the heterotic frame[6]. The partition function is given by the partition function of the chiral conformal field theory of 24 left-moving transverse bosons of the heterotic string. The Hilbert space $\mathcal{H}$ of this theory is a unitary Fock space representation of the commutation algebra

$$[a_{in}, a^{\dagger}_{jm}] \;=\; \delta_{ij}\,\delta_{n+m,0} \qquad (i,\, j = 1, \ldots, 24\,, \quad n,\, m = 1,\, 2, \ldots, \infty) \tag{3.16}$$

of harmonic modes of oscillations of the string in 24 different directions. The Hamiltonian is

$$H \;=\; \sum_{i=1}^{24} n\, a^{\dagger}_{in}\, a_{in} \;-\; 1\,, \tag{3.17}$$

and the partition function is

$$Z(\tau) \;=\; \mathrm{Tr}_{\mathcal{H}}(q^{H})\,. \tag{3.18}$$

This can be readily evaluated since each oscillator mode of energy n contributes to the trace

$$1 + q^n + q^{2n} + \ldots \;=\; \frac{1}{1 - q^n}\,. \tag{3.19}$$

The partition function then becomes

$$Z(\tau) \;=\; \frac{1}{\Delta(\tau)}\,, \tag{3.20}$$

where Δ is the cusp form (3.6). Since Δ has a simple zero at $q = 0$, the partition function itself has a pole at $q = 0$, but has no other poles in $\mathbb{H}$. Hence, $Z(\tau)$ is a weakly holomorphic modular form of weight -12. This property is essential in the present physical context since it determines the asymptotic growth of the Fourier coefficients.

---

[6] Not all DH states are half-BPS. For example, the states that are perturbative in the Type-II frame correspond to a Type-II string winding and carrying momentum along a cycle in T^2. For such states both M and N are nonzero and nonparallel, and hence the state is quarter- BPS.

The degeneracy $d(n)$ of the state with electric charge N depends only on the T-duality invariant integer n and is given by

$$Z(\tau) \;=\; \sum_{n=-1}^{\infty} d(n)\, q^n \,. \tag{3.21}$$

For the Fourier integral

$$d(n) \;=\; \int_C e^{-2\pi i\tau n} Z(\tau) d\tau \,, \tag{3.22}$$

one can choose the contour $\mathcal{C}$ in $\mathbb{H}$ to be

$$0 \le \mathrm{Re}(\tau) < 1 \,, \tag{3.23}$$

for a fixed imaginary part $\mathrm{Im}(\tau)$. Since the partition function has no poles in $\mathbb{H}$ except at $q = 0$, smooth deformations of the contour do not change the Fourier coefficients and consequently the degeneracies $d(n)$ are uniquely determined from the partition function. This reflects the fact that the half-BPS states are immortal and do not decay anywhere in the moduli space. As a result, there is no wall crossing phenomenon, and no jumps in the degeneracy.

In number theory, the partition function above is well-known in the context of the problem of partitions of integers. We can therefore identify

$$d(n) \;=\; p_{24}(n+1) \qquad (n \ge 0) \,. \tag{3.24}$$

where $p_{24}(I)$ is the number of colored partitions of a positive integer I using integers of 24 different colors.

These states have a dual description in the Type-II frame where they can be viewed as bound states of Q_1 number of D1-branes and Q_5 number of D5-branes with $M^2/2 = Q_1 Q_5 \equiv m$. This corresponds to setting $n = \tilde{K} = l = 0$ in (2.15). In this description, the number of such bound states $d(m)$ equals the orbifold Euler character $\chi(\mathrm{Sym}^{m+1}(K3))$ of the symmetric product of $(m+1)$ copies of $K3$-surface [120]. The generating function for the orbifold Euler character

$$\hat{Z}(\sigma) = \sum_{m=-1}^{\infty} \chi(\mathrm{Sym}^{m+1}(K3))\, p^m \qquad \big(p := e^{2\pi i\sigma}\big) \tag{3.25}$$

can be evaluated [65] to obtain

$$\hat{Z}(\sigma) = \frac{1}{\Delta(\sigma)} \,. \tag{3.26}$$

Duality requires that the number of immortal BPS-states of a given charge must equal the number of BPS-states with the dual charge. The equality of the two partition functions (3.20) and (3.26) coming from two very different counting problems is consistent with this expectation. This fact was indeed one of the early indications of a possible duality between heterotic and Type-II strings [120].

The DH-states correspond to the microstates of a small black hole [103, 28, 40] for large n. The macroscopic entropy $S(n)$ of these black holes should equal the asymptotic growth of the degeneracy by the Boltzmann relation

$$S(n) = \log d(n); \quad n \gg 1\,. \tag{3.27}$$

In the present context, the macroscopic entropy can be evaluated from the supergravity solution of small black holes [81, 84, 83, 82, 28, 40]. The asymptotic growth of the microscopic degeneracy can be evaluated using the Hardy-Ramanujan expansion (Cardy formula). There is a beautiful agreement between the two results [28, 79]

$$S(n) \;=\; \log d(n) \sim 4\pi\sqrt{n} \quad n \gg 1\,. \tag{3.28}$$

Given the growth properties of the Fourier coefficients mentioned above, it is clear that, for a black hole whose entropy scales as a power of n and not as $\log(n)$, the partition function counting its microstates can be only weakly holomorphic and not holomorphic.

These considerations generalize in a straightforward way to congruence subgroups of $SL(2,\mathbb{Z})$ which are relevant for counting the DH-states in various orbifold compactifications with $\mathcal{N} = 4$ or $\mathcal{N} = 2$ supersymmetry [29, 104, 30].

4. Jacobi forms

4.1 Basic definitions

Consider a holomorphic function $\varphi(\tau, z)$ from $\mathbb{H} \times \mathbb{C}$ to $\mathbb{C}$ which is "modular in τ and elliptic in z" in the sense that it transforms under the modular group as

$$\varphi\Big(\frac{a\tau+b}{c\tau+d}, \frac{z}{c\tau+d}\Big) \;=\; (c\tau+d)^k\, e^{\frac{2\pi i m c z^2}{c\tau+d}}\, \varphi(\tau, z) \qquad \forall \quad \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in SL(2;\mathbb{Z}) \tag{4.1}$$

and under the translations of z by $\mathbb{Z}\tau + \mathbb{Z}$ as

$$\varphi(\tau, z+\lambda\tau+\mu) \;=\; e^{-2\pi i m(\lambda^2\tau+2\lambda z)}\varphi(\tau, z) \qquad \forall \quad \lambda,\, \mu \in \mathbb{Z}\,, \tag{4.2}$$

where k is an integer and m is a positive integer.

These equations include the periodicities $\varphi(\tau+1, z) = \varphi(\tau, z)$ and $\varphi(\tau, z+1) = \varphi(\tau, z)$, so φ has a Fourier expansion

$$\varphi(\tau, z) \;=\; \sum_{n,r} c(n, r)\, q^n\, y^r\,, \qquad\qquad (q := e^{2\pi i\tau},\; y := e^{2\pi i z})\;. \tag{4.3}$$

Equation (4.2) is then equivalent to the periodicity property

$$c(n,r) \;=\; C(4nm-r^2,\,r)\;, \qquad \text{where } C(\Delta,r) \text{ depends only on } r \pmod{2m}\;. \tag{4.4}$$

(We will sometimes denote $c(n,r)$ and $C(\Delta,r)$ by $c_\varphi(n,r)$ and $C_\varphi(\Delta,r)$ or by $c(\varphi;n,r)$ and $C(\varphi\,;\Delta,r)$ when this is required for emphasis or clarity.) The function $\varphi(\tau,z)$ is called a *holomorphic Jacobi form* (or simply a *Jacobi form*) of weight k and index m if the coefficients $C(\Delta,r)$ vanish for $\Delta<0$, *i.e.* if

$$c(n,r) \;=\; 0 \qquad \text{unless} \qquad 4mn \geq r^2\,. \tag{4.5}$$

It is called a *Jacobi cusp form* if it satisfies the stronger condition that $C(\Delta,r)$ vanishes unless Δ is strictly positive, *i.e.*

$$c(n,r)=0 \qquad \text{unless} \qquad 4mn > r^2\;, \tag{4.6}$$

and it is called a *weak Jacobi form* if it satisfies the weaker condition

$$c(n,r) \;=\; 0 \qquad \text{unless} \qquad n\geq 0 \tag{4.7}$$

rather than (4.5), whereas a merely *weakly holomorphic Jacobi form* satisfies only the yet weaker condition that $c(n,r)=0$ unless $n\geq n_0$ for some possibly negative integer n_0 (or equivalently $C(\Delta,r)=0$ unless $\Delta\geq\Delta_0$ for some possibly negative integer Δ_0). The space of all holomorphic (resp. cuspidal, weak, or weakly holomorphic) Jacobi forms of weight k and index m will be denoted by $J_{k,m}$ (resp. $J^0_{k,m}$, $\widetilde{J}_{k,m}$, or $\widetilde{J}^!_{k,m}$).

Finally, the quantity $\Delta=4mn-r^2$, which by virtue of the above discussion is the crucial invariant of a monomial q^ny^r occurring in the Fourier expansion of φ, will be referred to as its *discriminant*. (It would be mathematically more correct to use this word for the quantity $-\Delta$, but Δ is usually positive and it is more convenient to work with positive numbers.)

4.2 Theta expansion and Taylor expansion

A Jacobi form has two important representations, the *theta expansion* and the *Taylor expansion*. In this subsection, we explain both of these and the relation between them.

If $\varphi(\tau,z)$ is a Jacobi form, then the transformation property (4.2) implies its Fourier expansion with respect to z has the form

$$\varphi(\tau,z) \;=\; \sum_{\ell\,\in\,\mathbb{Z}} q^{\ell^2/4m}\; h_\ell(\tau)\; e^{2\pi i\ell z} \tag{4.8}$$

where $h_\ell(\tau)$ is periodic in ℓ with period $2m$. In terms of the coefficients (4.4) we have

$$h_\ell(\tau) \;=\; \sum_{\Delta} C(\Delta,\ell)\, q^{\Delta/4m} \qquad\qquad (\ell\,\in\,\mathbb{Z}/2m\mathbb{Z})\;. \tag{4.9}$$

Because of the periodicity property, equation (4.8) can be rewritten in the form

$$\varphi(\tau,z) = \sum_{\ell\,\in\,\mathbb{Z}/2m\mathbb{Z}} h_\ell(\tau)\,\vartheta_{m,\ell}(\tau,z)\,, \tag{4.10}$$

where $\vartheta_{m,\ell}(\tau,z)$ denotes the standard index m theta function

$$\vartheta_{m,\ell}(\tau,z) \;:=\; \sum_{\substack{r\,\in\,\mathbb{Z}\\ r\,\equiv\,\ell\,(\mathrm{mod}\,2m)}} q^{r^2/4m}\,y^r \;\;=\; \sum_{n\,\in\,\mathbb{Z}} q^{(\ell+2mn)^2/4m}\,y^{\ell+2mn} \tag{4.11}$$

(which is a Jacobi form of weight $\frac{1}{2}$ and index m on some subgroup of $SL(2,\mathbb{Z})$). This is the theta expansion of φ. The coefficiens $h_\ell(\tau)$ are modular forms of weight $k-\frac{1}{2}$ and are weakly holomorphic, holomorphic or cuspidal if φ is a weak Jacobi form, a Jacobi form or a Jacobi cusp form, respectively. More precisely, the vector $h := (h_1,\ldots,h_{2m})$ transforms like a modular form of weight $k-\frac{1}{2}$ under $SL(2,\mathbb{Z})$.

The theta decomposition (4.10) leads to the definition of a differential operator on Jacobi forms as follows. Let

$$\mathcal{L}_m \;=\; \frac{4m}{2\pi i}\,\frac{\partial}{\partial\tau} \;-\; \frac{1}{(2\pi i)^2}\,\frac{\partial^2}{\partial z^2}$$

be the index m heat operator, which sends $\varphi = \sum c(n,r)q^ny^r$ to $\sum(4nm-r^2)c(n,r)q^ny^r$. Here the Fourier coefficients have the same periodicity property (4.4) as for φ, so $\mathcal{L}_m\varphi$ has the same elliptic transformation properties as a Jacobi form of index m. Moreover, since $\mathcal{L}_m$ annihilates all the $\vartheta_{m,\ell}$, we have $\mathcal{L}_m(\sum h_\ell\vartheta_{m,\ell}) = 4m\sum h_\ell'\vartheta_{m,\ell}$, so the modified heat operator

$$\mathcal{L}_{k,m} = \mathcal{L}_m - \frac{m(k-\frac{1}{2})}{3}\,E_2 \;\;:\;\; \sum_\ell h_\ell(\tau)\,\vartheta_{m,\ell}(\tau,z) \;\mapsto\; 4m\sum_\ell \partial^{\mathrm{RS}}_{k-\frac{1}{2}} h_\ell(\tau)\,\vartheta_{m,\ell}(\tau,z)\,, \tag{4.12}$$

where $\partial^{\mathrm{RS}}_{*}$ is the Ramanujan-Serre derivative defined in (3.7), sends $J_{k,m}$ to $J_{k+2,m}$ (and also $\widetilde{J}_{k,m}$ to $\widetilde{J}_{k+2,m}$ and $J^!_{k,m}$ to $J^!_{k+2,m}$). These operators will be used later.

A Jacobi form $\varphi \in \widetilde{J}_{k,m}$ also has a Taylor expansion in z which for k even takes the form

$$\varphi(\tau,z) \;=\; \xi_0(\tau) + \left(\frac{\xi_1(\tau)}{2} + \frac{m\xi_0'(\tau)}{k}\right)(2\pi iz)^2 + \left(\frac{\xi_2(\tau)}{24} + \frac{m\xi_1'(\tau)}{2\,(k+2)} + \frac{m^2\xi_0''(\tau)}{2k(k+1)}\right)(2\pi iz)^4 + \cdots \tag{4.13}$$

with $\xi_\nu \in M_{k+2\nu}(SL(2,\mathbb{Z}))$ and the prime denotes $\frac{1}{2\pi i}\frac{d}{d\tau}$ as before. In terms of the Fourier coefficients of φ, the modular form ξ_ν is given by

$$\frac{(k+2\nu-2)!}{(k+\nu-2)!}\,\xi_\nu(\tau) \;=\; \sum_{n=0}^{\infty}\left(\sum_r P_{\nu,k}(nm,r^2)c(n,r)\right)q^n\,, \tag{4.14}$$

where $P_{\nu,k}$ is a homogeneous polynomial of degree ν in r^2 and n with coefficients depending on k and m, the first few being

$$\begin{aligned} P_{0,k} &= 1 \,, \\ P_{1,k} &= kr^2 \,-\, 2nm \,, \\ P_{2,k} &= (k+1)(k+2)r^4 \,-\, 12(k+1)r^2mn \,+\, 12m^2n^2 \,. \end{aligned} \tag{4.15}$$

The Jacobi form φ is determined by the first $m+1$ coefficients ξ_ν, and the map $\varphi \mapsto (\xi_0, \dots, \xi_m)$ is an isomorphism from $\widetilde{J}_{k,m}$ to $M_k \oplus M_{k+2} \oplus \cdots \oplus M_{k+2m}$. For k odd, the story is similar except that (4.13) must be replaced by

$$\varphi(\tau, z) \;=\; \xi_0(\tau)\,(2\pi iz) \,+\, \left(\frac{\xi_1(\tau)}{6} + \frac{m\xi_0'(\tau)}{k+2}\right)(2\pi iz)^3 \,+\, \cdots \tag{4.16}$$

with $\xi_\nu \in M_{k+2\nu+1}(SL(2,\mathbb{Z}))$, and the map $\varphi \mapsto (\xi_0, \dots, \xi_{m-2})$ gives an isomorphism from $\widetilde{J}_{k,m}$ to $M_{k+1} \oplus M_{k+3} \oplus \cdots \oplus M_{k+2m-3}$.

We also observe that even if φ is weak, so that the individual coefficients $c(n,r)$ grow like $C^{\sqrt{4nm-r^2}}$, the coefficients $\sum_r P_{\nu,k}(nm, r^2)\, c(n,r)$ of ξ_ν still have only polynomial growth. We thus have the following descriptions (analogous to those given for classical modular forms in §3.1) of holomorphic and weak Jacobi forms in terms of their asymptotic properties:

Holomorphic Jacobi $\iff$ $c(n,r) = 0$ for $4mn - r^2 < 0$
$\iff$ the function $q^{m\alpha^2}\varphi(\tau, \alpha\tau+\beta)$ (which is a modular form of weight k and some level) is bounded as $\tau_2 \to \infty$ for every $\alpha, \beta \in \mathbb{Q}$
$\iff$ all $h_j(\tau)$ in (4.10) are bounded as $\tau_2 \to \infty$
$\iff$ $c(n,r)$ have polynomial growth.

Weak Jacobi $\iff$ $c(n,r) = 0$ for $n < 0$
$\iff$ $\varphi(\tau, \alpha\tau+\beta)$ is bounded as $\tau_2 \to \infty$ for any fixed $z \in \mathbb{C}$
$\iff$ all $h_j(\tau) = O(q^{-j^2/4m})$ as $\tau_2 \to \infty$
$\iff$ $\sum_r P_{\nu,k}(nm, r^2)c(n,r)$ have polynomial growth.

Finally, the relation between the Taylor expansion (4.13) of a Jacobi form and its theta expansion (4.10) is given by

$$\xi_\nu(\tau) \;=\; (4m)^\nu \binom{k+2\nu-2}{\nu}^{-1} \sum_{\ell\,(\mathrm{mod}\,2m)} \big[h_\ell(\tau),\, \vartheta^0_{m,\ell}(\tau)\big]_\nu \;, \tag{4.17}$$

where $[\ ,\ ]_\nu = [\ ,\ ]_\nu^{(k-\frac{1}{2},\frac{1}{2})}$ denotes the Rankin-Cohen bracket (which, as we mentioned above, also works in half-integral weight), and $\vartheta^0_{m,\ell}(\tau) = \vartheta_{m,\ell}(\tau, 0)$ (Thetanullwerte). There is a similar formula in the odd case, but with $\vartheta^0_{m,\ell}(\tau)$ replaced by

$$\vartheta^1_{m,\ell}(\tau) \;=\; \frac{1}{2\pi i}\,\frac{\partial}{\partial z}\vartheta_{m,\ell}(\tau,z)\Big|_{z=0} \;=\; \sum_{r\equiv\ell\,(\mathrm{mod}\,2m)} r\,q^{r^2/4m}\,. \tag{4.18}$$

4.3 Example: Jacobi forms of index 1

If $m=1$, (4.4) reduces to $c(n,r)=C(4n-r^2)$ where $C(\Delta)$ is a function of a single argument, because $4n-r^2$ determines the value of $r\,(\mathrm{mod}\,2)$. So any $\varphi\in J^{\mathrm{weak}}_{k,1}$ has an expansion of the form

$$\varphi(\tau,z) \;=\; \sum_{n,r\in\mathbb{Z}} C(4n-r^2)\,q^n\,y^r\,. \tag{4.19}$$

It also follows that k must be even, since in general, $C(\Delta,-r)=(-1)^kC(\Delta,r)$.

One has the isomorphisms $J_{k,1}\cong M_k\oplus S_{k+2}$ and $J^{\mathrm{weak}}_{k,1}\cong M_k\oplus M_{k+2}$. If $\varphi\in J^{\mathrm{weak}}_{k,1}$ with an expansion as in (4.19), then

$$\varphi(\tau,0) \;=\; \sum_{n=0}^{\infty} a(n)\,q^n\,, \qquad \frac{1}{2(2\pi i)^2}\varphi''(\tau,0) \;=\; \sum_{n=0}^{\infty} b(n)\,q^n\,, \tag{4.20}$$

where

$$a(n) \;=\; \sum_{r\in\mathbb{Z}} C(4n-r^2)\,, \qquad b(n) \;=\; \sum_{r>0} r^2\,C(4n-r^2)\,, \tag{4.21}$$

and the isomorphisms are given (if $k>0$) by the map $\varphi\mapsto(\mathcal{A},\mathcal{B})$ with

$$\mathcal{A}(\tau) \;=\; \sum a(n)\,q^n\in M_k\,, \qquad \mathcal{B}(\tau) \;=\; \sum\bigl(kb(n)-na(n)\bigr)\,q^n\in M_{k+2}\,. \tag{4.22}$$

For $J_{k,1}$ one also has the isomorphism $J_{k,1}\cong M^+_{k-\frac{1}{2}}(\Gamma_0(4))$ given by

$$\varphi(\tau,z)\leftrightarrow g(\tau) \;=\; \sum_{\substack{\Delta\geq 0\\ \Delta\equiv 0,\,3\,\mathrm{mod}4}} C(\Delta)\,q^{\Delta}\,. \tag{4.23}$$

We have four particularly interesting examples $\varphi_{k,1}$

$$\varphi_{k,1}(\tau,z) \;=\; \sum_{n,\,r\in\mathbb{Z}} C_k(4n-r^2)\,q^n\,y^r\,, \quad k=-2,\,0,\,10,\,12\,, \tag{4.24}$$

which have the properties (defining them uniquely up to multiplication by scalars)

- $\varphi_{10,1}$ and $\varphi_{12,1}$ are the two index 1 Jacobi cusp forms of smallest weight;
- $\varphi_{-2,1}$ and $\varphi_{0,1}$ are the unique weak Jacobi forms of index 1 and weight ≤ 0;

- $\varphi_{-2,1}$ and $\varphi_{0,1}$ generate the ring of weak Jacobi forms of even weight freely over the ring of modular forms of level 1, so that

$$J_{k,m}^{\text{weak}} \;=\; \bigoplus_{j=0}^{m} M_{k+2j}\left(SL(2,\mathbb{Z})\right)\cdot\varphi_{-2,1}^{j}\,\varphi_{0,1}^{m-j} \qquad (k \text{ even})\,; \tag{4.25}$$

- $\varphi_{-2,1} = \varphi_{10,1}/\Delta$, $\varphi_{0,1} = \varphi_{12,1}/\Delta$, and the quotient $\varphi_{0,1}/\varphi_{-2,1} = \varphi_{12,1}/\varphi_{10,1}$ is a multiple of the Weierstrass $\wp$ function.

The Fourier coefficients of these functions can be computed from the above recursions, since the pairs $(\mathcal{A},\mathcal{B})$ for $\varphi = \varphi_{-2,1}$, $\varphi_{0,1}$, $\varphi_{10,1}$ and $\varphi_{12,1}$ are proportional to $(0,1)$, $(1,0)$, $(0,\Delta)$ and $(\Delta,0)$, respectively[7]. The results for the first few Fourier coefficients are given in Table 4.3 below. In particular, the Fourier expansions of $\varphi_{-2,1}$ and $\varphi_{0,1}$ begin

$$\varphi_{-2,1} \;=\; \frac{(y-1)^2}{y} \;-\; 2\,\frac{(y-1)^4}{y^2}\,q \;+\; \frac{(y-1)^4(y^2-8y+1)}{y^3}\,q^2 \;+\;\cdots\;, \tag{4.26}$$

$$\varphi_{0,1} \;=\; \frac{y^2+10y+1}{y} \;+\; 2\frac{(y-1)^2\,(5y^2-22y+5)}{y^2}\,q \;+\;\cdots\;. \tag{4.27}$$

k	$C_k(-1)$	$C_k(0)$	$C_k(3)$	$C_k(4)$	$C_k(7)$	$C_k(8)$	$C_k(11)$	$C_k(12)$	$C_k(15)$
-2	1	-2	8	-12	39	-56	152	-208	513
0	1	10	-64	108	-513	808	-2752	4016	-11775
10	0	0	1	-2	-16	36	99	-272	-240
12	0	0	1	10	-88	-132	1275	736	-8040

Table 1: Some Fourier coefficients

The functions $\varphi_{k,1}$ ($k = 10,\ 0,\ -2$) can be expressed in terms of the Dedekind eta function (3.12) and the Jacobi theta functions ϑ_1, ϑ_2, ϑ_3, ϑ_4 by the formlas

$$\varphi_{10,1}(\tau,z) \;=\; \eta^{18}(\tau)\,\vartheta_1^2(\tau,z)\,, \tag{4.28}$$

$$\varphi_{-2,1}(\tau,z) \;=\; \frac{\vartheta_1^2(\tau,z)}{\eta^6(\tau)} \;=\; \frac{\varphi_{10,1}(\tau,z)}{\Delta(\tau)}\;. \tag{4.29}$$

$$\varphi_{0,1}(\tau,z) \;=\; 4\left(\frac{\vartheta_2(\tau,z)^2}{\vartheta_2(\tau)^2}+\frac{\vartheta_3(\tau,z)^2}{\vartheta_3(\tau)^2}+\frac{\vartheta_4(\tau,z)^2}{\vartheta_4(\tau)^2}\right)\,, \tag{4.30}$$

Finally, we say a few words about Jacobi forms of odd weight. Such a form cannot have index 1, as we saw. In index 2, the isomorphisms $J_{k,2} \cong S_{k+1}$ and $J_{k,2}^{\text{weak}} \cong M_{k+1}$ show that the first examples of holomorphic and weak Jacobi forms occur in weights 11 and −1, respectively, and are related by $\varphi_{-1,2} = \varphi_{11,2}/\Delta$. The function $\varphi_{-1,2}$ is given explicitly by

---

[7] For $k = 0$, the second formula in (4.22) must be modified, and the function $\sum b(n)q^n$ for $\varphi_{0,1}$ is in fact $E_2(\tau)$.

$$\varphi_{-1,2}(\tau, z) \;=\; \frac{\vartheta_1(\tau, 2z)}{\eta^3(\tau)}\;, \tag{4.31}$$

with Fourier expansion beginning

$$\varphi_{-1,2} \;=\; \frac{y^2-1}{y} \;-\; \frac{(y^2-1)^3}{y^3}\,q \;-\; 3\,\frac{(y^2-1)^3}{y^3}\,q^2 \;+\; \cdots\;, \tag{4.32}$$

and its square is related to the index 1 Jacobi forms defined above by

$$432\,\varphi_{-1,2}^2 \;=\; \varphi_{-2,1}\left(\varphi_{0,1}^3 \;-\; 3\,E_4\,\varphi_{-2,1}^2\,\varphi_{0,1} \;+\; 2\,E_6\,\varphi_{-2,1}^3\right)\,. \tag{4.33}$$

(In fact, $\varphi_{-1,2}/\varphi_{-2,1}^2$ is a multiple of $\wp'(\tau,z)$ and this equation, divided by $\varphi_{-2,1}^4$, is just the usual equation expressing $\wp'^{\,2}$ as a cubic polynomial in $\wp$.) It is convenient to introduce abbreviations

$$A \;=\; \varphi_{-2,1}\,, \qquad B \;=\; \varphi_{0,1}\,, \qquad C \;=\; \varphi_{-1,2}\,. \tag{4.34}$$

With these notations, the structure of the full bigraded ring of weak Jacobi forms is given by

$$J_{*,*}^{\text{weak}} \;=\; \mathbb{C}[E_4, E_6, A, B, C]\,\big/\,(432C^2 - AB^3 + 3E_4A^3B - 2E_6A^4)\,. \tag{4.35}$$

4.4 Hecke-like operators

In [57] Hecke operators T_ℓ acting on $J_{k,m}$ were introduced, but also various "Hecke-like" operators, again defined by the action of certain combinations of elements of $GL(2,\mathbb{Q}) \rtimes \mathbb{Q}^2$, which send Jacobi forms to Jacobi forms, but now possibly changing the index. We describe these operators here. This subsection is more technical than the preceding three, but will be essential later.

The first is the very simple operator U_s $(s \geq 1)$ which sends $\varphi(\tau, z)$ to $\varphi(\tau, sz)$, i.e.,

$$U_s\;:\quad \sum_{n,r} c(n,r)\,q^n\,y^r \quad\mapsto\quad \sum_{n,r} c(n,r)\,q^n\,y^{sr}\;, \tag{4.36}$$

This operator maps $J_{k,m}$ to J_{k,s^2m}.

The second operator, $V_{k,t}$ $(t \geq 1)$, sends $J_{k,m}$ to $J_{k,tm}$. It is given in terms of its action on Fourier coefficients by

$$c(\varphi|V_{k,t}\,;n,r) \;=\; \sum_{d|(n,r,t)} d^{k-1}c\Big(\varphi\,;\frac{nt}{d^2},\frac{r}{d}\Big)\,, \qquad C(\varphi|V_{k,t}\,;\Delta,r) \;=\; \sum_{d|(\frac{r^2+\Delta}{4mt},r,t)} d^{k-1}C\Big(\varphi\,;\frac{\Delta}{d^2},\frac{r}{d}\Big)\,. \tag{4.37}$$

In §9, we will also need the modified operator $\mathcal{V}_{k,t}^{(m)} : J_{k,m} \mapsto J_{k,tm}$ defined by

$$\mathcal{V}_{k,t}^{(m)} \;=\; \sum_{\substack{s^2|t\\(s,m)=1}} \mu(s)\, s^{k-1}\, V_{k,t/s^2}\, U_s\,, \tag{4.38}$$

so that, for instance, $\mathcal{V}_{k,t}^{(m)} = V_{k,t}$ if t is square-free, but $\mathcal{V}_{k,4}^{(m)} = V_{k,4} - 2^{k-1}U_2$ if m is odd.

Next, for each positive integer m_1 with $m_1 \| m$ (this means that $m = m_1 m_2$ with m_1 and m_2 coprime) we have an involution W_{m_1} on $J_{k,m}$, which we will call an *Atkin-Lehner involution,*[8] that is defined in terms of the theta expansion of Jacobi forms by

$$W_{m_1}\;:\quad \sum_{\ell\;(\mathrm{mod}\,2m)} h_\ell(\tau)\,\vartheta_{m,\ell}(\tau,z) \quad\mapsto\quad \sum_{\ell\;(\mathrm{mod}\,2m)} h_{\ell^*}(\tau)\,\vartheta_{m,\ell}(\tau,z) \tag{4.39}$$

(or equivalently by $C(\Delta,r) \mapsto C(\Delta,r^*)$), where the involution $\ell \mapsto \ell^*$ on $\mathbb{Z}/2m\mathbb{Z}$ is defined by

$$\ell^* \equiv -\ell \,(\mathrm{mod}\,2m_1), \qquad \ell^* \equiv +\ell\,(\mathrm{mod}\,2m_2)\;. \tag{4.40}$$

These operators commute and satisfy $W_{m/m_1} = (-1)^k W_{m_1}$, so that we get an eigenspace decomposition

$$J_{k,m} \;=\; \bigoplus_{\substack{\boldsymbol{\varepsilon}=(\varepsilon_1,\ldots,\varepsilon_t)\,\in\,\{\pm1\}^t\\ \varepsilon_1\cdots\varepsilon_t\,=\,(-1)^k}} J_{k,m}^{\boldsymbol{\varepsilon}}\;, \tag{4.41}$$

where $m = p_1^{r_1}\cdots p_t^{r_t}$ is the prime power decomposition of m and ε_i is the eigenvalue of $W_{p_i^{r_i}}$. One can also introduce the "p-adic Atkin-Lehner involution" W_{p^∞}, which acts on any $J_{k,m}$ as W_{p^ν} where $p^\nu \| m$. (In particular, it acts as the identity if $p \nmid m$.) This operator simply changes the second index r in $C(\Delta,r)$ to r^*, where r is equal to the negative of r^* p-adically and to r^* p'-adically for any $p' \neq p$. In particular, W_{p^∞} commutes with all U_s, $V_{k,t}$, and $\mathcal{V}_{k,t}^m$.

We now describe a further Hecke-like operator, which was not given in [57] but is mentioned briefly in [115], p. 139, and which we will also need in the sequel. If t is a positive integer whose square divides m, then we define $u_t:\; J_{k,m} \;\longrightarrow J_{k,m/t^2}$ by

$$u_t\;:\quad \sum_{n,r} c(n,r)\,q^n\,y^r \quad\mapsto\quad \sum_{n,r}\Bigg(\sum_{a\;(\mathrm{mod}\;t)} c\big(n + ar + \frac{m}{t^2}a^2,\; tr + \frac{2ma}{t}\big)\Bigg)\,q^n\,y^r \tag{4.42}$$

or equivalently by

$$C_{\varphi|u_t}(\Delta,\;\ell\;(\mathrm{mod}\;2m/t^2)) \;=\; \sum_{\substack{r\;(\mathrm{mod}\;2m/t)\\ r\equiv\ell\;(\mathrm{mod}\;2m/t^2)}} C_\varphi(\Delta t^2,\; rt\;(\mathrm{mod}\;2m))\;. \tag{4.43}$$

---

[8] This terminology was not used in [57], where these involutions were introduced, but is justified by the results of [115] where it is shown that they correspond in a precise sense to the Atkin-Lehner involutions on the space of modular forms of weight $2k-2$ and level m.

It is easily checked that this map does indeed send Jacobi forms to Jacobi forms of the index stated, and that for any integers m, $t > 0$, the composite map $J_{k,m/t^2} \xrightarrow{U_t} J_{k,m} \xrightarrow{u_t} J_{k,m/t^2}$ is simply multiplication by t (because, if $\varphi = \varphi_1 \,|\, U_t$ with φ_1 of index m/t^2, then each term on the right of (4.43) equals $C_{\varphi_1}(\Delta, \ell)$). It follows that we have

$$J_{k,m} \;=\; \bigoplus_{t^2|m} J^{\text{prim}}_{k,\frac{m}{t^2}} \,|\, U_t \,, \tag{4.44}$$

where

$$J^{\text{prim}}_{k,m} \;=\; \bigcap_{\substack{t^2|m\\ t>1}} \ker\big(J_{k,m} \xrightarrow{u_t} J_{k,m/t^2}\big) \;=\; \bigcap_{\substack{p^2|m\\ p\text{ prime}}} \ker\big(J_{k,m} \xrightarrow{u_p} J_{k,m/p^2}\big) \tag{4.45}$$

(the equivalence of the two definitions follows because $u_t\, u_{t'} \,=\, u_{tt'}$ for any t, t'), with the projection map $\pi^{\text{prim}} : J_{k,m} \mapsto J^{\text{prim}}_{k,m}$ onto the first factor in (4.44) given by

$$\pi^{\text{prim}}(\varphi) \;=\; \sum_{t^2|m} \frac{\mu(t)}{t}\, \varphi \,|\, u_t \,|\, U_t \,. \tag{4.46}$$

We will sometimes find it useful to work, not with the space of Jacobi forms, but with the larger space of holomorphic functions on $\mathbb{H} \times \mathbb{C}$ that obey the elliptic transformation law (4.2) of Jacobi forms, but are not required to obey the modular transformation property (4.1). We shall call such functions *elliptic forms*. (The word *Jacobi-like forms* has been used in the literature to denote functions which, conversely, satisfy (4.1) but not (4.2).) Any elliptic form has a Fourier expansion as in (4.3) with the periodicity condition (4.4). We will denote by $\mathcal{E}_m$, $\mathcal{E}^0_m$, $\widetilde{\mathcal{E}}_m$ the spaces of all elliptic forms of index m satisfying the growth conditions (4.5), (4.6), and (4.7), respectively, and we will call them *holomorphic, cuspidal*, and *weak* respectively. We also denote by $\mathcal{E}_{\pm,m}$, $\mathcal{E}^0_{\pm,m}$, $\widetilde{\mathcal{E}}_{\pm,m}$ the $(\pm1)-$eigenspaces of theta functions under the involution $\varphi(\tau, z) \mapsto \varphi(\tau, -z)$, i.e., those functions whose Fourier coefficients $c(n, r)$ satisfy the parity condition $c(n, -r) = \pm c(n, r)$. Because any Jacobi form of weight k satisfies this parity condition with $\pm1 = (-1)^k$ (by (4.1) applied to $-\mathbf{1}_2$), we have

$$J_{k,m} \subset \mathcal{E}_{\pm,m}\,, \quad J^0_{k,m} \subset \mathcal{E}^0_{\pm,m}\,, \quad \widetilde{J}_{k,m} \subset \widetilde{\mathcal{E}}_{\pm,m} \qquad \big((-1)^k = \pm1\big)\,. \tag{4.47}$$

It is now clear from the definitions above that all of the Hecke-like operators V_t, U_t, W_{m_1} for $(m_1, m/m_1) = 1$ and u_t for $t^2|m$ defined in this section extend from the space of Jacobi forms to the space of elliptic forms, and that the decompositions (4.41) and (4.44) remain true if we replace all the J_ks by $\mathcal{E}_+$s.

Finally, we should warn the reader explicitly that, although the operators U_t and V_t also act on the spaces $\widetilde{J}_{k,*}$ and $\widetilde{\mathcal{E}}_{\pm,*}$ of weak Jacobi or weak elliptic forms, the operators W_{m_1} and u_t do not: the condition (4.7) is equivalent to saying that $C(\Delta, \ell)$ for $|\ell| \le m$ vanishes whenever $\Delta <$

$-\ell^2$, and this condition is preserved neither under the permutation $\ell \pmod{2m} \mapsto \ell^* \pmod{2m}$ defining W_{m_1}, nor by the summation conditions in (4.43). As a concrete example, the 7-dimensional space $\widetilde{J}_{2,6}$ contains a 6-dimensional subspace of forms invariant under the involution W_2, but no anti-invariant form, and its image under the projection operator $\pi_2^- = \frac{1}{2}(1 - W_2)$ to anti-invariant forms is the 1-dimensional space spanned by

$$\varphi_{2,6}^-(\tau, z) \;=\; j'(\tau)\,\frac{\vartheta_1(\tau, 4z)}{\vartheta_1(\tau, 2z)} \;=\; \sum_{n,\,r\in\mathbb{Z}} \chi_{12}(r)\, C_{2,6}(24n - r^2)\; q^n\, y^r\,, \tag{4.48}$$

with

Δ	≤ -49	-25	-1	23	47	71	$\cdots$
$C_{2,6}(\Delta)$	0	-1	-1	196882	43184401	2636281193	$\cdots$

,

which is a weakly holomorphic but not a weak Jacobi form. (Specifically, for any $\varphi \in \widetilde{J}_{2,6}$ we have $\pi_2^-(\varphi) = 6\, c_\varphi(0,5)\, \varphi_{2,6}^-\,$.)

4.5 Quantum black holes and Jacobi forms

Jacobi forms usually arise in string theory as elliptic genera of two-dimensional superconformal field theories (SCFT) with $(2,2)$ or more worldsheet supersymmetry[9]. We denote the superconformal field theory by $\sigma(\mathcal{M})$ when it corresponds to a sigma model with a target manifold $\mathcal{M}$. Let H be the Hamiltonian in the Ramond sector, and J be the left-moving $U(1)$ R-charge. The elliptic genus $\chi(\tau, z; \mathcal{M})$ is then defined as [123, 3, 97] a trace over the Hilbert space $\mathcal{H}_R$ in the Ramond sector

$$\chi(\tau, z; \mathcal{M}) \;=\; \mathrm{Tr}_{\mathcal{H}_R}\big((-1)^F q^H y^J\big)\,, \tag{4.49}$$

where F is the fermion number.

An elliptic genus so defined satisfies the modular transformation property (4.1) as a consequence of modular invariance of the path integral. Similarly, it satisfies the elliptic transformation property (4.2) as a consequence of spectral flow. Furthermore, in a unitary SCFT, the positivity of the Hamiltonian implies that the elliptic genus is a weak Jacobi form. The decomposition (4.10) follows from bosonizing the $U(1)$ current in the standard way so that the contribution to the trace from the momentum modes of the boson can be separated into the theta function (4.11). See, for example, [77, 93] for a discussion. This notion of the elliptic genus can be generalized to a $(0,2)$ theory using a left-moving $U(1)$ charge J which may not be an R- charge. In this case spectral flow is imposed as an additional constraint and follows from gauge invariance under large gauge transformations [44, 61, 80, 48].

A particularly useful example in the present context is $\sigma(K3)$, which is a $(4,4)$ SCFT whose target space is a $K3$ surface. The elliptic genus is a topological invariant and is independent of the moduli of the $K3$. Hence, it can be computed at some convenient point in the $K3$ moduli space, for example, at the orbifold point where the $K3$ is the Kummer surface. At this point, the $\sigma(K3)$ SCFT can be regarded as a $\mathbb{Z}_2$ orbifold of the $\sigma(T^4)$ SCFT, which is an SCFT with a torus T^4 as the target space. A simple computation using standard techniques of orbifold conformal field theory [43, 63] yields

---

[9] An SCFT with (r,s) supersymmetries has r left-moving and s right-moving supersymmetries.

$$\chi(\tau, z; K3) \;=\; 2\,\varphi_{0,1}(\tau, z) \;=\; 2\sum C_0(4n - l^2)\, q^n\, y^l\,. \tag{4.50}$$

Note that for $z = 0$, the trace (4.49) reduces to the Witten index of the SCFT and correspondingly the elliptic genus reduces to the Euler character of the target space manifold. In our case, one can readily verify from (4.50) and (4.30) that $\chi(\tau, 0; K3)$ equals 24, which is the Euler character of $K3$.

A well-known physical application of Jacobi forms is in the context of the five-dimensional Strominger-Vafa black hole[118], which is a bound state of Q_1 D1-branes, Q_5 D5-branes, n units of momentum and l units of five-dimensional angular momentum [12]. The degeneracies $d_m(n, l)$ of such black holes depend only on $m = Q_1Q_5$. They are given by the Fourier coefficients $c(n, l)$ of the elliptic genus $\chi(\tau, z; \mathrm{Sym}^{m+1}(K3))$ of symmetric product of $(m+1)$ copies of $K3$-surface.

Let us denote the generating function for the elliptic genera of symmetric products of K3 by

$$\widehat{Z}(\sigma, \tau, z) := \sum_{m=-1}^{\infty} \chi(\tau, z; \mathrm{Sym}^{m+1}(K3))\, p^m \tag{4.51}$$

where $\chi_m(\tau, z)$ is the elliptic genus of $\mathrm{Sym}^m(K3)$. A standard orbifold computation [50] gives

$$\widehat{Z}(\sigma, \tau, z) = \frac{1}{p} \prod_{r>0,\; s\geq 0,\; t} \frac{1}{(1 - q^s y^t p^r)^{2C_0(rs,t)}} \tag{4.52}$$

in terms of the Fourier coefficients $2C_o$ of the elliptic genus of a single copy of $K3$.

For $z = 0$, it can be checked that, as expected, the generating function (4.52) for elliptic genera reduces to the generating function (3.26) for Euler characters

$$\widehat{Z}(\sigma, \tau, 0) = \hat{Z}(\sigma) = \frac{1}{\Delta(\sigma)}\,. \tag{4.53}$$

5. Siegel modular forms

5.1 Definitions and examples of Siegel modular forms

Let $Sp(2, \mathbb{Z})$ be the group of (4×4) matrices g with integer entries satisfying $gJg^t = J$ where

$$J \equiv \begin{pmatrix} 0 & -I_2 \\ I_2 & 0 \end{pmatrix} \tag{5.1}$$

is the symplectic form. We can write the element g in block form as

$$\begin{pmatrix} A & B \\ C & D \end{pmatrix}, \tag{5.2}$$

where A, B, C, D are all (2×2) matrices with integer entries. Then the condition $gJg^t = J$ implies

$$AB^t = BA^t, \qquad CD^t = DC^t, \qquad AD^t - BC^t = \mathbf{1}\,, \tag{5.3}$$

Let $\mathbb{H}_2$ be the (genus two) Siegel upper half plane, defined as the set of (2×2) symmetric matrix Ω with complex entries

$$\Omega = \begin{pmatrix} \tau & z \\ z & \sigma \end{pmatrix} \tag{5.4}$$

satisfying

$$\mathrm{Im}(\tau) > 0, \quad \mathrm{Im}(\sigma) > 0, \quad \det(\mathrm{Im}(\Omega)) > 0\,. \tag{5.5}$$

An element $g \in Sp(2,\mathbb{Z})$ of the form (5.2) has a natural action on $\mathbb{H}_2$ under which it is stable:

$$\Omega \to (A\Omega + B)(C\Omega + D)^{-1}. \tag{5.6}$$

The matrix Ω can be thought of as the period matrix of a genus two Riemann surface[10] on which there is a natural symplectic action of $Sp(2,\mathbb{Z})$.

A Siegel form $F(\Omega)$ of weight k is a holomorphic function $\mathbb{H}_2 \to \mathbb{C}$ satisfying

$$F\big((A\Omega + B)(C\Omega + D)^{-1}\big) \;=\; \det(C\Omega + D)^k\, F(\Omega)\,. \tag{5.7}$$

A Siegel modular form can be written in terms of its Fourier series

$$F(\Omega) \;=\; \sum_{\substack{n,\,r,\,m\,\in\,\mathbb{Z} \\ r^2 \le 4mn}} a(n,r,m)\, q^n\, y^r\, p^m\,. \tag{5.8}$$

If one writes this as

$$F(\Omega) = \sum_{m=0}^{\infty} \varphi^{\mathrm{F}}_m(\tau,z)\, p^m \tag{5.9}$$

with

$$\varphi^F_m(\tau,z) \;=\; \sum_{n,\,r} a(n,r,m)\, q^n\, y^r\,, \tag{5.10}$$

then each $\varphi^{\mathrm{F}}_m (m \ge 0)$ is a Jacobi form of weight k and index m.

---

[10] See [59, 41, 9] for a discussion of the connection with genus-two Riemann surfaces.

An important special class of Siegel forms were studied by Maass which he called the *Spezialschar*. They have the property that $a(n,r,m)$ depends only on the discriminant $4mn-r^2$ if (n,r,m) are coprime, and more generally

$$a(n,r,m) \;=\; \sum_{d|(n,r,m),\; d>0} d^{k-1} C\Big(\frac{4mn-r^2}{d^2}\Big) \tag{5.11}$$

for some coefficients $C(N)$. Specializing to $m=1$, we can see that these numbers are simply the coefficients associated via (4.19) to the Jacobi form $\varphi = \varphi_1^{\mathrm{F}} \in J_{k,1}$, and that (5.11) says precisely that the other Fourier-Jacobi coefficients of F are given by $\varphi_m^{\mathrm{F}} = \varphi_1^{\mathrm{F}}|V_m$ with V_m as in (4.37). Conversely, if φ is any Jacobi form of weight k and index 1 with Fourier expansion (4.19), then the function $F(\Omega)$ defined by (5.8) and (5.11) or by $F(\Omega) = \sum_{m=0}^{\infty}\big(\varphi|V_m\big)(\tau,z)\,p^m$ is a Siegel modular form of weight k with $\varphi_1^{\mathrm{F}} = \varphi$. The resulting map from $J_{k,1}$ to the Spezialschar is called the Saito-Kurokawa lift or *additive lift* since it naturally gives the sum representation of a Siegel form using the Fourier coefficients of a Jacobi form as the input. (More information about the additive lift can be found in [57].)

The example of interest to us is the Igusa cusp form Φ_{10} (the unique cusp form of weight 10) which is the Saito-Kurokawa lift of the Jacobi form $\varphi_{10,1}$ introduced earlier, so that

$$\Phi_{10}(\Omega) \;=\; \sum_{m=1}^{\infty}\big(\varphi_{10,1}|V_m\big)(\tau,z)\,p^m \;=\; \sum_{n,\,r,\,m} a_{10}(n,r,m)\,q^n\,y^r\,p^m\,, \tag{5.12}$$

where a_{10} is defined by (5.11) with $k=10$ in terms of the coefficients $C_{10}(d)$ given in Table 4.3.

A Siegel modular form sometimes also admits a product representation, and can be obtained as Borcherds lift or *multiplicative lift* of a weak Jacobi form of weight zero and index one. This procedure is in a sense an exponentiation of the additive lift and naturally results in the product representation of the Siegel form using the Fourier coefficients of a Jacobi form as the input. Several examples of Siegel forms that admit product representation are known but at present there is no general theory to determine under what conditions a given Siegel form admits a product representation.

For the Igusa cusp form Φ_{10}, a product representation does exist. It was obtained by Gritsenko and Nikulin [67, 68] as a multiplicative lift of the elliptic genus $\chi(\tau,z;K3) = 2\varphi_{0,1}(\tau,z)$ and is given by

$$\Phi_{10}(\Omega) \;=\; qyp \prod_{(r,s,t)>0} \big(1-q^s y^t p^r\big)^{2C_0(4rs-t^2)}, \tag{5.13}$$

in terms of C_0 given by (4.30, 4.24). Here the notation $(r,s,t)>0$ means that $r,\ s,\ t\ \in \mathbb{Z}$ with either $r>0$ or $r=0,\ s>0$, or $r=s=0,\ t<0$. In terms of the V_m, this can be rewritten in the form $\Phi_{10} = p\,\varphi_{10,1}\,\exp\!\big(-2\sum_{m=1}^{\infty}(\varphi_{0,1}|V_m)\,p^m\big)$.

5.2 Quantum black holes and Siegel modular forms

Siegel forms occur naturally in the context of counting of quarter-BPS dyons. The partition function for these dyons depends on three (complexified) chemical potentials (σ, τ, z), conjugate to the three T-duality invariant integers (m, n, ℓ) respectively and is given by

$$\mathrm{Z}(\Omega) \;=\; \frac{1}{\Phi_{10}(\Omega)} \;. \tag{5.14}$$

The product representation of the Igusa form is particularly useful for the physics application because it is closely related to the generating function for the elliptic genera of symmetric products of $K3$ introduced earlier. This is a consequence of the fact that the multiplicative lift of the Igusa form is obtained starting with the elliptic genus of $K3$ as the input. Comparing the product representation for the Igusa form (5.13) with (4.52), we get the relation:

$$\mathrm{Z}(\tau, z, \sigma) \;=\; \frac{1}{\Phi_{10}(\tau, z, \sigma)} \;=\; \frac{\widehat{Z}(\tau, z, \sigma)}{\varphi_{10,1}(\tau, z)} \;. \tag{5.15}$$

This relation to the elliptic genera of symmetric products of $K3$ has a deeper physical significance based on what is known as the 4d-5d lift [60]. The main idea is to use the fact that the geometry of the Kaluza-Klein monopole in the charge configuration (2.15) reduces to five-dimensional flat Minkowski spacetime in the limit when the radius of the circle $\tilde{S}^1$ goes to infinity. In this limit, the charge l corresponding to the momentum around this circle gets identified with the angular momentum l in five dimensions. Our charge configuration (2.15) then reduces essentially to the Strominger-Vafa black hole [118] with angular momentum [12] discussed in the previous subsection. Assuming that the dyon partition function does not depend on the moduli, we thus essentially relate $Z(\Omega)$ to $\hat{Z}(\Omega)$. The additional factor in (5.15) involving $\Phi_{10}(\sigma, \tau, z)$ comes from bound states of momentum n with the Kaluza-Klein monopole and from the center of mass motion of the Strominger-Vafa black hole in the Kaluza-Klein geometry [59, 42].

The Igusa cusp form has double zeros at $z = 0$ and its $Sp(2, \mathbb{Z})$ images. The partition function is therefore a *meromorphic* Siegel form (5.7) of weight -10 with double poles at these divisors. This fact is responsible for much of the interesting physics of wall-crossings in this context as we explain in the next section.

Using (5.12) or (5.13), one can compute the coefficients ψ_m in the Fourier-Jacobi expansion (1.1). The first few, multiplied by Δ and a suitable integer, are given by

$$\begin{aligned} \Delta\,\psi_{-1} &= A^{-1}\,, \\ \Delta\,\psi_0 &= 2\,A^{-1}B\,, \\ 4\,\Delta\,\psi_1 &= 9\,A^{-1}B^2 + 3E_4A\,, \\ 27\,\Delta\,\psi_2 &= 50\,A^{-1}B^3 + 48E_4AB + 10E_6A^2\,, \\ 384\,\Delta\,\psi_3 &= 475\,A^{-1}B^4 + 886E_4AB^2 + 360E_6A^2B + 199E_4^2A^3\,, \\ 72\,\Delta\,\psi_4 &= 51\,A^{-1}B^5 + 155E_4AB^3 + 93E_6A^2B^2 + 102E_4^2A^3B + 31E_4E_6A^4\,. \end{aligned} \tag{5.16}$$

(Here E_4, E_6, Δ are as in §3 and $A = \varphi_{-2,1}$, $B = \varphi_{0,1}$ as in §4.) The double zero of Φ_{10} at $z = 0$ is reflected by the denominator A in the $A^{-1}B^{m+1}$ terms in these formulas. Note that, by (5.15), the right-hand side of (5.16) multiplied by A and divided by a suitable denominator are equal to the elliptic genus of symmetric products of a $K3$ surface. For example,

$$\chi(\mathrm{Sym}^4K3;\tau,z) = \frac{1}{384}\big(475\,B^4 + 886E_4A^2B^2 + 360E_6A^3B + 199E_4^2A^4\,\big)\,. \tag{5.17}$$

6. Walls and contours

Given the partition function (5.14), one can extract the black hole degeneracies from the Fourier coefficients. The three quadratic T-duality invariants of a given dyonic state can be organized as a 2×2 symmetric matrix

$$\Lambda = \begin{pmatrix} N\cdot N & N\cdot M \\ M\cdot N & M\cdot M \end{pmatrix} = \begin{pmatrix} 2n & \ell \\ \ell & 2m \end{pmatrix}\,, \tag{6.1}$$

where the dot products are defined using the $O(22,6;\mathbb{Z})$ invariant metric L. The matrix Ω in (5.14) and (5.4) can be viewed as the matrix of complex chemical potentials conjugate to the charge matrix Λ. The charge matrix Λ is manifestly T-duality invariant. Under an S-duality transformation (2.4), it transforms as

$$\Lambda \rightarrow \gamma\Lambda\gamma^t \tag{6.2}$$

There is a natural embedding of this physical S-duality group $SL(2,\mathbb{Z})$ into $Sp(2,\mathbb{Z})$:

$$\begin{pmatrix} A & B \\ C & D \end{pmatrix} = \begin{pmatrix} (\gamma^t)^{-1} & \mathbf{0} \\ \mathbf{0} & \gamma \end{pmatrix} = \begin{pmatrix} d & -c & 0 & 0 \\ -b & a & 0 & 0 \\ 0 & 0 & a & b \\ 0 & 0 & c & d \end{pmatrix} \in Sp(2,\mathbb{Z})\,. \tag{6.3}$$

The embedding is chosen so that $\Omega \to (\gamma^T)^{-1}\Omega\gamma^{-1}$ and $\mathrm{Tr}(\Omega \cdot \Lambda)$ in the Fourier integral is invariant. This choice of the embedding ensures that the physical degeneracies extracted from the Fourier integral are S-duality invariant if we appropriately transform the moduli at the same time as we explain below.

To specify the contours, it is useful to define the following moduli-dependent quantities. One can define the matrix of right-moving T-duality invariants

$$\Lambda_R = \begin{pmatrix} Q_R \cdot Q_R & Q_R \cdot P_R \\ P_R \cdot Q_R & P_R \cdot P_R \end{pmatrix} , \tag{6.4}$$

which depends both on the integral charge vectors N, M as well as the T-moduli μ. One can then define two matrices naturally associated to the S-moduli $S = S_1 + iS_2$ and the T-moduli μ respectively by

$$\mathcal{S} = \frac{1}{S_2}\begin{pmatrix} |S|^2 & S_1 \\ S_1 & 1 \end{pmatrix} \quad , \quad \mathcal{T} = \frac{\Lambda_R}{|\det(\Lambda_R)|^{\frac{1}{2}}} . \tag{6.5}$$

Both matrices are normalized to have unit determinant. In terms of them, we can construct the moduli-dependent 'central charge matrix'

$$\mathcal{Z} = |\det(\Lambda_R)|^{\frac{1}{4}} \left(\mathcal{S} + \mathcal{T}\right), \tag{6.6}$$

whose determinant equals the BPS mass

$$M_{Q,P} = |\det \mathcal{Z}| . \tag{6.7}$$

We define

$$\widetilde{\Omega} \equiv \begin{pmatrix} \sigma & -z \\ -z & \tau \end{pmatrix} . \tag{6.8}$$

This is related to Ω by an $SL(2,\mathbb{Z})$ transformation

$$\tilde{\Omega} = \widehat{S}\Omega\widehat{S}^{-1} \quad \text{where} \quad \widehat{S} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} , \tag{6.9}$$

so that, under a general S-duality transformation γ, we have the transformation $\tilde{\Omega} \to \gamma\widetilde{\Omega}\gamma^T$ as $\Omega \to (\gamma^T)^{-1}\Omega\gamma^{-1}$.

With these definitions, $\Lambda, \Lambda_R, \mathcal{Z}$ and $\tilde{\Omega}$ all transform as $X \to \gamma X \gamma^T$ under an S-duality transformation (2.4) and are invariant under T-duality transformations. The moduli-dependent Fourier contour can then be specified in a duality-invariant fashion by[26]

$$\mathcal{C} = \{\mathrm{Im}(\widetilde{\Omega}) = \varepsilon^{-1}\mathcal{Z}; \quad 0 \leq \mathrm{Re}(\tau),\, \mathrm{Re}(\sigma),\, \mathrm{Re}(z) < 1\}, \tag{6.10}$$

where $\varepsilon \to 0^+$. For a given set of charges, the contour depends on the moduli S, μ through the definition of the central charge vector (6.6). The degeneracies $d(n, \ell, m)|_{S,\mu}$ of states with the T-duality invariants (n, ℓ, m) at a given point (S, μ) in the moduli space are then given by[11]

$$d(n, \ell, m)|_{S,\mu} = \int_{\mathcal{C}} e^{-i\pi \mathrm{Tr}(\Omega \cdot \Lambda)} \; \mathrm{Z}(\Omega) \, d^3\Omega \,. \tag{6.11}$$

This contour prescription thus specifies how to extract the degeneracies from the partition function for a given set of charges and in any given region of the moduli space. In particular, it also completely summarizes all wall-crossings as one moves around in the moduli space for a fixed set of charges. Even though the indexed partition function has the same functional form throughout the moduli space, the spectrum is moduli dependent because of the moduli dependence of the contours of Fourier integration and the pole structure of the partition function. Since the degeneracies depend on the moduli *only* through the dependence of the contour $\mathcal{C}$, moving around in the moduli space corresponds to deforming the Fourier contour. This does not change the degeneracy except when one encounters a pole of the partition function. Crossing a pole corresponds to crossing a wall in the moduli space. The moduli space is thus divided up into domains separated by "walls of marginal stability." In each domain the degeneracy is constant but it jumps upon crossing a wall as one goes from one domain to the other. The jump in the degeneracy has a nice mathematical characterization. It is simply given by the residue at the pole that is crossed while deforming the Fourier contour in going from one domain to the other.

We now turn to the degeneracies of single-centered black holes. Given the T-duality invariants Λ, a single centered black hole solution is known to exist in all regions of the moduli space as long as $\det(\Lambda)$ is large and positive. The moduli fields can take any values $(\lambda_\infty, \mu_\infty)$ at asymptotic infinity far away from the black hole but the vary in the black hole geometry. Because of the attractor phenomenon [58, 116], the moduli adjust themselves so that near the horizon of the black hole of charge Λ they get attracted to the values $(\lambda_*(\Lambda), \mu_*(\Lambda))$ which are determined by the requirement that the central charge $\mathcal{Z}_*(\Lambda)$ evaluated using these moduli becomes proportional to Λ. These attractor values are independent of the asymptotic values and depend only on the charge of black hole. We call these moduli the attractor moduli. This enables us to define the *attractor contour* for a given charge Λ by fixing the asymptotic moduli to the attractor values corresponding to this charge. In this case

$$\mathcal{Z}(\lambda_\infty, \mu_\infty) \;=\; \mathcal{Z}(\lambda_*(\Lambda), \mu_*(\Lambda)) \sim \Lambda \tag{6.12}$$

and we have the attractor contour

$$\mathcal{C}_* \;=\; \{\mathrm{Im}(\widetilde{\Omega}) \;=\; \varepsilon^{-1}\Lambda; \quad 0 \leq \mathrm{Re}(\tau),\, \mathrm{Re}(\sigma),\, \mathrm{Re}(z) < 1\} \tag{6.13}$$

---

[11] The physical degeneracies have an additional multiplicative factor of $(-1)^{\ell+1}$ which we omit here for simplicity of notation in later chapters.

which depends only on the integral charges and not on the moduli. The significance of the attractor moduli in our context stems from the fact if the asymptotic moduli are tuned to these values for given (n, ℓ, m), then only single-centered black hole solution exists. The degeneracies $d^*(n, \ell, m)$ obtained using the attractor contour

$$d^*(n, \ell, m) = \int_{\mathcal{C}_*} e^{-i\pi \mathrm{Tr}(\Omega\cdot\Lambda)} \, \mathrm{Z}(\Omega) \, d^3\Omega \tag{6.14}$$

are therefore expected to be the degeneracies of the immortal single-centered black holes.

7. Mock modular forms

Mock modular forms are a relatively new class of modular objects, although individual examples had been known for some time. They were first isolated explicitly by S. Zwegers in his thesis [130] as the explanation of the "mock theta functions" introduced by Ramanujan in his famous last letter to Hardy. An expository account of this work can be found in [129].

Ramanujan's mock theta functions are examples of what we will call "pure" mock modular forms. By this we mean a holomorphic function in the upper half plane which transforms under modular transformations almost, but not quite, as a modular form. The non-modularity is of a very special nature and is governed by another holomorphic function called the *shadow* which is itself an ordinary modular form. We will describe this more precisely in §7.1 and give a number of examples. In §7.2, we introduce a notion of mock Jacobi forms (essentially, holomorphic functions of τ and z with theta expansions like that of usual Jacobi forms, but in which the coefficients $h_\ell(\tau)$ are mock modular forms) and show how all the examples given in the first subsection occur naturally as pieces of mock Jacobi forms. Finally in §7.3 we define a more general notion of mock modular forms in which the shadow is replaced by a sum of products of holomorphic and anti-holomorphic modular forms. This has the advantage that there are now many examples of strongly holomorphic mock modular forms, whereas pure mock modular forms almost always have a negative power of q at at least one cusp, and also that almost all of the examples occurring naturally in number theory, algebraic geometry, or physics are of this more general "mixed" type, with the pure mock modular forms arising as quotients of mixed mock modular forms by eta products.

7.1 Pure mock modular forms

We define a (weakly holomorphic) *pure mock modular form* of weight $k \in \frac{1}{2}\mathbb{Z}$ as the first member of a pair (h, g), where

1. h is a holomorphic function in $\mathbb{H}$ with at most exponential growth at all cusps,

2. the function $g(\tau)$, called the *shadow* of h, is a holomorphic[12] modular form of weight $2-k$, and
3. the sum $\widehat{h} := h + g^*$, called the *completion* of h, transforms like a holomorphic modular form of weight k, *i.e.* $\widehat{h}(\tau)/\theta(\tau)^{2k}$ is invariant under $\tau \to \gamma\tau$ for all $\tau \in \mathbb{H}$ and for all γ in some congruence subgroup of $SL(2,\mathbb{Z})$.

Here $g^*(\tau)$, called the *non-holomorphic Eichler integral*, is a solution of the differential equation

$$(4\pi\tau_2)^k \, \frac{\partial g^*(\tau)}{\partial\overline{\tau}} \;=\; -2\pi i \, \overline{g(\tau)} \, . \tag{7.1}$$

If g has the Fourier expansion $g(\tau) = \sum_{n\ge0} b_n \, q^n$, we fix the choice of g^* by setting

$$g^*(\tau) \;=\; \overline{b}_0 \, \frac{(4\pi\tau_2)^{-k+1}}{k-1} \;+\; \sum_{n>0} n^{k-1} \, \overline{b}_n \, \Gamma(1-k, 4\pi n\tau_2) \, q^{-n} \, , \tag{7.2}$$

where $\tau_2 = \mathrm{Im}(\tau)$ and $\Gamma(1-k,x) = \int_x^\infty t^{-k} \, e^{-t} \, dt$ denotes the incomplete gamma function, and where the first term must be replaced by $-\overline{b}_0 \, \log(4\pi\tau_2)$ if $k=1$. Note that the series in (7.2) converges despite the exponentially large factor q^{-n} because $\Gamma(1-k,x) = O(x^{-k}e^{-x})$. If we assume either that $k>1$ or that $b_0 = 0$, then we can define g^* alternatively by the integral

$$g^*(\tau) = \left(\frac{i}{2\pi}\right)^{k-1} \int_{-\overline{\tau}}^{\infty} (z+\tau)^{-k} \; \overline{g(-\overline{z})} \; dz \, . \tag{7.3}$$

(The integral is independent of the path chosen because the integrand is holomorphic in z.) Since h is holomorphic, (7.1) implies that the completion of h is related to its shadow by

$$(4\pi\tau_2)^k \, \frac{\partial\widehat{h}(\tau)}{\partial\overline{\tau}} \;=\; -2\pi i \, \overline{g(\tau)} \, . \tag{7.4}$$

We denote by $\mathbb{M}^!_{k|0}$ the space of weakly holomorphic pure mock modular forms of weight k and arbitrary level. (The "0" in the notation corresponds to the word "pure" and will be replaced by an arbitrary integer or half-integer in §7.3.) This space clearly contains the space $M^!_k$ of ordinary weakly holomorphic modular forms (the special case $g=0$, $h=\widehat{h}$) and we have an exact sequence

$$0 \longrightarrow M^!_k \longrightarrow \mathbb{M}^!_{k|0} \xrightarrow{\mathcal{S}} \overline{M_{2-k}} \;\; , \tag{7.5}$$

where the *shadow map* $\mathcal{S}$ sends h to $\overline{g}$.[13]

---

[12] One can also consider the case where the shadow is allowed to be a weakly holomorphic modular form, but we do not do this since none of our examples will be of this type.

[13] We will use the word "shadow" to denote either $g(\tau)$ or $\overline{g(\tau)}$, but the shadow *map*, which should be linear over $\mathbb{C}$, always sends h to $\overline{g}$, the complex conjugate of its holomorphic shadow. We will also often be sloppy and say that the shadow of a certain mock modular form "is" some modular form g when in fact it is merely proportional to g, since the constants occurring are arbitrary and are often messy.

In the special case when the shadow g is a unary theta series as in (3.10) or (3.11) (which can only hapen if k equals $3/2$ or $1/2$, respectively), the mock modular form h is called a *mock theta function.* All of Ramanujan's examples, and all of ours in this paper, are of this type. In these cases the incomplete gamma functions in (7.2) can be expressed in terms of the complementary error function $\operatorname{erfc}(x) = 2\pi^{-1/2}\int_x^\infty e^{-t^2}dt$:

$$\Gamma\bigl(-\frac{1}{2},\,x\bigr) \;=\; \frac{2}{\sqrt{x}}\,e^{-x} \;-\; 2\sqrt{\pi}\,\operatorname{erfc}\bigl(\sqrt{x}\bigr)\,, \qquad \Gamma\bigl(\frac{1}{2},\,x\bigr) \;=\; \sqrt{\pi}\,\operatorname{erfc}\bigl(\sqrt{x}\bigr)\,. \tag{7.6}$$

A very simple, though somewhat artificial, example of a mock modular form is the weight 2 Eisenstein series $E_2(\tau)$ mentioned in §3.1, which is also a quasimodular form. Here the shadow $g(\tau)$ is a constant and its non-holomorphic Eichler integral $g^*(\tau)$ simply a multiple of $1/\tau_2$. This example, however, is atypical, since most quasimodular forms (like $E_2(\tau)^2$) are not mock modular forms. We end this subsection by giving a number of less trivial examples. Many more will occur later.

Example 1. In Ramanujan's famous last letter to Hardy in 1920, he gives 17 examples of mock theta functions, though without giving any complete definition of this term. All of them have weight 1/2 and are given as q-hypergeometric series. A typical example (Ramanujan's second mock theta function of "order 7" — a notion that he also does not define) is

$$\mathcal{F}_{7,2}(\tau) = -q^{-25/168}\sum_{n=1}^{\infty}\frac{q^{n^2}}{(1-q^n)\cdots(1-q^{2n-1})} \;=\; -q^{143/168}\left(1+q+q^2+2q^3+\cdots\right)\,. \tag{7.7}$$

This is a mock theta function of weight 1/2 on $\Gamma_0(4)\cap\Gamma(7)$ with shadow the unary theta series

$$\sum_{n\equiv 2\,(\mathrm{mod}\ 7)} \chi_{12}(n)\,n\,q^{n^2/168}\,, \tag{7.8}$$

with $\chi_{12}(n)$ as in (3.13). The product $\eta(\tau)\mathcal{F}_{7,2}(\tau)$ is a strongly holomorphic mixed mock modular form of weight $(1,1/2)$, and by an identity of Hickerson [72] is equal to an indefinite theta series:

$$\eta(\tau)\,\mathcal{F}_{7,2}(\tau) \;=\; \sum_{r,\,s\,\in\,\mathbb{Z}+\frac{5}{14}} \frac{1}{2}\bigl(\operatorname{sgn}(r)+\operatorname{sgn}(s)\bigr)\,(-1)^{r-s}\,q^{(3r^2+8rs+3s^2)/2}\,. \tag{7.9}$$

Example 2. The second example is the generating function of the Hurwitz-Kronecker class numbers $H(N)$. These numbers are defined for $N>0$ as the number of $PSL(2,\mathbb{Z})$-equivalence classes of integral binary quadratic forms of discriminant $-N$, weighted by the reciprocal of the number of their automorphisms (if $-N$ is the discriminant of an imaginary quadratic field

K other than $\mathbb{Q}(i)$ or $\mathbb{Q}(\sqrt{-3})$, this is just the class number of K), and for other values of N by $H(0) = -1/12$ and $H(N) = 0$ for $N < 0$. It was shown in [126] that the function

$$\mathbf{H}(\tau) \ := \ \sum_{N=0}^{\infty} H(N)\, q^N \ = \ -\frac{1}{12} \ + \ \frac{1}{3}q^3 \ + \ \frac{1}{2}q^4 \ + \ q^7 \ + \ q^8 \ + \ q^{11} \ + \ \cdots \tag{7.10}$$

is a mock modular form of weight 3/2 on $\Gamma_0(4)$, with shadow the classical theta function $\theta(\tau) = \sum q^{n^2}$. Here $\mathbf{H}(\tau)$ is strongly holomorphic, but this is very exceptional. In fact, up to minor variations it is essentially the *only* known non-trivial example of a strongly holomorphic pure mock modular form, which is why we will introduce mixed mock modular forms below. As mentioned earlier, this mock modular form has appeared in the physics literature in the context of topologically twisted supersymmetric Yang-Mills theory on $\mathbb{CP}^2$ [120].

Example 3. This example is taken from [129]. Set

$$F_2^{(6)}(\tau) \ = \ -\sum_{r>s>0} \chi_{12}(r^2 - s^2)\, s\, q^{rs/6} \ = \ q + 2q^2 + q^3 + 2q^4 - q^5 + \cdots \tag{7.11}$$

with χ_{12} as in (3.13), and let $E_2(\tau)$ be the quasimodular Eisenstein series of weight 2 on $SL(2,\mathbb{Z})$ as defined in §3.1. Then the function

$$h^{(6)}(\tau) \ = \ \frac{12F_2^{(6)}(\tau) - E_2(\tau)}{\eta(\tau)} \ = \ q^{-1/24}\left(-1 + 35q + 130q^2 + 273q^3 + 595q^4 + \cdots\right) \tag{7.12}$$

is a weakly holomorphic mock modular form of weight 3/2 on $SL(2,\mathbb{Z})$ with shadow proportional to $\eta(\tau)$. More generally, if we define

$$F_k^{(6)}(\tau) \ = \ -\sum_{r>s>0} \chi_{12}(r^2 - s^2)\, s^{k-1} q^{rs/6} \qquad (k > 2,\ k \text{ even})\,, \tag{7.13}$$

then for all $\nu \geq 0$ we have

$$\frac{24^\nu}{\binom{2\nu}{\nu}}\, [h^{(6)}, \eta]_\nu \ = \ 12F_k^{(6)} \ - \ E_k \ + \ \text{cusp form of weight } k\ , \quad k = 2\nu + 2\ , \tag{7.14}$$

where $[h^{(6)}, \eta]_\nu$ denotes the νth Rankin-Cohen bracket of the mock modular form $h^{(6)}$ and the modular form η in weights $(3/2, 1/2)$. This statement, and the similar statements for other mock modular forms which come later, are proved by the method of holomorphic projection, which we do not explain here, and are intimately connected with the mock Jacobi forms introduced in the next subsection. That connection will also explain the superscript "6" in (7.11)–(7.14).

Example 4. Our last example is very similar to the preceding one. Set

$$F_2^{(2)}(\tau) \ = \ \sum_{\substack{r>s>0 \\ r-s \text{ odd}}} (-1)^r\, s\, q^{rs/2} \ = \ q + q^2 - q^3 + q^4 - q^5 + \cdots\,. \tag{7.15}$$

Then the function

$$h^{(2)}(\tau) \;=\; \frac{24F_2^{(2)}(\tau)-E_2(\tau)}{\eta(\tau)^3} \;=\; q^{-1/8}\left(-1+45q+231q^2+770q^3+2277q^4+\cdots\right) \tag{7.16}$$

is a weakly holomorphic mock modular form of weight $1/2$ on $SL(2,\mathbb{Z})$ with shadow proportional to $\eta(\tau)^3$ and, as in Example 3, if we set

$$F_k^{(2)}(\tau) \;=\; -\sum_{\substack{r>s>0\\ r-s\ \mathrm{odd}}}(-1)^r\, s^{k-1}\, q^{rs/2} \qquad (k>2,\ k\ \text{even})\,, \tag{7.17}$$

then for all $\nu \geq 0$ we have

$$\frac{8^\nu}{\binom{2\nu}{\nu}}\,[h^{(2)},\eta^3]_\nu \;=\; 24F_k^{(2)} \;-\; E_k \;+\; \text{cusp form of weight } k\ , \quad k=2\nu+2\ , \tag{7.18}$$

where $[h^{(2)},\eta^3]_\nu$ denotes the Rankin-Cohen bracket in weights $(1/2,3/2)$.

In fact, the mock modular form $h^{(2)}$, with the completely different definition

$$h^{(2)}(\tau) \;=\; \frac{\vartheta_2(\tau)^4-\vartheta_4(\tau)^4}{\eta(\tau)^3} \;-\; \frac{24}{\vartheta_3(\tau)}\sum_{n\in\mathbb{Z}}\frac{q^{n^2/2-1/8}}{1+q^{n-1/2}}\,, \tag{7.19}$$

arose from the works of Eguchi-Taormina [56] and Eguchi–Ooguri–Taormina–Yang [53] in the late 1980's in connection with characters of the $\mathcal{N}=4$ superconformal algebra in two dimensions and the elliptic genus of $K3$ surfaces, and appears explicitly in the work of Ooguri [99] (it is $q^{-1/8}(-1+F(\tau)/2)$ in Ooguri's notation) and Wendland [121]. It has recently aroused considerable interest because of the "Mathieu moonshine" discovery by Eguchi, Ooguri and Tachikawa (see [52, 24]) that the coefficients 45, 231, 770, … in (7.16) are the dimensions of certain representations of the Mathieu group M_{24}. The equality of the right-hand sides of (7.16) and (7.19), which is not a priori obvious, follows because both expressions define mock modular forms whose shadow is the same multiple of $\eta(\tau)^3$, and the first few Fourier coefficients agree.

7.2 Mock Jacobi forms

By a (pure) *mock Jacobi form*[14] (resp. *weak mock Jacobi form*) of weight k and index m we will mean a holomorphic function φ on $\mathbb{H}\times\mathbb{C}$ that satisfies the elliptic transformation property (4.2), and hence has a Fourier expansion as in (4.3) with the periodicity property (4.4) and a theta expansion as in (4.10), and that also satisfies the same cusp conditions (4.5) (resp. (4.7)) as in the classical case, but in which the modularity property with respect to the action of $SL(2,\mathbb{Z})$ on $\mathbb{H}\times\mathbb{Z}$ is weakened: the coefficients $h_\ell(\tau)$ in (4.10) are now mock modular forms rather than modular forms of weight $k-\frac{1}{2}$, and the modularity property of φ is that the *completed* function

---

[14] We mention that there are related constructions and definitions in the literature. The weak Maass-Jacobi forms of [14] include the completions of our mock Jacobi forms, but in general are non-holomorphic in z as well as in τ. See also [27] and [18]. The functions discussed in this paper will be holomorphic in z.

$$\widehat{\varphi}(\tau,z) \;=\; \sum_{\ell\,\in\,\mathbb{Z}/2m\mathbb{Z}} \widehat{h}_\ell(\tau)\,\vartheta_{m,\ell}(\tau,z)\,, \tag{7.20}$$

rather than φ itself, transforms according to (4.1). If g_ℓ denotes the shadow of h_l, then we have

$$\widehat{\varphi}(\tau,z) \;= \varphi(\tau,z) \;+ \sum_{\ell\,\in\,\mathbb{Z}/2m\mathbb{Z}} g^*_\ell(\tau)\,\vartheta_{m,\ell}(\tau,z)$$

with g^*_ℓ as in (7.2) and hence, by (7.1),

$$\psi(\tau,z) \;:=\; \tau_2^{k-1/2}\,\frac{\partial}{\partial\overline{\tau}}\widehat{\varphi}(\tau,z) \;\doteq\; \sum_{\ell\,\in\,\mathbb{Z}/2m\mathbb{Z}} \overline{g_\ell(\tau)}\,\vartheta_{m,\ell}(\tau,z)\,. \tag{7.21}$$

(Here $\doteq$ indicates an omitted constant.) The function $\psi(\tau,z)$ is holomorphic in z, satisfies the same elliptic transformation property (4.2) as φ does (because each $\vartheta_{m,\ell}$ satisfies this), satisfies the heat equation $\left(8\pi i m\,\frac{\partial}{\partial\tau}-\frac{\partial^2}{\partial z^2}\right)\psi=0$ (again, because each $\vartheta_{m,\ell}$ does), and, by virtue of the modular invariance property of $\widehat{\varphi}(\tau,z)$, also satisfies the transformation property

$$\psi\Big(\frac{a\tau+b}{c\tau+d},\frac{z}{c\tau+d}\Big) \;=\; |c\tau+d|\,(c\overline{\tau}+d)^{2-k}\,e^{\frac{2\pi i m c z^2}{c\tau+d}}\,\psi(\tau,z) \qquad \forall \begin{pmatrix} a & b\\ c & d\end{pmatrix} \in SL(2;\mathbb{Z}) \tag{7.22}$$

with respect to the action of the modular group. These properties say precisely that ψ is a *skew-holomorphic Jacobi form* of weight $3-k$ and index m in the sense of Skoruppa [112, 113], and the above discussion can be summarized by saying that we have an exact sequence

$$0 \longrightarrow J^{\text{weak}}_{k,m} \longrightarrow \mathbb{J}^{\text{weak}}_{k|0,m} \xrightarrow{\mathcal{S}} J^{\text{skew}}_{3-k,m} \tag{7.23}$$

(and similarly with the word "weak" omitted), where $\mathbb{J}^{\text{weak}}_{k|0,m}$ (resp. $\mathbb{J}_{k|0,m}$) denotes the space of weak (resp. strong) pure mock Jacobi forms and the "shadow map" $\mathcal{S}$ sends[15] φ to ψ.

It turns out that most of the classical examples of mock theta functions occur as the components of a vector-valued mock modular form which gives the coefficients in the theta series expansion of a mock Jacobi form. We illustrate this for the four examples introduced in the previous subsection.

Example 1. The function $\mathcal{F}_{7,2}(\tau)$ in the first example of §7.1 is actually one of three "order 7 mock theta functions" $\{\mathcal{F}_{7,j}\}_{j=1,2,3}$ defined by Ramanujan, each given by a q-hypergeometric formula like (7.7), each having a shadow $\Theta_{7,j}$ like in (7.8) (but now with the summation over

---

[15] This shadow map was introduced in the context of weak Maass-Jacobi forms in [14].

$n \equiv j$ rather than $n \equiv 2$ modulo 7), and each satisfying an indefinite theta series identity like (7.9). We extend $\{\mathcal{F}_{7,j}\}$ to all j by defining it to be an odd periodic function of j of period 7, so that the shadow of $\mathcal{F}_{7,j}$ equals $\Theta_{7,j}$ for all $j \in \mathbb{Z}$. Then the function

$$\mathcal{F}_{42}(\tau, z) \;=\; \sum_{\ell \pmod{84}} \chi_{12}(\ell)\, \mathcal{F}_{7,\ell}(\tau)\, \vartheta_{42,\ell}(\tau, z) \tag{7.24}$$

belongs to $\mathbb{J}^{\text{weak}}_{1,42}$. The Taylor coefficients ξ_ν as defined in equation (4.16) are proportional to $\sum_{j=1}^{3}\big[\mathcal{F}_{7,j}, \Theta_{7,j}\big]_\nu$ and have the property that their completions $\widehat{\xi}_\nu = \sum_{j=1}^{3}\big[\widehat{\mathcal{F}}_{7,j}, \Theta_{7,j}\big]_\nu$ transform like modular forms of weight $2\nu + 2$ on the full modular group $SL(2, \mathbb{Z})$.

Example 2. Set $\mathcal{H}_0(\tau) = \sum_{n=0}^{\infty} H(4n) q^n$ and $\mathcal{H}_1(\tau) = \sum_{n=1}^{\infty} H(4n-1) q^{n-\frac{1}{4}}$ so that $\mathcal{H}_0(\tau) + \mathcal{H}_1(t) = \mathbf{H}(\tau/4)$. Then the function

$$\mathcal{H}(\tau, z) \;=\; \mathcal{H}_0(\tau)\vartheta_{1,0}(\tau, z) \;+\; \mathcal{H}_1(\tau)\vartheta_{1,1}(\tau, z) \;=\; \sum_{\substack{n,\, r \in \mathbb{Z} \\ 4n - r^2 \geq 0}} H(4n - r^2)\, q^n\, y^r\,, \tag{7.25}$$

is a mock Jacobi form of weight 2 and index 1 with shadow $\overline{\vartheta_{1,0}(\tau,0)}\,\vartheta_{1,0}(\tau,z) + \overline{\vartheta_{1,1}(\tau,0)}\,\vartheta_{1,1}(\tau,z)$. The νth Taylor coefficient ξ_ν of $\mathcal{H}$ is given by

$$\frac{4^\nu}{\binom{2\nu}{\nu}} \sum_{j=0}^{1} [\vartheta_{1,j}, \mathcal{H}_j]_\nu \;=\; \delta_{k,2}\, E_k \;-\; F_k^{(1)} \;+\; (\text{cusp form of weight } k \text{ on } SL(2,\mathbb{Z}))\,, \tag{7.26}$$

where $k = 2\nu + 2$ and

$$F_k^{(1)}(\tau) \;:=\; \sum_{n>0} \Big(\sum_{d|n} \min\big(d, \frac{n}{d}\big)^{k-1} \Big) q^n \qquad (k \text{ even},\ k \geq 2)\,. \tag{7.27}$$

In fact the cusp form appearing in (7.26) is a very important one, namely (up to a factor -2) the sum of the normalized Hecke eigenforms in $S_k(SL(2,\mathbb{Z}))$, and equation (7.26) is equivalent to the famous formula of Eichler and Selberg expressing the traces of Hecke operators on $S_k(SL(2,\mathbb{Z}))$ in terms of class numbers of imaginary quadratic fields.

Example 3. Write the function $h^{(6)}$ defined in (7.12) as

$$h^{(6)}(\tau) \;=\; \sum_{\substack{\Delta \geq -1 \\ \Delta \equiv -1 \pmod{24}}} C^{(6)}(\Delta)\, q^{\Delta/24} \tag{7.28}$$

with the first few coefficients $C^{(6)}(\Delta)$ given by

Δ	-1	23	47	71	95	119	143	167	191	215	239
$C^{(6)}(\Delta)$	-1	35	130	273	595	1001	1885	2925	4886	7410	11466

.

Then the function

$$\mathcal{F}_6(\tau,z) \;=\; \sum_{\substack{n,\,r\in\mathbb{Z}\\ 24n-r^2\ge -1}} \chi_{12}(r)\,C^{(6)}(24n-r^2)\,q^n\,y^r \tag{7.29}$$

is a mock Jacobi form of index 6 (explaining the notation $h^{(6)}$). Note that, surprisingly, this is even *simpler* than the expansion of the index 1 mock Jacobi form just discussed, because its twelve Fourier coefficients h_ℓ are all multiples of just one of them, while the two Fourier coefficients h_ℓ of $\mathcal{H}(\tau,z)$ were not proportional. (This is related to the fact that the shadow $\eta(\tau)$ of $h^{(6)}(\tau)$ is a modular form on the full modular group, while the shadow $\theta(\tau)$ of $\mathcal{H}(\tau)$ is a modular form on a congruence subgroup.) Specifically, we have $h_\ell(\tau) = \chi_{12}(\ell)h^{(6)}(\tau)$ for all $\ell \in \mathbb{Z}/12\mathbb{Z}$, where χ_{12} is the character defined in (3.13), so that $\mathcal{F}_6$ has the factorization

$$\mathcal{F}_6(\tau,z) \;=\; h^{(6)}(\tau) \sum_{\ell\ (\mathrm{mod} 12)} \chi_{12}(\ell)\,\vartheta_{6,\ell}(\tau,z) \;=\; \eta(\tau)\,h^{(6)}(\tau)\,\frac{\vartheta_1(\tau,4z)}{\vartheta_1(\tau,2z)}\,. \tag{7.30}$$

Combining this with (4.17) and noting that $\vartheta^0_{6,1} - \vartheta^0_{6,5} = \vartheta^0_{6,11} - \vartheta^0_{6,7} = \eta$, we see that the functions described in (7.14) are proportional to the Taylor coefficients $\xi_\nu(\tau)$ of $\mathcal{F}_6(\tau,z)$.

Example 4. The fourth example is very similar. Write the mock modular form (7.16) as

$$h^{(2)}(\tau) \;=\; \sum_{\substack{\Delta\ge -1\\ \Delta\equiv -1\ (\mathrm{mod}\ 8)}} C^{(2)}(\Delta)\,q^{\Delta/8} \tag{7.31}$$

with initial coefficients given by

Δ	-1	7	15	23	31	39	47	55	63	71
$C^{(2)}(\Delta)$	-1	45	231	770	2277	5796	13915	30843	65550	132825

.

Then the function

$$\begin{aligned}\mathcal{F}_2(\tau,z) \;&=\; \sum_{\substack{n,\,r\in\mathbb{Z}\\ 8n-r^2\ge -1}} \chi_4(r)\,C^{(2)}(8n-r^2)\,q^n\,y^r \;=\; h^{(2)}(\tau)\,\big(\vartheta_{2,1}(\tau,z)-\vartheta_{2,3}(\tau,z)\big)\\ &=\; h^{(2)}(\tau)\,\vartheta_1(\tau,2z) = \eta(\tau)^3\,h^{(2)}(\tau)\,C(\tau,z)\end{aligned} \tag{7.32}$$

(where $\chi_4(r) = \pm1$ for $r \equiv \pm1\,(\mathrm{mod}\ 4)$ and $\chi_4(r) = 0$ for r even) is a mock Jacobi form of index 2. (Here C is the Jacobi form of weight -1 and index 2 introduced in §4.3.) As in Example 3, the functions given in (7.18) are proportional to the Taylor coefficients ξ_ν of $\mathcal{F}_2$, because $\vartheta^1_{2,1} = -\vartheta^1_{2,3} = \eta^3$, where $\vartheta^1_{2,\ell}$ is defined by (4.18).

7.3 Mock modular forms: the general case

If we replace the condition "exponential growth" in 1. of 7.1 by "polynomial growth," we get the class of *strongly holomorphic mock modular forms*, which we can denote $\mathbb{M}_{k|0}$, and an exact sequence $0 \to M_k \to \mathbb{M}_{k|0} \to \overline{M_{2-k}}$. This is not very useful, however, because there are almost no examples of "pure" mock modular forms that are strongly holomorphic, essentially the only ones being the function $\mathcal{H}$ of Example 2 of §7.1 and its variants. It becomes useful if we generalize to *mixed mock modular forms* of mixed weight $k|\ell$. (Here k and ℓ can be integers or half-integers.) These are holomorphic functions $h(\tau)$, with polynomial growth at the cusps, that have completions $\widehat{h}$ of the form $\widehat{h} = h + \sum_j f_j\, g_j^*$ with $f_j \in M_\ell$, $g_j \in M_{2-k+\ell}$ that transform like modular forms of weight k. The space $\mathbb{M}_{k|\ell}$ of such forms thus fits into an exact sequence

$$0 \longrightarrow M_k \longrightarrow \mathbb{M}_{k|\ell} \xrightarrow{\mathcal{S}} M_\ell \otimes \overline{M_{2-k+\ell}}\,, \tag{7.33}$$

where the shadow map $\mathcal{S}$ now sends h to $\sum_j f_j\, \overline{g}_j$. If $\ell = 0$ this reduces to the previous definition, since $M_0 = \mathbb{C}$, but with the more general notion of mock modular forms there are now plenty of strongly holomorphic examples, and, just as for ordinary modular forms, they have much nicer properties (notably, polynomial growth of their Fourier coefficients) than the weakly holomorphic ones. If the shadow of a mixed mock modular form $h \in \mathbb{M}_{k|\ell}$ happens to contain only one term $f(\tau)\overline{g(\tau)}$, and if $f(\tau)$ has no zeros in the upper half-plane, then $f^{-1}\,h$ is a weakly holomorphic pure mock modular form of weight $k-\ell$ (and in fact, all weakly holomorphic pure mock modular forms arise in this way). For functions in the larger space $\mathbb{M}^!_{k|\ell}$ of weakly holomorphic mixed mock modular forms, defined in the obvious way, this always happens, so $\mathbb{M}^!_{k|\ell}$ simply coincides with $M_\ell \otimes \mathbb{M}^!_{k-\ell}$ and does not give anything new, but the smaller space $\mathbb{M}_{k|\ell}$ does not have such a decomposition and is more interesting. Moreover, there are many examples. In fact, apart from Ramanujan's original examples of mock theta functions, which were defined as q-hypergeometric series and were weakly holomorphic pure mock modular forms of weight 1/2, most of the examples of mock modular forms occurring "in nature," such as Appell-Lerch sums or indefinite theta series, are strongly holomorphic mixed modular forms.

We can also define "even more mixed" mock modular forms by replacing $\mathbb{M}_{k|\ell}$ by the space $\mathbb{M}_k = \sum_\ell \mathbb{M}_{k|\ell}$, i.e., by allowing functions whose shadow is a finite sum of products $f_j(\tau)\overline{g_j(\tau)}$ with the f_j of varying weights ℓ_j and g_j of weight $2-k+\ell_j$. This space fits into an exact sequence

$$0 \longrightarrow M_k \longrightarrow \mathbb{M}_k \xrightarrow{\mathcal{S}} \bigoplus_\ell M_\ell \otimes \overline{M_{2-k+\ell}}\;. \tag{7.34}$$

In fact, the functions in this space are the most natural objects, and from now on we will use "mock modular forms" to refer to this more general class, including the adjectives "mixed" and "pure" only when needed for emphasis. To justify this claim, we consider the space $\mathfrak{M}_k$ of all *real-analytic modular forms of weight* k, i.e., real-analytic functions that transform like modular forms of weight k and have polynomial growth at all cusps. More generally, one can consider the space $\mathfrak{M}_{k,\ell}$ of real-analytic functions of polynomial growth that transform according to $F(\gamma\tau) = (c\tau+d)^k(c\overline{\tau}+d)^\ell F(\tau)$ for all matrices $\gamma = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ belonging to some subgroup of finite index of $SL(2,\mathbb{Z})$. Since the function $\tau_2 = \mathrm{Im}(\tau)$ transforms by $(\gamma\tau)_2 = \tau_2/|c\tau+d|^2$, the spaces $\mathfrak{M}_{k,\ell}$ and $\tau_2^r\,\mathfrak{M}_{k+r,\ell+r}$ coincide for all r. (Here, k, ℓ and r can each be integral or half-integral.) Obviously the space $\mathfrak{M}_{k,\ell}$ contains the space $M_k \otimes \overline{M_\ell}$, so by the comment just made, it also contains the direct sum $\bigoplus_{r\in\mathbb{Z}} \tau_2^r\, M_{k+r} \otimes \overline{M_{\ell+r}}$. Elements of this subspace will be called *decomposable*. Now, if a function $F \in \mathfrak{M}_k = \mathfrak{M}_{k,0}$ has the property that its $\overline{\tau}$-derivative (which automatically belongs to $\mathfrak{M}_{k,2}$) is decomposable, say as $\sum_j {\tau_2}^{r_j}\, f_j\, \overline{g_j}$ (where the weights of f_j and g_j are necessarily equal to $k+r_j$ and $2+r_j$, respectively), then F is the sum of a holomorphic function h and a multiple of $\sum_j f_j g_j^*$ and the function h is a (mixed) mock modular form in the sense just explained. Conversely, a holomorphic function h is a (mixed) mock modular form of weight k if and only if there exist numbers r_j and modular forms $f_j \in M_{k+r_j}$ and $g_j \in M_{2+r_j}$ such that the sum $\widehat{h} := h + \sum_j f_j g_j^*$ belongs to $\mathfrak{M}_k$. We can thus summarize the entire discussion by the following very simple definition:

> *A mock modular form is the holomorphic part of a real-analytic modular form whose $\overline{\tau}$-derivative is decomposable.*

As examples of this more general class we mention the functions $F_2^{(6)}$ and $F_2^{(2)}$ defined in equations (7.11) and (7.15), which are both (strong) mixed mock modular forms of total weight 2 and trivial character on the full modular group $SL(2,\mathbb{Z})$, but with different mixed weights: $12F_2^{(6)}$ is the sum of the functions $E_2(\tau)$ and $\eta(\tau)\,h^{(6)}(\tau)$ of weights $2|0$ and $\frac{3}{2}|\frac{1}{2}$, while $24F_2^{(2)}$ is the sum of the functions $E_2(\tau)$ and $\eta(\tau)^3 h^{(2)}(\tau)$ of weights $2|0$ and $\frac{1}{2}|\frac{3}{2}$.

We remark that in the pure case we have $\tau_2^k \cdot \partial_{\overline{\tau}} F \in \overline{M_{2-k}} = \mathrm{Ker}\big(\partial_\tau : \mathfrak{M}_{0,2-k} \to \mathfrak{M}_{2,2-k}\big)$, so that the subspace $\mathbb{M}_{k,0}$ of $\mathbb{M}_k$ can be characterized by a *single* second-order differential equation $\Delta_k \widehat{h} = 0$, where $\Delta_k = \tau_2^{2-k}\partial_\tau \tau_2^k \partial_{\overline{\tau}}$ is the Laplacian in weight k. For this reason, (weak) pure mock modular forms can be, and often are, viewed as the holomorphic parts of (weak) harmonic Maass forms, i.e., of functions in $\mathfrak{M}_k^!$ annihilated by Δ_k. But in the general case, there is no connection between mock modular forms or their completions and any second-order operators. Only the Cauchy-Riemann operator $\partial/\partial\overline{\tau}$ is needed, and the new definition of mock modular forms as given above is both more flexible and more readily generalizable than the more familiar definition of pure mock modular forms in terms of harmonic Maass forms.

Finally, we can define mixed mock Jacobi forms in exactly the same way as we defined pure ones (i.e., they have theta expansions in which the coefficients are mixed mock modular forms, with completions that transform like ordinary Jacobi forms). We will see in the next section that such objects arise very naturally as the "finite parts" of meromorphic Jacobi forms.

7.4 Superconformal characters and mock modular forms

As already mentioned, mock modular forms first made their appearance in physics some ten years before the work of Zwegers, in connection with the characters of superconformal algebas [56, 53]. The representations of the $\mathcal{N}=4$ superconformal algeba with central charge $c=6k$ are labeled by two quantum numbers, the energy h and spin l of the lowest weight state $|\Omega\rangle$, which satisfy $h>k/4$, $l\in\{1/2,1,\ldots,k/2\}$ for the non-BPS (massive) case and $h=k/4$, $l\in\{0,1/2,\ldots,k/2\}$ for the BPS (massless) case. The corresponding character, defined by

$$\mathrm{ch}^{\tilde{R}}_{k,h,l}(\tau,z) \;=\; \mathrm{Tr}\big(q^{L_0-c/24}\,e^{4\pi i z J_0}\big) \qquad \big(\,L_0|\Omega\rangle=h|\Omega\rangle, \quad J_0|\Omega\rangle=l|\Omega\rangle\big)\,,$$

turns out to be, up to a power of q, a Jacobi form in the non-BPS case but a "mock" object in the BPS case. In particular, for $k=1$ the non-BPS characters are given by

$$\mathrm{ch}^{\tilde{R}}_{1,h,\frac12}(\tau,z) \;=\; -\,q^{h-\frac38}\,\frac{\vartheta_1(\tau,z)^2}{\eta(\tau)^3} \;=\; -\,q^{h-\frac38}\,\eta(\tau)^3\,\varphi_{-2,1}(\tau,z) \qquad \big(h>\frac14\big) \tag{7.35}$$

and the BPS characters by

$$\mathrm{ch}^{\tilde{R}}_{1,\frac14,0}(\tau,z) \;=\; -\,\frac{\vartheta_1(\tau,z)^2}{\eta(\tau)^3}\,\mu(\tau,z)\,, \qquad \mathrm{ch}^{\tilde{R}}_{1,\frac14,\frac12}(z,\tau)+2\mathrm{ch}^{\tilde{R}}_{1,\frac14,0}(\tau,z) \;=\; -\,q^{-\frac18}\,\frac{\vartheta_1(\tau,z)^2}{\eta(\tau)^3}\,, \tag{7.36}$$

where $\mu(\tau,z)$ is the function defined by

$$\mu(\tau,z) \;=\; \frac{e^{\pi i z}}{\vartheta_1(z,\tau)}\sum_{n\in\mathbb{Z}}\frac{(-1)^n q^{\frac{n^2+n}{2}}e^{2\pi i n z}}{1\,-\,q^n\,e^{2\pi i z}} \qquad \big(q=e^{2\pi i\tau},\; y=e^{2\pi i z}\big)\,, \tag{7.37}$$

an "Appell-Lerch sum" of a type that also played a central role in Zwegers's work[16] and that we will discuss in the next section. The "mock" aspect is the fact that $\mu(\tau,z)$ must be completed by an appropriate non-holomorphic correction term in order to transform like a Jacobi form.

The mock modular form $h^{(2)}$ arises in connection with the decomposition of the elliptic genus of a $K3$ surface as a linear combination of these characters. This elliptic genus is, as discussed in 4.5, equal to the weak Jacobi form $2B=2\varphi_{0,1}$. It can be represented as a specialization of the partition function (= generating function of states) of superstrings compactified on a $K3$ surface [53] and as such can be decomposed into pieces corresponding to the representations of the $N=4$ superconformal algebra with central charge $6k=6$. The decomposition has the form [99, 121, 55]

$$2\varphi_{0,1}(\tau,z) \;=\; 20\,\mathrm{ch}^{\tilde{R}}_{1,\frac14,0}(z,\tau)\;+\;A_0\,\mathrm{ch}^{\tilde{R}}_{1,\frac14,\frac12}(z,\tau)\;+\;\sum_{n=1}^{\infty}A_n\,\mathrm{ch}^{\tilde{R}}_{1,n+\frac14,\frac12}(z,\tau)\,, \tag{7.38}$$

---

[16] More precisely, the function $\mu(\tau,z)$ is the specialization to $u=v=z$ of the 2-variable function $\mu(u,v;\tau)$ considered by Zwegers.

where $A_0 = -2$, $A_1 = 90$, $A_2 = 462$, $\ldots$ are the Fourier coefficients $2C^{(2)}(8n-1)$ of the mock modular form $2h^{(2)}(\tau)$. Inserting (7.35) and (7.36), we can rewrite this as

$$\eta(\tau)^{-3}\,\frac{\varphi_{0,1}(\tau,z)}{\varphi_{-2,1}(\tau,z)} \;=\; -\,12\,\mu(\tau,z) \,-\, h^{(2)}(\tau)\,. \tag{7.39}$$

In the next section we will see how to interpret this equation as an example of a certain canonical decomposition of meromorphic Jacobi forms (8.52).

8. From meromorphic Jacobi forms to mock modular forms

In this section we consider Jacobi forms $\varphi(\tau,z)$ that are meromorphic with respect to the variable z. It was discovered by Zwegers [130] that such forms, assuming that their poles occur only at points $z \in \mathbb{Q}\tau + \mathbb{Q}$ (i.e., at torsion points on the elliptic curve $\mathbb{C}/\mathbb{Z}\tau + \mathbb{Z}$), have a modified theta expansion related to mock modular forms. Our treatment is based on his, but the presentation is quite different and the results go further in one key respect. We show that φ decomposes canonically into two pieces, one constructed directly from its poles and consisting of a finite linear combination of Appell-Lerch sums with modular forms as coefficients, and the other being a mock Jacobi form in the sense introduced in the preceding section. Each piece separately transforms like a Jacobi form with respect to elliptic transformations. Neither piece separately transforms like a Jacobi form with respect to modular transformations, but each can be completed by the addition of an explicit and elementary non-holomorphic correction term so that it does transform correctly with respect to the modular group.

In §8.1 we explain how to modify the Fourier coefficients h_ℓ defined in (4.8) when φ has poles, and use these to define a "finite part" of φ by the theta decomposition (4.10). In §8.2 we define (in the case when φ has simple poles only) a "polar part" of φ as a finite linear combination of standard Appell-Lerch sums times modular forms arising as the residues of φ at its poles, and show that φ decomposes as the sum of its finite part and its polar part. Subsection 8.3 gives the proof that the finite part of φ is a mock Jacobi form and a description of the non-holomorphic correction term needed to make it transform like a Jacobi form. This subsection also contains a summary in tabular form of the various functions that have been introduced and the relations between them. In §8.4 we describe the modifications needed in the case of double poles (the case actually needed in this paper) and in §8.5 we present a few examples to illustrate the theory. Among the "mock" parts of these are two of the most interesting mock Jacobi forms from §7 (the one related to class numbers of imaginary quadratic fields and the one conjecturally related to representations of the Mathieu group M_{24}). Many other examples will be given in §9.

Throughout the following sections, we use the convenient notation $\mathbf{e}(x) := e^{2\pi i x}$.

8.1 The Fourier coefficients of a meromorphic Jacobi form

As indicated above, the main problem we face is to find an analogue of the theta decomposition (4.10) of holomorphic Jacobi forms in the meromorphic case. We will approach this problem from two sides: computing the Fourier coefficients of $\varphi(\tau, z)$ with respect to z, and computing the contribution from the poles. In this subsection we treat the first of these questions.

Consider a meromorphic Jacobi form $\varphi(\tau, z)$ of weight k and index m. We assume that $\varphi(\tau, z)$ for each $\tau \in \mathbb{H}$ is a meromorphic function of z which has poles only at points $z = \alpha\tau + \beta$ wit α and β rational. In the case when φ was holomorphic, we could write its Fourier expansion in the form (4.8). By Cauchy's theorem, the coefficient $h_\ell(\tau)$ in that expansion could also be given by the integral formula

$$h_\ell^{(z_0)}(\tau) \;=\; q^{-\ell^2/4m} \int_{z_0}^{z_0+1} \varphi(\tau, z)\, \mathbf{e}(-\ell z)\, dz\,, \tag{8.1}$$

where z_0 is an arbitrary point of $\mathbb{C}$. From the holomorphy and transformation properties of φ it follows that the value of this integral is independent of the choice of z_0 and of the path of integration and depends only on ℓ modulo $2m$ (implying that we have the theta expansion (4.10)) and that each h_ℓ is a modular form of weight $k - \frac{1}{2}$. Here each of these properties fails: the integral (8.1) is not independent of the path of integration (it jumps when the path crosses a pole); it is not independent of the choice of the initial point z_0; it is not periodic in ℓ (changing ℓ by $2m$ corresponds to changing z_0 by τ); it is not modular; and of course the expansion (4.10) cannot possibly hold since the right-hand-side has no poles in z.

To take care of the first of these problems, we specify the path of integration in (8.1) as the horizontal line from z_0 to $z_0 + 1$. If there are poles of $\varphi(\tau, z)$ along this line, this does not make sense; in that case, we define the value of the integral as the average of the integral over a path deformed to pass just above the poles and the integral over a path just below them. (We do not allow the initial point z_0 to be a pole of φ, so this makes sense.) To take care of the second and third difficulties, the dependence on z_0 and the non-periodicity in ℓ, we play one of these problems off against the other. From the elliptic transformation property (4.2) we find that

$$\begin{aligned} h_\ell^{(z_0+\tau)}(\tau) \;&=\; q^{-\ell^2/4m} \int_{z_0}^{z_0+1} \varphi(\tau,\, z+\tau)\, \mathbf{e}(-\ell\,(z+\tau))\, dz \\ &=\; q^{-(\ell+2m)^2/4m} \int_{z_0}^{z_0+1} \varphi(\tau,\, z)\, \mathbf{e}(-(\ell+2m)\, z)\, dz \;=\; h_{\ell+2m}^{(z_0)}(\tau)\,, \end{aligned}$$

i.e., changing z_0 by τ corresponds to changing ℓ by $2m$, as already mentioned. It follows that if we choose z_0 to be $-\ell\tau/2m$ (or $-\ell\tau/2m + B$ for any $B \in \mathbb{R}$, since it is clear that the value of the integral (8.1) depends only on the height of the path of integration and not on the initial point on this line), then the quantity

$$h_\ell(\tau) \;:=\; h_\ell^{(-\ell\tau/2m)}(\tau)\,, \tag{8.2}$$

which we will call the ℓth **canonical Fourier coefficient** of φ, depends only on the value of $\ell \pmod{2m}$. This in turn implies that the sum

$$\varphi^F(\tau,z) \;:=\; \sum_{\ell\,\in\,\mathbb{Z}/2m\mathbb{Z}} h_\ell(\tau)\,\vartheta_{m,\ell}(\tau,z)\,, \tag{8.3}$$

which we will call the **finite** (or **Fourier**) **part** of φ, is well defined. If φ is holomorphic, then of course $\varphi^F = \varphi$, by virtue of (4.10). Hence if we define the **polar part** φ^P of φ to be $\varphi - \varphi^F$, then φ^P only depends on the principal part of φ at its singularities. We will give explicit formulas in §8.2 and §8.4 in the cases when all poles are single or double.

Note that the definiton of $h_\ell(\tau)$ can also be written

$$h_\ell(\tau) \;=\; q^{\ell^2/4m} \int_{\mathbb{R}/\mathbb{Z}} \varphi(\tau, z - \ell\tau/2m)\,\mathbf{e}(-\ell z)\,dz\,, \tag{8.4}$$

with the same convention as above if $\varphi(\tau, z - \ell\tau/2m)$ has poles on the real line.

Finally, we remark that none of these definitions have anything to do with the modular transformation property (4.1), and would also work if our initial function $\varphi(\tau,z)$ satisfied only the elliptic transformation property (4.2). (In that case, however, the functions h_ℓ in general need not be modular, and in fact will be mock modular when $\varphi(\tau,z)$ is a meromorphic Jacobi form.) What we have said so far can be summarized by a commutative diagram

$$\begin{tikzcd} \mathcal{E}^{\mathrm{Mer}}_{\pm,m} \arrow[r, "F"] \arrow[d, phantom, "\cup"] & \mathcal{E}_{\pm,m} \arrow[d, phantom, "\cup"] \\ J^{\mathrm{Mer}}_{k,m} \arrow[r, "F"] & \mathbb{J}_{k,m} \end{tikzcd}\;, \tag{8.5}$$

where $J^{\mathrm{Mer}}_{k,m}$ (resp. $\mathcal{E}^{\mathrm{Mer}}_{\pm,m}$) denote the subspace of meromorphic Jacobi (resp. elliptic) forms having poles only at torsion points $z \in \mathbb{Q}\tau + \mathbb{Q}$, and the map F sends $\varphi \mapsto \varphi^{\mathrm{F}}$.

8.2 The polar part of φ (case of simple poles)

We now consider the contribution from the poles. To present the results we first need to fix notations for the positions and residues of the poles of our meromorphic function φ. We assume for now that the poles are all simple.

By assumption, $\varphi(\tau,z)$ has poles only at points of the form $z = z_s = \alpha\tau + \beta$ for $s = (\alpha,\beta)$ belonging to some subset S of $\mathbb{Q}^2$. The double periodicity property (4.2) implies that S is invariant under translation by $\mathbb{Z}^2$, and of course $S/\mathbb{Z}^2$ must be finite. The modular transformation property (4.1) of φ implies that S is $SL(2,\mathbb{Z})$-invariant. For each $s = (\alpha,\beta) \in S$, we set

$$D_s(\tau) \;=\; 2\pi i\,\mathbf{e}(m\alpha z_s)\,\mathrm{Res}_{z=z_s}\big(\varphi(\tau,z)\big) \qquad (s = (\alpha,\beta) \in S,\; z_s = \alpha\tau + \beta)\,. \tag{8.6}$$

The functions $D_s(\tau)$ are holomorphic modular forms of weight $k-1$ and some level, and only finitely many of them are distinct. More precisely, they satisfy

- $$D_{(\alpha+\lambda,\beta+\mu)}(\tau) \;=\; \mathbf{e}(m(\mu\alpha-\lambda\beta))\, D_{(\alpha,\beta)}(\tau) \quad \text{for} \quad (\lambda,\mu) \,\in\, \mathbb{Z}^2\,, \tag{8.7}$$
- $$D_s\Big(\frac{a\tau+b}{c\tau+d}\Big) \;=\; (c\tau+d)^{k-1}\, D_{s\gamma}(\tau) \quad \text{for} \quad \gamma = \big(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\big) \,\in\, SL(2,\mathbb{Z})\,, \tag{8.8}$$

as one sees from the transformation properties of φ. (The calculation for equation (8.8) is given in §8.4.) It is precisely to obtain the simple transformation equation (8.8) that we included the factor $\mathbf{e}(m\alpha z_s)$ in (8.6). Since we are assuming for the time being that there are no higher-order poles, all of the information about the non-holomorphy of φ is contained in these functions.

The strategy is to define a "polar part" of φ by taking the poles z_s in some fundamental parallelogram for the action of the lattice $\mathbb{Z}\tau+\mathbb{Z}$ on $\mathbb{C}$ (i.e., for $s=(\alpha,\beta)$ in the intersection of S with some square box $[A,A+1)\times[B,B+1)$) and then averaging the residues at these poles over all translations by the lattice. But we must be careful to do this in just the right way to get the desired invariance properties. For each $m\in\mathbb{N}$ we introduce the *averaging operator*

$$\mathrm{Av}^{(m)}\big[F(y)\big] \;:=\; \sum_{\lambda} q^{m\lambda^2} y^{2m\lambda} F(q^\lambda y) \tag{8.9}$$

which sends any function of y (= $\mathbb{Z}$-invariant function of z) of polynomial growth in y to a function of z transforming like an index m Jacobi form under translations by the full lattice $\mathbb{Z}\tau+\mathbb{Z}$. For example, we have

$$q^{\ell^2/4m}\,\mathrm{Av}^{(m)}\big[y^\ell\big] \;=\; \sum_{\lambda\,\in\,\mathbb{Z}} q^{(\ell+2m\lambda)^2/4m}\, y^{\ell+2m\lambda} \;=\; \vartheta_{m,\ell}(\tau,z) \tag{8.10}$$

for any $\ell\in\mathbb{Z}$. If $F(y)$ itself is given as the average

$$F(y) \;=\; \mathrm{Av}_{\mathbb{Z}}\big[f(z)\big] \;:=\; \sum_{\mu\in\mathbb{Z}} f(z+\mu) \qquad (z\in\mathbb{C},\;\; y=\mathbf{e}(z)) \tag{8.11}$$

of a function $f(z)$ in $\mathbb{C}$ (of sufficiently rapid decay at infinity), then we have

$$\mathrm{Av}^{(m)}\big[F(y)\big] \;=\; \mathrm{Av}^{(m)}_{\mathbb{Z}\tau+\mathbb{Z}}\big[f(z)\big] \;:=\; \sum_{\lambda,\,\mu\in\mathbb{Z}} e^{2\pi i m(\lambda^2\tau+2\lambda z)}\, f(z+\lambda\tau+\mu)\,. \tag{8.12}$$

We want to apply the averaging operator (8.9) to the product of the function $D_s(\tau)$ with a standard rational function of y having a simple pole of residue 1 at $y=y_s=\mathbf{e}(z_s)$, but the choice of this rational function is not obvious. The right choice turns out to be $\mathcal{R}_{-2m\alpha}(y)$, where $\mathcal{R}_c(y)$ for $c\in\mathbb{R}$ is defined by

$$\mathcal{R}_c(y) \;=\; \begin{cases} \dfrac{1}{2}\, y^c\, \dfrac{y+1}{y-1} & \text{if } c\in\mathbb{Z}\,, \\[2ex] y^{\lceil c\rceil}\, \dfrac{1}{y-1} & \text{if } c\in\mathbb{R}\smallsetminus\mathbb{Z}\,. \end{cases} \tag{8.13}$$

(Here $\lceil c \rceil$ denotes the "ceiling" of c, i.e., the smallest integer $\geq c$. The right-hand side can also be written more uniformly as $\dfrac{1}{2}\,\dfrac{y^{\lfloor c \rfloor + 1} + y^{\lceil c \rceil}}{y-1}$, where $\lfloor c \rfloor = -\lceil -c \rceil$ denotes the "floor" of c, i.e., the largest integer $\leq c$.) This function looks artificial, but is in fact quite natural. First of all, by expanding the right-hand side of (8.13) in a geometric series we find

$$\mathcal{R}_c(y) \;=\; \begin{cases} -\sum^*_{\ell \geq c} y^\ell & \text{if } |y| < 1, \\ \;\;\sum^*_{\ell \leq c} y^\ell & \text{if } |y| > 1, \end{cases} \tag{8.14}$$

where the asterisk on the summation sign means that the term $\ell = c$ is to be counted with multiplicity $1/2$ when it occurs (which happens only for $c \in \mathbb{Z}$, explaining the case distinction in (8.13)). This formula, which can be seen as the prototypical example of wall-crossing, can also be written in terms of z as a Fourier expansion (convergent for all $z \in \mathbb{C} \smallsetminus \mathbb{R}$)

$$\mathcal{R}_c(\mathbf{e}(z)) \;=\; -\sum_{\ell \in \mathbb{Z}} \frac{\operatorname{sgn}(\ell - c) \,+\, \operatorname{sgn}(z_2)}{2}\, \mathbf{e}(\ell z) \qquad (y = \mathbf{e}(z),\;\; z_2 = \operatorname{Im}(z) \neq 0)\,, \tag{8.15}$$

without any case distinction. Secondly, $R_c(y)$ can be expressed in a natural way as an average:

Proposition 8.1. *For $c \in \mathbb{R}$ and $z \in \mathbb{C} \smallsetminus \mathbb{Z}$ we have*

$$\mathcal{R}_c(\mathbf{e}(z)) \;=\; Av_{\mathbb{Z}}\Big[\frac{\mathbf{e}(cz)}{2\pi i z}\Big]\,. \tag{8.16}$$

Proof: If $c \in \mathbb{Z}$, then

$$\operatorname{Av}_{\mathbb{Z}}\Big[\frac{\mathbf{e}(cz)}{2\pi i z}\Big] \;=\; \frac{y^c}{2\pi i} \sum_{n \in \mathbb{Z}} \frac{1}{z-n} \;=\; \frac{y^c}{2\pi i}\,\frac{\pi}{\tan \pi z} \;=\; \frac{y^c}{2}\,\frac{y+1}{y-1}$$

by a standard formula of Euler. If $c \notin \mathbb{Z}$ then the Poisson summation formula and (8.15) give

$$\begin{aligned} \operatorname{Av}_{\mathbb{Z}}\Big[\frac{\mathbf{e}(cz)}{2\pi i z}\Big] \;&=\; \sum_{n \in \mathbb{Z}} \frac{\mathbf{e}(c(z+n))}{2\pi i (z+n)} \;=\; \sum_{\ell \in \mathbb{Z}} \bigg(\int_{iz_2 - \infty}^{iz_2 + \infty} \frac{\mathbf{e}(c(z+u))}{2\pi i(z+u)}\, \mathbf{e}(-\ell u)\, du\bigg)\, \mathbf{e}(\ell z) \\ &=\; -\sum_{\ell \in \mathbb{Z}} \frac{\operatorname{sgn}(\ell - c) \,+\, \operatorname{sgn}(z_2)}{2}\, \mathbf{e}(\ell z) \;=\; \mathcal{R}_c(\mathbf{e}(z)) \end{aligned}$$

if $z_2 \neq 0$, and the formula remains true for $z_2 = 0$ by continuity. An alternative proof can be obtained by noting that $\mathbf{e}(-cz)\mathcal{R}_c(\mathbf{e}(z))$ is periodic of period 1 with respect to c and expanding it as a Fourier series in c, again by the Poisson summation formula.

For $m \in \mathbb{N}$ and $s = (\alpha, \beta) \in \mathbb{Q}^2$ we now define a *universal Appell-Lerch sum* $\mathcal{A}^s_m(\tau, z)$ by

$$\mathcal{A}^s_m(\tau, z) \;=\; \mathbf{e}(-m\alpha z_s)\, \operatorname{Av}^{(m)}\big[\mathcal{R}_{-2m\alpha}(y/y_s)\big] \qquad (y_s = \mathbf{e}(z_s) = \mathbf{e}(\beta) q^\alpha)\,. \tag{8.17}$$

It is easy to check that this function satisfies

$$\mathcal{A}_m^{(\alpha+\lambda,\beta+\mu)} \;=\; \mathbf{e}(-m(\mu\alpha-\lambda\beta))\,\mathcal{A}_m^{(\alpha,\beta)} \qquad (\lambda,\,\mu\in\mathbb{Z}) \tag{8.18}$$

and hence, in view of the corresponding property (8.7) of D_s, that the product $D_s(\tau)\mathcal{A}_m^s(\tau,z)$ depends only on the class of s in $S/\mathbb{Z}^2$. We can therefore define

$$\varphi^P(\tau,z) \;:=\; \sum_{s\in S/\mathbb{Z}^2} D_s(\tau)\,\mathcal{A}_m^s(\tau,z)\,, \tag{8.19}$$

and it is obvious from the above discussion that this function, which we will call the **polar part** of φ, satisfies the index m elliptic transformation property (4.2) and has the same poles and residues as φ, so that the difference $\varphi-\varphi^P$ is holomorphic and has a theta expansion. In fact, we have:

Theorem 8.1. *Let $\varphi(\tau,z)$ be a meromorphic Jacobi form with simple poles at $z=z_s=\alpha\tau+\beta$ for $s=(\alpha,\beta)\in S\subset\mathbb{Q}^2$, with Fourier coefficients $h_\ell(\tau)$ defined by (8.1) and (8.2) or by (8.4) and residues $D_s(\tau)$ defined by (8.6). Then φ has the decomposition*

$$\varphi(\tau,z) \;=\; \varphi^F(\tau,z) \,+\, \varphi^P(\tau,z)\,, \tag{8.20}$$

where φ^F and φ^P are defined by equations (8.3) and (8.19), respectively.

Proof: Fix a point $P=A\tau+B\in\mathbb{C}$ with $(A,B)\in\mathbb{R}^2\smallsetminus S$. Since φ, φ^F and φ^P are meromorphic, it suffices to prove the decomposition (8.20) on the horizontal line $\operatorname{Im}(z)=\operatorname{Im}(P)=A\tau_2$. On this line we have the Fourier expansion

$$\varphi(\tau,z) \;=\; \sum_{\ell\in\mathbb{Z}} q^{\ell^2/4m}\,h_\ell^{(P)}(\tau)\,y^\ell\,,$$

where the coefficients $h_\ell^{(P)}$ are defined by (8.1) (modified as explained in the text there if $A=\alpha$ for any $(\alpha,\beta)\in S$, but for simplicity we will simply assume that this is not the case, since we are free to choose A any way we want). Comparing this with (8.3) gives

$$\varphi(\tau,z) \,-\, \varphi^F(\tau,z) \;=\; \sum_{\ell\in\mathbb{Z}}\bigl(h_\ell^{(P)}(\tau)-h_\ell(\tau)\bigr)\,q^{\ell^2/4m}\,y^\ell \qquad (\operatorname{Im}(z)=\operatorname{Im}(P))\,. \tag{8.21}$$

But $q^{\ell^2/4m}(h_\ell^{(P)}(\tau)-h_\ell(\tau))$ is just $2\pi i$ times the sum of the residues of $\varphi(\tau,z)\mathbf{e}(-\ell z)$ in the parallelogram with width 1 and horizontal sides at heights $A\tau_2$ and $-\ell\tau_2/2m$, with the residues of any poles on the latter line being counted with multiplicity 1/2 because of the way we defined h_ℓ in that case, so

$$\begin{aligned} q^{\ell^2/4m}\bigl(h_\ell^{(P)}(\tau)-h_\ell(\tau)\bigr) \;&=\; 2\pi i \sum_{s=(\alpha,\beta)\,\in\, S/\mathbb{Z}} \frac{\operatorname{sgn}(\alpha-A)-\operatorname{sgn}(\alpha+\ell/2m)}{2}\,\operatorname{Res}_{z=z_s}\bigl(\varphi(\tau,z)\mathbf{e}(-\ell z)\bigr)\\ &=\; \sum_{s=(\alpha,\beta)\,\in\, S/\mathbb{Z}} \frac{\operatorname{sgn}(\alpha-A)-\operatorname{sgn}(\ell+2m\alpha)}{2}\;D_s(\tau)\,\mathbf{e}(-(\ell+m\alpha)z_s)\,. \end{aligned}$$

(Here "$(\alpha,\beta)\in S/\mathbb{Z}$" means that we consider all α, but β only modulo 1, which is the same by periodicity as considering only the (α,β) with $B\le\beta<B+1$.) Inserting this formula into (8.21) and using (8.15), we find

$$\begin{aligned}\varphi(\tau,z)\;-\;\varphi^F(\tau,z)\;&=\;-\sum_{s=(\alpha,\beta)\,\in\,S/\mathbb{Z}}\mathbf{e}(-m\alpha z_s)\,D_s(\tau)\sum_{\ell\in\mathbb{Z}}\frac{\operatorname{sgn}(\operatorname{Im}(z-z_s))+\operatorname{sgn}(\ell+2m\alpha)}{2}\,\Bigl(\frac{y}{y_s}\Bigr)^{\ell}\\&=\;\sum_{s=(\alpha,\beta)\,\in\,S/\mathbb{Z}}\mathbf{e}(-m\alpha z_s)\;D_s(\tau)\;\mathcal{R}_{-2m\alpha}(y/y_s)\\&=\;\sum_{s=(\alpha,\beta)\,\in\,S/\mathbb{Z}^2}\;\sum_{\lambda\in\mathbb{Z}}\mathbf{e}\bigl(-m(\alpha-\lambda)(z_s-\lambda\tau)\bigr)\,D_{(\alpha-\lambda,\beta)}(\tau)\;\mathcal{R}_{-2m(\alpha-\lambda)}(q^{\lambda}y/y_s)\\&=\;\sum_{s=(\alpha,\beta)\,\in\,S/\mathbb{Z}^2}D_s(\tau)\,\mathbf{e}(-m\alpha z_s)\;\sum_{\lambda\in\mathbb{Z}}q^{m\lambda^2}\,y^{2m\lambda}\,\mathcal{R}_{-2m\alpha}(q^{\lambda}y/y_s)\,,\end{aligned}$$

where in the last line we have used the periodicity property (8.7) of $D_s(\tau)$ together with the obvious periodicity property $\mathcal{R}_{c+n}(y)=y^n\mathcal{R}_c(y)$ of $\mathcal{R}_c(y)$. But the inner sum in the last expression is just $\mathrm{Av}^{(m)}\bigl[\mathcal{R}_{-2m\alpha}(y/y_s)\bigr]$, so from the definition (8.17) we see that this agrees with $\varphi^P(\tau,z)$, as claimed.

8.3 Mock modularity of the Fourier coefficients

In subsections §8.1 and §8.2 we introduced a canonical splitting of a meromorphic Jacobi form φ into a finite part φ^F and a polar part φ^P, but there is no reason yet (apart from the simplicity of equation (8.2)) to believe that the choice we have made is the "right" one: we could have defined periodic Fourier coefficients $h_\ell(\tau)$ in many other ways (for instance, by taking $P=P_0-\ell/2m\tau$ with any fixed $P_0\in\mathbb{C}$ or more generally $P=P_\ell-\ell\tau/2m$ where P_ℓ depends only on ℓ modulo $2m$) and obtained other functions φ^F and φ^P. What makes the chosen decomposition special is that, as we will now show, the Fourier coefficients defined in (8.2) are (mixed) mock modular forms and the function φ^F therefore a (mixed) mock Jacobi form in the sense of §7.3. The corresponding shadows will involve theta series that we now introduce.

For $m\in\mathbb{N}$, $\ell\in\mathbb{Z}/2m\mathbb{Z}$ and $s=(\alpha,\beta)\in\mathbb{Q}^2$ we define the unary theta series

$$\Theta^s_{m,\ell}(\tau)\;=\;\mathbf{e}(-m\alpha\beta)\sum_{\lambda\,\in\,\mathbb{Z}+\alpha+\ell/2m}\lambda\,\mathbf{e}(2m\beta\lambda)\,q^{m\lambda^2}\tag{8.22}$$

of weight 3/2 and its Eichler integral[17]

$$\Theta^{s\,*}_{m,\ell}(\tau)\;=\;\frac{\mathbf{e}(m\alpha\beta)}{2}\sum_{\lambda\,\in\,\mathbb{Z}+\alpha+\ell/2m}\operatorname{sgn}(\lambda)\,\mathbf{e}(-2m\beta\lambda)\operatorname{erfc}\bigl(2|\lambda|\sqrt{\pi m\tau_2}\bigr)\,q^{-m\lambda^2}\tag{8.23}$$

---

[17] Strictly speaking, the Eichler integral as defined by equation (7.2) with $k=1/2$ would be this multiplied by $2\sqrt{\pi/m}$, but this normalization will lead to simpler formulas and, as already mentioned, there is no good universal normalization for the shadows of mock modular forms.

(cf. (7.2) and (7.6)). One checks easily that these functions transform by

$$\begin{aligned}\Theta^{(\alpha+\lambda,\beta+\mu)}_{m,\ell}(\tau) &= \mathbf{e}(m(\mu\alpha-\lambda\beta))\,\Theta^{(\alpha,\beta)}_{m,\ell}(\tau) \qquad (\lambda,\,\mu\in\mathbb{Z})\,, & (8.24)\\ \Theta^{(\alpha+\lambda,\beta+\mu)\,*}_{m,\ell}(\tau) &= \mathbf{e}(-m(\mu\alpha-\lambda\beta))\,\Theta^{(\alpha,\beta)\,*}_{m,\ell}(\tau) \qquad (\lambda,\,\mu\in\mathbb{Z})\,. & (8.25)\end{aligned}$$

with respect to translations of s by elements of $\mathbb{Z}^2$. From this and (8.7) it follows that the products $D_s\overline{\Theta^s_{m,\ell}}$ and $D_s\Theta^{s\,*}_{m,\ell}$ depend only on the class of s in $S/\mathbb{Z}^2$, so that the sums over s occurring in the following theorem make sense.

Theorem 8.2. *Let φ, h_ℓ and φ^F be as in Theorem 8.1. Then each h_ℓ is a mixed mock modular form of weight $k-\frac{1}{2}\,|\,k-1$, with shadow $\sum_{s\in S/\mathbb{Z}^2} D_s(\tau)\,\overline{\Theta^s_{m,\ell}(\tau)}$, and the function φ^F is a mixed mock Jacobi form. More precisely, for each $\ell\in\mathbb{Z}/2m\mathbb{Z}$ the completion of h_ℓ defined by*

$$\widehat{h}_\ell(\tau) \;:=\; h_\ell(\tau) \;-\; \sum_{s\in S/\mathbb{Z}^2} D_s(\tau)\,\Theta^{s\,*}_{m,\ell}(\tau)\,, \qquad (8.26)$$

with $\Theta^{s\,*}_{m,\ell}$ as in (8.23), tranforms like a modular form of weight $k-1/2$ with respect to some congruence subgroup of $SL(2,\mathbb{Z})$, and the completion of φ^F defined by

$$\widehat{\varphi}^F(\tau,z) \;:=\; \sum_{\ell\ (\mathrm{mod}\ 2m)} \widehat{h}_\ell(\tau)\,\vartheta_{m,\ell}(\tau,z) \qquad (8.27)$$

transforms like a Jacobi form of weight k and index m with respect to the full modular group.

The key property needed to prove this theorem is the following proposition, essentially due to Zwegers, which says that the functions $\mathcal{A}^s_m(\tau,z)$ defined in §8.2 are (meromorphic) mock Jacobi forms of weight 1 and index m, with shadow $\sum_{\ell\ (\mathrm{mod}\ 2m)}\overline{\Theta^s_{m,\ell}(\tau)}\,\vartheta_{m,\ell}(\tau,z)$ (more precisely, that each $\mathcal{A}^s_m$ is a meromorphic mock Jacobi form of this weight, index and shadow with respect to some congruence subgroup of $SL(2,\mathbb{Z})$ depending on s and that the collection of all of them is a vector-valued mock Jacobi form on the full modular group):

Proposition 8.2. *For $m\in\mathbb{N}$ and $s\in\mathbb{Q}^2$ the completion $\widehat{\mathcal{A}}^s_m$ of $\mathcal{A}^s_m$ defined by*

$$\widehat{\mathcal{A}}^s_m(\tau,z) \;:=\; \mathcal{A}^s_m(\tau,z) \;+\; \sum_{\ell\ (\mathrm{mod}\ 2m)} \Theta^{s\,*}_{m,\ell}(\tau)\,\vartheta_{m,\ell}(\tau,z)\;. \qquad (8.28)$$

satisfies

$$\begin{aligned}\widehat{\mathcal{A}}^{(\alpha+\lambda,\beta+\mu)}_m(\tau,z) &= \mathbf{e}(-m(\mu\alpha-\lambda\beta))\,\widehat{\mathcal{A}}^{(\alpha,\beta)}_m(\tau) \qquad (\lambda,\,\mu\in\mathbb{Z})\,, & (8.29)\\ \widehat{\mathcal{A}}^s_m(\tau,z+\lambda\tau+\mu) &= \mathbf{e}(-m(\lambda^2\tau+2\lambda z))\,\widehat{\mathcal{A}}^s_m(\tau) \qquad (\lambda,\,\mu\in\mathbb{Z})\,, & (8.30)\\ \widehat{\mathcal{A}}^s_m\Big(\frac{a\tau+b}{c\tau+d},\,\frac{z}{c\tau+d}\Big) &= (c\tau+d)\,\mathbf{e}\Big(\frac{mcz^2}{c\tau+d}\Big)\,\widehat{\mathcal{A}}^{s\gamma}_m(\tau,z) \quad \Big(\gamma=\begin{pmatrix}a&b\\c&d\end{pmatrix}\in SL(2,\mathbb{Z})\Big)\,. & (8.31)\end{aligned}$$

Proof: The first two properties are easy to check because they hold for each term in (8.28) separately. The modular transformation property, considerably less obvious, is essentially the content of Proposition 3.5 of [130], but the functions he studies are different from ours and we need a small calculation to relate them. Zwegers defines two functions $f_u^{(m)}(z;\tau)$ and $\tilde{f}_u^{(m)}(z;\tau)$ $(m \in \mathbb{N},\ \tau \in \mathbb{H},\ z,\, u \in \mathbb{C})$ by

$$f_u^{(m)}(z;\tau) = \mathrm{Av}^{(m)}\Big[\frac{1}{1-y/\mathbf{e}(u)}\Big], \qquad \tilde{f}_u^{(m)}(z;\tau) = f_u^{(m)}(z;\tau) - \frac{1}{2}\sum_{\ell \ (\mathrm{mod}\ 2m)} R_{m,\ell}(u;\tau)\,\vartheta_{m,\ell}(\tau,z)$$

(here we have rewritten Definition 3.2 of [130] in our notation), where

$$R_{m,\ell}(u;\tau) \;=\; \sum_{r\in \ell+2m\mathbb{Z}} \Big\{\mathrm{sgn}\big(r+\frac{1}{2}\big) \,-\, \mathrm{erf}\Big(\sqrt{\pi}\,\frac{r\tau_2+2mu_2}{\sqrt{m\tau_2}}\Big)\Big\}\, q^{-r^2/4m}\,\mathbf{e}(-ru)\,, \tag{8.32}$$

and shows (Proposition 3.5) that $\tilde{f}_u^{(m)}$ satisfies the modular transformation property

$$\tilde{f}^{(m)}_{u/(c\tau+d)}\Big(\frac{z}{c\tau+d};\frac{a\tau+b}{c\tau+d}\Big) \;=\; (c\tau+d)\,\mathbf{e}\Big(\frac{mc(z^2-u^2)}{c\tau+d}\Big)\,\tilde{f}_u^{(m)}(z;\tau) \tag{8.33}$$

for all $\gamma = \begin{pmatrix} a & b\\ c & d\end{pmatrix} \in SL(2,\mathbb{Z})$. Noting that $\mathrm{erf}(x) = \mathrm{sgn}(x)(1-\mathrm{erfc}(|x|))$, we find that

$$\frac{1}{2}\,R_{m,\ell}(z_s;\tau) \;=\; \sum_{r\equiv \ell \ (\mathrm{mod}\ 2m)} \frac{\mathrm{sgn}(r+\frac{1}{2})-\mathrm{sgn}(r+2m\alpha)}{2}\,q^{-r^2/4m}\,y_s^{-r} \;+\; \mathbf{e}(m\alpha z_s)\,\Theta^{s\,*}_{m,l}(\tau)$$

in our notation. On the other hand, from (8.13) we have

$$\mathcal{R}_{-2m\alpha}(y) \;=\; \frac{1}{y-1} \;+\; \sum_{r\in\mathbb{Z}} \frac{\mathrm{sgn}(r+\frac{1}{2})-\mathrm{sgn}(r+2m\alpha)}{2}\,y^r \tag{8.34}$$

(note that the sum here is finite). Replacing y by y/y_s and applying the operator $\mathrm{Av}^{(m)}$, we find (using (8.10))

$$\mathbf{e}(m\alpha z_s)\,\mathcal{A}^s_m(\tau,z) \;=\; -f^{(m)}_{z_s}(z;\tau) \;+\; \sum_{r\in\mathbb{Z}} \frac{\mathrm{sgn}(r+\frac{1}{2})-\mathrm{sgn}(r+2m\alpha)}{2}\,q^{-r^2/4m}\,y_s^{-r}\,\vartheta_{m,r}(\tau,z)\,.$$

Combining these two equations and rearranging, we obtain

$$\widehat{\mathcal{A}}^s_m(\tau,z) \;=\; -\,\mathbf{e}(-m\alpha z_s)\,\tilde{f}^{(m)}_{z_s}(z;\tau)\,,$$

and the modularity property (8.31) then follows from (8.33) after a short calculation.

The proof of Theorem 8.2 follows easily from Proposition 8.2. We define the completion of the function φ^P studied in §8.2 by

$$\widehat{\varphi}^P(\tau,z) \;:=\; \sum_{s\in S/\mathbb{Z}^2} D_s(\tau)\,\widehat{\mathcal{A}}^s_m(\tau,z)\,. \tag{8.35}$$

The sum makes sense by (8.29), and from the transformation equations (8.30)–(8.31) together with the corresponding properties (8.7)–(8.8) of the residue functions $D_s(\tau)$ it follows that $\widehat{\varphi}^P(\tau,z)$ transforms like a Jacobi form of weight k and index m with respect to the full modular group. Comparing equations (8.35) and (8.28) with equations (8.27) and (8.26), we find that

$$\widehat{\varphi}^P(\tau,z) \,-\, \varphi^P(\tau,z) \;=\; \sum_{\ell\,\in\,\mathbb{Z}/2m\mathbb{Z}}\;\sum_{s\,\in\,S/\mathbb{Z}^2} D_s(\tau)\,\Theta^{s\,*}_{m,\ell}(\tau)\,\vartheta_{m,\ell}(\tau,z) \;=\; \varphi^F(\tau,z) \,-\, \widehat{\varphi}^F(\tau,z)$$

and hence, using Theorem 8.1, that

$$\widehat{\varphi}^F(\tau,z) \,+\, \widehat{\varphi}^P(\tau,z) \;=\; \varphi^F(\tau,z) \,+\, \varphi^P(\tau,z) \;=\; \varphi(\tau,z)\,.$$

Since both $\varphi(\tau,z)$ and $\widehat{\varphi}^P(\tau,z)$ transform like Jacobi forms of weight k and index m, it follows that $\widehat{\varphi}^F(\tau,z)$ also does, and then the fact that each $\widehat{h}_\ell$ transforms like a modular form of weight $k-1/2$ (and hence that each h_ℓ is a mixed mock modular form with the weight and shadow given in the theorem) follows by the same argument that proves the modularity of the coefficients h_ℓ in the theta expansion (4.10) in the classical case.

Summary. For the reader's convenience, we give a brief summary of the results given up to now. We have the following six functions of two variables $(\tau,z)\in\mathbb{H}\times\mathbb{C}$:

- $\varphi(\tau,z)$, a meromorphic Jacobi form of weight k and index m, assumed to have only simple poles at $z=z_s=\alpha\tau+\beta$ for $s=(\alpha,\beta)$ in some discrete subset $S\subset\mathbb{Q}^2$;
- $\varphi^F(\tau,z)$, the **finite** part of φ, defined by the theta expansion $\sum_{\ell \pmod{2m}} h_\ell(\tau)\vartheta_{m,\ell}(\tau,z)$ where $h_\ell(\tau)$ is $q^{\ell^2/4m}$ times the ℓth Fourier coefficient of $\varphi(\tau,z-\ell\tau/2m)$ on the real line;
- $\varphi^P(\tau,z)$, the **polar** part of φ, defined as $\sum_{s\in S/\mathbb{Z}^2} D_s(\tau)\mathcal{A}^s_m(\tau,z)$, where $\mathcal{A}^s_m$ is an explicit Appell-Lerch sum having simple poles at $z\in z_s+\mathbb{Z}\tau+\mathbb{Z}$;
- $\varphi^C(\tau,z)$, a non-holomorphic **correction** term, defined as $\sum_s\sum_\ell D_s(\tau)\Theta^{s\,*}_{m,\ell}(\tau)\vartheta_{m,\ell}(\tau,z)$ where the $\Theta^{s\,*}_{m,\ell}$ are the Eichler integrals of explicit unary theta series of weight $3/2$;
- $\widehat{\varphi}^F(\tau,z)$, the completed finite part, defined as $\varphi^F(\tau,z)-\varphi^C(\tau,z)$;
- $\widehat{\varphi}^P(\tau,z)$, the completed polar part, defined as $\varphi^P(\tau,z)+\varphi^C(\tau,z)$.

These six functions are related by

$$\varphi^F \,+\, \varphi^P \;=\; \varphi \;=\; \widehat{\varphi}^F \,+\, \widehat{\varphi}^P\,, \qquad \varphi^F \,-\, \widehat{\varphi}^F \;=\; \varphi^C \;=\; \widehat{\varphi}_P \,-\, \varphi_P\,. \tag{8.36}$$

Each of them is real-analytic in τ, meromorphic in z, satisfies the elliptic transformation property (4.2) with respect to z, and has precisely two of four further desirable properties of such a function (note that $6 = \binom{4}{2}$), as shown in the following table

	φ	φ^F	φ^{P}	φ^C	$\widehat{\varphi}^{\mathrm{F}}$	$\widehat{\varphi}^{\mathrm{P}}$
holomorphic in τ ?	✓	✓	✓	–	–	–
transforms like a Jacobi form ?	✓	–	–	–	✓	✓
holomorphic in z ?	–	✓	–	✓	✓	–
determined by the poles of φ ?	–	–	✓	✓	–	✓

in which the three checked entries in each row correspond to one of the equations (10.1). Each Fourier coefficient h_ℓ of φ is a mixed mock modular form of weight $(k-1, 1/2)$, and the finite part φ^F is a mixed mock Jacobi form. In the holomorphic case, the functions φ, φ^F and $\widehat{\varphi}^F$ coincide and the functions φ^P, φ^C and $\widehat{\varphi}^P$ vanish.

We end by mentioning one further property of the canonical decomposition $\varphi = \varphi^F + \varphi^P$ that seems of interest. The finite part φ^P of φ is a linear combination of terms $h_\ell(\tau)\,\vartheta_{m,\ell}(\tau, z)$ where $h_\ell(\tau)$ is a Laurent power series in q and $\vartheta_{m,\ell}(\tau, z)$ a linear combination of terms $q^{r^2/4m}y^r$, so it satisfies the same growth condition as a weak Jacobi form, viz., that it contains only monomials $q^n y^r$ with discriminant $4mn - r^2$ bounded from below. But the Appell-Lerch sums $\mathcal{A}_m^s(\tau, z)$ occurring in $\varphi^P(\tau, z)$ have the opposite property: substituting the Fourier expansion (8.15) of $\mathcal{R}_c$ into the definition (8.17), we find that they contain only terms $q^n y^r$ with $4mn - r^2 = -\delta^2$ where the numbers δ occurring are rational (more precisely, $\delta \in r + 2m(\mathbb{Z} + \alpha)$) and unbounded (more precisely, δ lies between 0 and $r + \mathrm{O}(1)$).

8.4 The case of double poles

In this subsection we extend our considerations to the case when φ is allowed to have double poles, again assumed to be at points $z = z_s = \alpha\tau + \beta$ for $s = (\alpha, \beta)$ belonging to some discrete subset S of $\mathbb{Q}^2$. The first thing we need to do is to generalize the definition (8.6) to this case. For $s \in S$ we define functions E_s and D_s on $\mathbb{H}$ by the Laurent expansion

$$\mathbf{e}(m\alpha z_s)\,\varphi(\tau, z_s + \varepsilon) \;=\; \frac{E_s(\tau)}{(2\pi i\varepsilon)^2} + \frac{D_s(\tau) - 2m\alpha\, E_s(\tau)}{2\pi i\varepsilon} + O(1) \qquad \text{as } \varepsilon \to 0. \tag{8.37}$$

(Notice that $D_s(\tau)$ is the same function as in (8.6) when the pole is simple.) It is easily checked that the behavior of these functions under translations of s by elements of $\mathbb{Z}^2$ is given by equation (8.7) and its analogue for E_s. For the modular behavior, we have:

Proposition 8.3. *The functions $E_s(\tau)$ and $D_s(\tau)$ defined by (8.37) are modular forms of weight $k-2$ and $k-1$, respectively. More respectively, for all $s \in S$ and $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in SL(2, \mathbb{Z})$ we have*

$$E_s\Big(\frac{a\tau + b}{c\tau + d}\Big) \;=\; (c\tau + d)^{k-2} E_{s\gamma}(\tau)\,, \qquad D_s\Big(\frac{a\tau + b}{c\tau + d}\Big) \;=\; (c\tau + d)^{k-1} D_{s\gamma}(\tau)\,. \tag{8.38}$$

Proof: We rewrite (8.37) as

$$\mathbf{e}(m\alpha(z_s+2\varepsilon))\,\varphi(\tau,z_s+\varepsilon) \;=\; \frac{E_s(\tau)}{(2\pi i\varepsilon)^2} \,+\, \frac{D_s(\tau)}{2\pi i\varepsilon} \,+\, \mathrm{O}(1)\,,$$

and also write α_s and $z_s(\tau)$ instead of just α and z_s. Then using the easily checked identities

$$z_s(\gamma\tau) \;=\; \frac{z_{s\gamma}(\tau)}{c\tau+d}\,, \qquad \alpha_{s\gamma}\,z_{s\gamma}(\tau) \,-\, \alpha_s\,z_s(\gamma\tau) \;=\; \frac{c\,z_{s\gamma}(\tau)^2}{c\tau+d} \qquad \Bigl(\gamma\tau := \frac{a\tau+b}{c\tau+d}\Bigr)\,,$$

and the modular transformation equation (4.1), we find

$$\begin{aligned}
\frac{(c\tau+d)^2\,E_s(\gamma\tau)}{(2\pi i\varepsilon)^2} + \frac{(c\tau+d)\,D_s(\gamma\tau)}{2\pi i\varepsilon} &\equiv \mathbf{e}\Bigl(m\alpha\Bigl(z_s(\gamma\tau)+\frac{2\varepsilon}{c\tau+d}\Bigr)\Bigr)\,\varphi\Bigl(\gamma\tau,\,z_s(\gamma\tau)+\frac{\varepsilon}{c\tau+d}\Bigr)\\
&\equiv \mathbf{e}\Bigl(m\alpha\frac{z_{s\gamma}(\tau)+2\varepsilon}{c\tau+d}\Bigr)\,\varphi\Bigl(\gamma\tau,\,\frac{z_{s\gamma}(\tau)+\varepsilon}{c\tau+d}\Bigr)\\
&\equiv (c\tau+d)^k\,\mathbf{e}\Bigl(m\alpha\frac{z_{s\gamma}+2\varepsilon}{c\tau+d}+\frac{mc(z_{s\gamma}+\varepsilon)^2}{c\tau+d}\Bigr)\,\varphi\bigl(\tau,\,z_{s\gamma}+\varepsilon\bigr)\\
&\equiv (c\tau+d)^k\,\mathbf{e}(m\alpha_{s\gamma}(z_{s\gamma}+2\varepsilon))\,\varphi(\tau,\,z_{s\gamma}+\varepsilon)\\
&\equiv (c\tau+d)^k\left[\frac{E_{s\gamma}(\tau)}{(2\pi i\varepsilon)^2}+\frac{D_{s\gamma}(\tau)}{2\pi i\varepsilon}\right],
\end{aligned}$$

where "$\equiv$" means equality modulo a quantity that is bounded as $\varepsilon\to 0$. The claim follows.

Next, we must define a standard Appell-Lerch sum with a double pole at $z=z_s$. We begin by defining a rational function $\mathcal{R}_c^{(2)}(y)$ with a double pole at $y=1$ for each $c\in\mathbb{R}$. Motivated by Proposition 8.1, we require

$$\mathcal{R}_c^{(2)}(\mathbf{e}(z)) \;=\; \mathrm{Av}_{\mathbb{Z}}\Bigl[\frac{\mathbf{e}(cz)}{(2\pi iz)^2}\Bigr] \;=\; \frac{1}{(2\pi i)^2}\sum_{n\in\mathbb{Z}}\frac{\mathbf{e}(c(z-n))}{(z-n)^2}\,. \tag{8.39}$$

To calculate this explicitly as a rational function, we could imitate the proof of Proposition 8.1, but it is easier to note that $\mathcal{R}_c^{(2)} = \bigl(-\frac{1}{2\pi i}\frac{d}{dz}+c\bigr)\mathcal{R}_c = \bigl(-y\frac{d}{dy}+c\bigr)\mathcal{R}_c$ and hence from equations (8.15), (8.14) and (8.13) we get three alternative definitions

$$\mathcal{R}_c^{(2)}(y) \;=\; \sum_{\ell\in\mathbb{Z}}\frac{|\ell-c|\,+\,\mathrm{sgn}(z_2)\,(\ell-c)}{2}\,y^\ell \tag{8.40}$$

$$= \begin{cases}\sum_{\ell\ge c}(\ell-c)\,y^\ell & \text{if } |y|<1\\ \sum_{\ell\le c}(c-\ell)\,y^\ell & \text{if } |y|>1\end{cases} \tag{8.41}$$

$$= y^{\lfloor c\rfloor+1}\Bigl(\frac{1}{(y-1)^2}+\frac{c\,-\,\lfloor c\rfloor}{y-1}\Bigr)\,. \tag{8.42}$$

of $\mathcal{R}^{(2)}_c(y)$. (Notice that in these equations neither the asterisk on the summation sign nor the case distinction for $c \in \mathbb{Z}$ and $c \notin \mathbb{Z}$ are needed as before, and that the function $\mathcal{R}^{(2)}_c(y)$, unlike $\mathcal{R}_c(y)$, is continuous in c.) For $s = (\alpha, \beta) \in \mathbb{Q}^2$ and $m \in \mathbb{N}$ we set

$$\mathcal{B}^s_m(\tau, z) \;=\; \mathbf{e}(-m\alpha z_s)\,\mathrm{Av}^{(m)}\bigl[\mathcal{R}^{(2)}_{-2m\alpha}(y/y_s)\bigr]\,, \tag{8.43}$$

in analogy with (8.17). If we then define the polar part φ^P of φ by

$$\varphi^P(\tau, z) \;=\; \sum_{s \in S/\mathbb{Z}^2} \Bigl(D_s(\tau)\,\mathcal{A}^s_m(\tau, z) \;+\; E_s(\tau)\,\mathcal{B}^s_m(\tau, z)\Bigr)\,; \tag{8.44}$$

then the definitions of the functions D_s, E_s, $\mathcal{A}^s_m$ and $\mathcal{B}^s_m$ immediately imply that φ^P has the same singularities as φ, so that the difference

$$\varphi^F(\tau, z) \;=\; \varphi(\tau, z) \;-\; \varphi^P(\tau, z) \tag{8.45}$$

is a holomorphic function of z.

As before, the key property of the Appell-Lerch sums is that they are again mock Jacobi forms, of a somewhat more complicated type than before. We introduce the unary theta series

$$\vartheta^s_{m,\ell}(\tau) \;=\; \mathbf{e}(-m\alpha\beta) \sum_{\lambda \in \mathbb{Z}+\alpha+\ell/2m} \mathbf{e}(2m\beta\lambda)\, q^{m\lambda^2} \tag{8.46}$$

of weight $1/2$ and its (again slightly renormalized) Eichler integral

$$\vartheta^{s\,*}_{m,\ell}(\tau) \;=\; \frac{\overline{\vartheta^s_{m,\ell}(\tau)}}{2\pi\sqrt{m\tau_2}} \;-\; \mathbf{e}(m\alpha\beta) \sum_{\lambda \in \mathbb{Z}+\alpha+\ell/2m} |\lambda|\,\mathbf{e}(-2m\beta\lambda)\,\mathrm{erfc}\bigl(2|\lambda|\sqrt{\pi m\tau_2}\bigr)\, q^{-m\lambda^2} \tag{8.47}$$

(cf. (7.2) and (7.6)). Then we can define the completion $\widehat{\mathcal{B}}^s_m$ of $\mathcal{B}^s_m$ by

$$\widehat{\mathcal{B}}^s_m(\tau, z) \;:=\; \mathcal{B}^s_m(\tau, z) \;+\; m \sum_{\ell \pmod{2m}} \vartheta^{s\,*}_{m,\ell}(\tau)\,\vartheta_{m,\ell}(\tau, z)\;. \tag{8.48}$$

Proposition 8.4. *For $m \in \mathbb{N}$ and $s \in \mathbb{Q}^2$ the completion $\widehat{\mathcal{B}}^s_m$ of $\mathcal{B}^s_m$ defined by (8.48) satisfies*

$$\widehat{\mathcal{B}}^{(\alpha+\lambda,\beta+\mu)}_m(\tau, z) \;=\; \mathbf{e}(-m(\mu\alpha - \lambda\beta + \lambda\mu))\,\widehat{\mathcal{B}}^{(\alpha,\beta)}_m(\tau) \qquad (\lambda,\,\mu \in \mathbb{Z})\,, \tag{8.49}$$

$$\widehat{\mathcal{B}}^s_m(\tau, z + \lambda\tau + \mu) \;=\; \mathbf{e}(-m(\lambda^2\tau + 2\lambda z))\,\widehat{\mathcal{B}}^s_m(\tau) \qquad (\lambda,\,\mu \in \mathbb{Z})\,, \tag{8.50}$$

$$\widehat{\mathcal{B}}^s_m\Bigl(\frac{a\tau + b}{c\tau + d}, \frac{z}{c\tau + d}\Bigr) \;=\; (c\tau + d)^2\,\mathbf{e}\Bigl(\frac{mcz^2}{c\tau + d}\Bigr)\,\widehat{\mathcal{B}}^{s\gamma}_m(\tau, z) \qquad \Bigl(\gamma = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in SL(2, \mathbb{Z})\Bigr)\,. \tag{8.51}$$

The proof is exactly similar to that of 8.2. We define functions $g_u^{(m)}(z;\tau)$ and $\tilde{g}_u^{(m)}(z;\tau)$ by applying the operator $\dfrac{1}{2\pi i}\dfrac{\partial}{\partial u} - 2m\dfrac{u_2}{\tau_2}$ to $f_u^{(m)}(z;\tau)$ and $\tilde{f}_u^{(m)}(z;\tau)$; then the transformation equation (8.33) of $\tilde{f}_u^{(m)}$ implies the same transformation equation for $\tilde{g}_u^{(m)}$ but with the initial factor $(c\tau+d)$ replaced by $(c\tau+d)^2$, and a calculation exactly similar to the one given before shows that $\mathbf{e}(m\alpha z_s)\mathcal{B}_m^s(\tau,z)$ differs from $g_{z_s}^{(m)}(z;\tau)$ by a finite linear combination of functions $\vartheta_{m,r}(\tau,z)$ and that $\mathbf{e}(m\alpha z_s)\widehat{\mathcal{B}}_m^s(\tau,z) = \tilde{g}_{z_s}^{(m)}(z;\tau)$. We omit the details.

Theorem 8.3. *Let φ be as above, with singularities at $z = z_s$ ($s \in S \subset \mathbb{Q}^2$) given by (8.37). Then the finite part φ^F as defined by (8.45) coincides with the finite part defined by the theta expansion (8.3), the coefficients $h_\ell(\tau)$ in this expansion are mixed mock modular forms, with completion given by*

$$\widehat{h}_\ell(\tau) \;=\; h_\ell(\tau) \;+\; \sum_{s\in S/\mathbb{Z}^2}\Big(D_s(\tau)\,\Theta^{s\,*}_{m,\ell}(\tau) \;+\; E_s(\tau)\,\vartheta^{s\,*}_{m,\ell}(\tau)\Big)\,,$$

and the completion $\widehat{\varphi}^F$ defined by (8.27) transforms like a Jacobi form of weight k and index m.

The proof follows the same lines as before: the equivalence of (8.3) and (8.45) is proved by expanding $\varphi(\tau,z)$ as a Fourier series along the horizontal line $\mathrm{Im}(z) = \mathrm{Im}(P)$ for some generic point $P \in \mathbb{C}$ and calculating the difference $\varphi - \varphi^F$ as a sum of residues, and the mock modularity is proved by decomposing φ as $\widehat{\varphi}^F + \widehat{\varphi}^P$ with $\widehat{\varphi}^F$ as in (8.27) and $\widehat{\varphi}^P = \sum_{s\in S/\mathbb{Z}^2}\big(D_s\widehat{\mathcal{A}}_m^s + E_s\widehat{\mathcal{B}}_m^s\big)$, which transforms like a Jacobi form by virtue of Proposition 8.4. Again the details are left to the reader. Note that here the mock modular forms $h_\ell(\tau)$ are of the "even more mixed" variety mentioned at the end of §7.2, since they now have a shadow that is a linear combination of two terms $\sum_s D_s\,\overline{\Theta^s_{m,l}}$ and $\sum_s E_s\,\overline{\vartheta^s_{m,l}}$ belonging to two different tensor products $M_{k-1}\otimes\overline{M_{3/2}}$ and $M_{k-2}\otimes\overline{M_{1/2}}$ and hence two different mixed weights $k-\frac{1}{2}\,|\,k-1$ and $k-\frac{1}{2}\,|\,k-2$ rather than a single mixed weight $k-\frac{1}{2}\,|\,k-1$ as in the case of simple poles.

8.5 Examples

We end this section by giving five examples of meromorphic Jacobi forms and their canonical decompositions into a mock Jacobi form and a finite linear combination of Appell-Lerch sums. We systematically use the notations $A = \varphi_{-2,1}$, $B = \varphi_{0,1}$, $C = \varphi_{-1,2}$ for the three basic generators of the ring of weak Jacobi forms as described in equations (4.26)–(4.35).

Example 1: Weight 1, index 1, simple pole at $z = 0$. As our first example we take the Jacobi form $\varphi = C/A \in J^{\mathrm{mer}}_{1,1}$, which has a simple pole of residue $1/\pi i$ at $z = 0$ and a Fourier expansion beginning

$$\frac{y+1}{y-1} \,-\, (y^2-y^{-2})\,q \,-\, 2(y^3-y^{-3})\,q^2 \,-\, 2(y^4-y^{-4})\,q^3 \,-\, (2y^5+y^4-y^{-4}-2y^{-5})\,q^4 \,-\, \cdots\,.$$

Calculating the Fourier expansion of the polar part $\varphi^P = \mathrm{Av}^{(1)}\bigl[\frac{y+1}{y-1}\bigr]$, we find that it begins the same way, and indeed, we must have $\varphi = \varphi^P$ because the Fourier coefficients h_ℓ all vanish (we have $h_{-\ell} = -h_\ell$ because the weight is odd and $h_{\ell+2} = h_\ell$ because the index is 1). So here there is no mock Jacobi form at all, but only the polar correction term given by the Appell-Lerch sum, a kind of a "Cheshire cat" example which is all smile and no cat.

Example 2: Weight 1, index 2, simple pole at $z = 0$. As a second example take $\varphi = BC/A \in J^{\mathrm{mer}}_{1,2}$. Here we find

$$\begin{aligned}\varphi^P \;&=\; 12\,\mathrm{Av}^{(2)}\Bigl[\frac{y+1}{y-1}\Bigr] \;=\; 12\,\frac{y+1}{y-1} \;-\; 12(y^4-y^{-4})q^2 \;+\; 24(y^5-y^{-5})\,q^3 \;+\;\cdots\\ \varphi^F \;&=\; (y-y^{-1}) \;-\; (y^3+45y-45y^{-1}-y^{-3})q \;+\; (45y^3-231y+231y^{-1}-45y^{-3})q^2 \;+\;\cdots\,,\end{aligned}$$

and by comparing the shadows and the first few Fourier coefficients (cf. eq. (7.32)), we see that φ^F is the negative of the mock Jacobi form $\mathcal{F}_2(\tau,z) = h^{(2)}(\tau)\,\vartheta_1(\tau,2z)$ discussed in Example 4 of §7.2 that is conjecturally related to representations of M_{24}. Using (4.31) and dividing by $\vartheta_1(\tau,2z)$, we can rewrite the identity $\varphi = \varphi^P + \varphi^F$ as

$$\eta(\tau)^{-3}\,\frac{\varphi_{0,1}(\tau,z)}{\varphi_{-2,1}(\tau,z)} \;=\; -\,\frac{12}{\vartheta_1(\tau,2z)}\,\mathrm{Av}^{(2)}\Bigl[\frac{1+y}{1-y}\Bigr] \;-\; h^{(2)}(\tau)\,. \qquad (8.52)$$

One can check that $\vartheta_1(\tau,2z)\mu(\tau,z) = \mathrm{Av}^{(2)}\bigl[\frac{1+y}{1-y}\bigr]$, so this agrees with the splitting (7.39) coming from the decomposition of the elliptic genus of $K3$ into superconformal characters.

Example 3: Weight 1, index 1/2, simple pole at $z = 0$. We can also multiply (7.39) by $\vartheta_1(\tau,z)$ and write it in the form

$$\frac{B}{\sqrt{A}} \;=\; -12\,\mathrm{Av}^{(\frac12,-)}\Bigl[\frac{\sqrt{y}}{1-y}\Bigr] \;-\; h^{(2)}(\tau)\,\vartheta_1(\tau,z)\,, \qquad (8.53)$$

where $\mathrm{Av}^{(\frac12,-)}[F(y)] := \sum_{n\in\mathbb{Z}}(-1)^n q^{n^2/2}\,y^n\,F(q^n y)$. This decomposition also fits into the scheme explained in this section, but slightly modified because the index here is half-integral.

Example 4: Weight 2, index 0, double pole at $z = 0$. Now take $\varphi = B/A$, which, as we saw in §4.3, is just a multiple of the Weierstrass $\wp$-function.This example does not quite fit in with the discussion given so far, since we did not allow $m = 0$ in the definition (8.9) of the averaging operator ($m < 0$ doesn't work at all, because the sum defining the average diverges, and $m = 0$ is less interesting since a form of index 0 is clearly determined up to a function of τ alone by its singularities, so that in our discussion we excluded that case too), but nevertheless it works. The decomposition $\varphi = \varphi^P + \varphi^F$ takes the form

$$\frac{\varphi_{0,1}(\tau,z)}{\varphi_{-2,1}(\tau,z)} \;=\; 12\,\mathrm{Av}^{(0)}\Bigl[\frac{y}{(1-y)^2}\Bigr] \;+\; E_2(\tau)\,, \qquad (8.54)$$

with the finite part being simply the quasimodular Eisenstein series $E_2(\tau)$, which is also a mock modular form. (It is automatically independent of z since the index is 0.)

Example 5: Weight 2, index 1, double pole at $z = 0$. The next example is a special case of an infinite family that will be treated in detail in §9. Take $\varphi = B^2/A \in J^{\mathrm{mer}}_{2,1}$. Then we find

$$\begin{aligned}\varphi \;&=\; \Big(\frac{144\,y}{(1-y)^2} + y + 22 + y^{-1}\Big) + \Big(22y^2 + 152y - 636 + 152y^{-1} + 22y^{-2}\Big)\,q \\ &\quad + \Big(145y^3 - 636y^2 + 3831y - 7544 + 3831y^{-1} - 636y^{-2} + 145y^{-3}\Big)\,q^2 + \cdots\,, \\ \varphi^{\mathrm{P}} \;&=\; \mathrm{Av}^{(1)}\Big[\frac{144\,y}{(1-y)^2}\Big] \;=\; \frac{144\,y}{(1-y)^2} + 0\,q + 144\,(y^3+y^{-3})q^2 + 288\,(y^4+y^{-4})q^3 + \cdots\end{aligned}$$

and hence that $\varphi^F = \varphi - \varphi^P = \sum_{4n-r^2\ge -1} C(4n-r^2)\,q^n\,y^r$ with the first few $C(\Delta)$ given by

Δ	-1	0	3	4	7	8	11	12	15
$C(\Delta)$	1	22	152	-636	3831	-7544	33224	-53392	191937

.

On the other hand, we have the weak Jacobi form $E_4(\tau)\varphi_{-2,1}(\tau,z) = \sum C^*(4n-r^2)q^ny^r$ with

Δ	-1	0	3	4	7	8	11	12	15
$C^*(\Delta)$	1	-2	248	-492	4119	-7256	33512	-53008	192513

,

We see that $C(\Delta)$ and $C^*(\Delta)$ are very close to each other (actually, asymptotically the same) and that their difference is precisely -288 times the Hurwitz-Kronecker class number $H(d)$. We thus have $\varphi^F = E_4A - 288\mathcal{H}$, and we have found $\mathcal{H}(\tau,z)$, the simplest of all mock Jacobi forms, as the finite part of the meromorphic Jacobi form $(E_4A^2 - B^2)/288A$. We remark that the numbers $-C^*(\Delta)$ have an interesting interpretation as "traces of singular moduli" [128].

Example 6: Weight -5, index 1, simple poles at the 2-torsion points. Finally, we give an example with more than one pole. Take $\varphi = A^3/C \in J_{1,-5}$. This function has three poles, all simple, at the three non-trivial 2-torsion points on the torus $\mathbb{C}/(\mathbb{Z}\tau+\mathbb{Z})$. The three corresponding modular forms, each of weight -6, are given by

$$D_{(0,\frac12)}(\tau) \;=\; 16\,\frac{\eta(2\tau)^{12}}{\eta(\tau)^{24}}\,, \quad D_{(\frac12,0)}(\tau) \;=\; -\frac{1}{4}\,\frac{\eta\big(\frac{\tau}{2}\big)^{12}}{\eta(\tau)^{24}}\,, \quad D_{(\frac12,\frac12)}(\tau) \;=\; \frac{i}{4}\,\frac{\eta\big(\frac{\tau+1}{2}\big)^{12}}{\eta(\tau)^{24}}\,,$$

and one finds

$$\begin{aligned}\varphi \;=\; \varphi^{\mathrm{P}} \;&=\; D_{(0,\frac12)}(\tau)\,\mathrm{Av}^{(1)}\Big[\frac{1}{2}\,\frac{y-1}{y+1}\Big] + q^{1/4}\,D_{(\frac12,0)}(\tau)\,\mathrm{Av}^{(1)}\Big[\frac{1}{2y}\,\frac{y+\sqrt{q}}{y-\sqrt{q}}\Big] \\ &\quad + q^{1/4}\,D_{(\frac12,\frac12)}(\tau)\,\mathrm{Av}^{(1)}\Big[\frac{1}{2y}\,\frac{y-\sqrt{q}}{y+\sqrt{q}}\Big]\,, \qquad \varphi^F \;\equiv\; 0\,,\end{aligned}$$

another "Cheshire cat" example (of necessity, for the same reason as in Example 1, since again $m = 1$ and k is odd).

9. Special mock Jacobi forms

We now turn to the study of certain families of meromorphic Jacobi forms of weights 1 or 2 and arbitrary positive index and of their related mock Jacobi forms, the weight 2 case being the one relevant for the application to black hole microstate counting. In this section, we introduce these families and formulate a nunmber of properties of them that were found experimentally and that we will prove in §10. In particular, it will turn out that all of these functions can be expressed, using the Hecke-like operators introduced in §4.4, in terms of a collection of mock Jacobi forms $\mathcal{Q}_m$ defined (though not quite uniquely: there is some choice involved starting at $m = 91$) for all square-free m, of weight either 1 or 2 depending on whether m has an odd or even number of prime factors. These functions, which seem to have particularly nice arithmetic properties, include all of the examples studied in §7, and several other special mock modular forms that have appeared in the literature.

9.1 The simplest meromorphic Jacobi forms

The two simplest situations for the theory described in §8 are when the meromorphic Jacobi form $\varphi = \varphi_{k,m}$ satisfies either

- $k = 1$ and $\varphi(\tau, z)$ has a simple pole at $z = 0$ and no other poles in $\mathbb{C}/(\mathbb{Z}\tau + \mathbb{Z})$ or
- $k = 2$ and $\varphi(\tau, z)$ has a double pole at $z = 0$ and no other poles in $\mathbb{C}/(\mathbb{Z}\tau + \mathbb{Z})$,

since in these two cases the modular forms $D_s(\tau)$ (resp. $E_s(\tau)$) defined in §8.2 (resp. §8.4) are simply constants and the canonical Fourier coefficients h_ℓ of φ are pure, rather than mixed, mock modular forms. If we normalize φ by $\varphi(\tau, z) \sim (2\pi i z)^{-1}$ in the first case and $\varphi(\tau, z) \sim (2\pi i z)^{-2}$ in the second case as $z \to 0$, then any two choices of φ differ by a (weakly) holomorphic Jacobi form whose Fourier coefficients are true modular forms and are therefore well understood. It therefore suffices in principle to make some specific choice of $\varphi_{1,m}$ and $\varphi_{2,m}$ for each m and to study their finite parts $\varphi^{\mathrm{F}}_{k,m}$, but, as we shall see, the problem of choosing a good representative φ is very interesting and has several subtleties. For any choice of $\varphi_{k,m}$, we will use the notation $\Phi_{k,m} := \varphi^{\mathrm{F}}_{k,m}$, with decorations like $\Phi^{\mathrm{stand}}_{k,m}$ or $\Phi^{\mathrm{opt}}_{k,m}$ corresponding to the choice of $\varphi_{k,m}$. The shadow of the mock Jacobi form $\Phi_{k,m}$ is independent of the choice of representative and is a multiple of $\sum_{\ell \pmod{2m}} \overline{\vartheta^{2-k}_{m,\ell}(\tau)}\, \vartheta_{m,\ell}(\tau, z)$, where $\vartheta^1_{m,\ell}$ and $\vartheta^0_{m,\ell}$ are defined as at the end of §4.2.

The Jacobi forms $\varphi_{2,m}$ are the ones related to the Fourier coefficients ψ_m of $\Phi_{10}(\Omega)^{-1}$ that appear in the application to black holes (eq. (1.1)). Indeed, since the principal part of the pole of $\psi_m(\tau, z)$ at $z = 0$ equals $p_{24}(m+1)\,\Delta(\tau)^{-1}\,(2\pi i z)^{-2}$, we can write $\Delta(\tau)\psi_m(\tau, z)$ as the sum of $p_{24}(m+1)\,\varphi_{2,m}$ and a weak Jacobi form. If we make the simplest choice for $\varphi_{2,m}$, namely

$$\varphi^{\mathrm{stand}}_{2,m} \;=\; \frac{B^{m+1}}{12^{m+1} A}\,, \tag{9.1}$$

where $A = \varphi_{-2,1}$, $B = \varphi_{0,1}$ are the special Jacobi forms introduced in §4 (which has the correct principal part because $A(\tau,z) \sim (2\pi iz)^2$ and $B(\tau,z) \to 12$ as $z \to 0$), then the first few values of $\Delta(\tau)\,\psi_m(\tau,z) - p_{24}(m+1)\,\varphi_{2,m}^{\text{stand}}(\tau,z)$ can be read off from (5.16). For instance, we have $p_{24}(3) = 3200$ and the fourth equation of (5.16) says that $\Delta\psi_2 = 3200\,\varphi_{2,2}^{\text{stand}} + \frac{16}{9}E_4AB + \frac{10}{27}E_6A^2$.

In the weight one case we can also make a simple standard choice of φ. It has to be divisible by C because the weight is odd, and since $C \sim 4\pi iz$ for $z \to 0$ we can choose

$$\varphi_{1,m}^{\text{stand}} \;=\; \frac{B^{m-1}\,C}{2\cdot 12^{m-1}\,A} \;=\; \frac{C}{2}\,\varphi_{2,m-2}^{\text{stand}}\,. \tag{9.2}$$

as our standard functions. However, we emphasize that (9.1) and (9.2) are only the starting points for our discussion and will be replaced by better choices as we go along.

We will apply the decomposition of §8 to the functions φ. The polar part is independent of the choice of φ and is given by $\varphi_{k,m}^{\text{P}} = \mathcal{A}_{k,m}$, where $\mathcal{A}_{k,m}$ is given (in the notation of equations (8.17) and (8.43)) by

$$\mathcal{A}_{1,m} \;=\; \mathcal{A}_{1,m}^{(0,0)} \;=\; \text{Av}^{(m)}\Big[\frac{1}{2}\,\frac{y+1}{y-1}\Big]\,, \qquad \mathcal{A}_{2,m} \;=\; \mathcal{A}_{2,m}^{(0,0)} \;=\; \text{Av}^{(m)}\Big[\frac{y}{(y-1)^2}\Big] \tag{9.3}$$

or—written out explicitly—by

$$\mathcal{A}_{1,m}(\tau,z) \;=\; -\frac{1}{2}\sum_{s\in\mathbb{Z}} q^{ms^2}\,y^{2ms}\,\frac{1+q^sy}{1-q^sy}\,, \qquad \mathcal{A}_{2,m}(\tau,z) \;=\; \sum_{s\in\mathbb{Z}} \frac{q^{ms^2+s}\,y^{2ms+1}}{(1-q^sy)^2}\,. \tag{9.4}$$

Also independent of the choice of φ is the correction term which must be added to the finite part and subtracted from the polar part of $\varphi_{2,m}$ in order to make these functions transform like Jacobi forms. In particular, for the double pole case, we find from (8.48) that the completion $\widehat{\Phi}_{2,m}$ of $\Phi_{2,m} = \varphi_{2,m}^{\text{F}}$ for any choice of $\varphi_{2,m}$ is given by

$$\widehat{\Phi}_{2,m}(\tau,z) \;=\; \Phi_{2,m}(\tau,z) \;-\; \sqrt{\frac{m}{4\pi}}\sum_{\ell\ (\text{mod}\ 2m)} \big(\vartheta^0_{m,\ell}\big)^*(\tau)\,\vartheta_{m,\ell}(\tau,z)\,, \tag{9.5}$$

where $\vartheta^0_{m,\ell}(\tau) = \vartheta_{m,\ell}(\tau,0)$ and $(\vartheta^0_{m,\ell})^*$ is normalized[18] as in equations (7.2) and (7.6).

The functions $\mathcal{A}_{1,m}$, $\mathcal{A}_{2,m}$ have wall-crossings, so their Fourier expansions depend on the value of $z_2 = \text{Im}(z)$. In the range $0 < z_2 < \tau_2$, or $|q| < |y| < 1$, they are given by

$$\mathcal{A}_{1,m} \;=\; \Big(-\sum_{s\geq 0}\sum_{\ell\geq 0}{}^{*} + \sum_{s<0}\sum_{\ell\leq 0}{}^{*}\Big)\, q^{ms^2+\ell s}\,y^{2ms+\ell}\,, \tag{9.6}$$

$$\mathcal{A}_{2,m} \;=\; \Big(\sum_{s\geq 0}\sum_{\ell\geq 0}{}^{*} - \sum_{s<0}\sum_{\ell\leq 0}{}^{*}\Big)\,\ell\, q^{ms^2+\ell s}\,y^{2ms+\ell}\,, \tag{9.7}$$

---

[18] Note that the function $\vartheta^{(0,0)\,*}_{m,\ell}$ as defined in (8.47) is equal to $1/\sqrt{4\pi m}$ times $(\vartheta^0_{m,\ell})^*$.

where the asterisk on the summation sign has the usual meaning (count the term $\ell = 0$ with multiplicity 1/2). Hence the coefficient of $q^n y^r$ is zero unless $\Delta = 4mn - r^2$ is the negative of the square of an integer congruent to r modulo $2m$, in which case it is 0, $\pm\frac{1}{2}$, ± 1 or ± 2 if $k = 1$ and is 0, $\pm\sqrt{-\Delta}$ or $\pm 2\sqrt{-\Delta}$ if $k = 2$. (Compare the remark at the end of §8.3.) If we expand $\mathcal{A}_{1,m}$ and $\mathcal{A}_{2,m}$ in Fourier series for z_2 in some other interval $(N, N+1)\tau_2$, then the formulas (9.6) and (9.7) are unchanged except for a shift in the inequalities defining the summation. In summary, the Fourier coefficients of the polar part of φ, although not quite like the coefficients of a usual Jacobi form—they do not only depend on Δ and on r mod $2m$, they are non-zero for infinitely many negative Δ, and there is wall-crossing—are extremely simple and have very slow growth (at most like $\sqrt{|\Delta|}$).

The interesting part of the Fourier expansion of $\varphi_{k,m}$ is therefore the mock part $\Phi_{k,m}$. Here the choice of $\varphi_{k,m}$ makes a big difference. For instance, Examples 1–4 of §8.5 say that the mock Jacobi forms $\Phi^{\text{stand}}_{k,m}$ corresponding to the standard choices (9.1) and (9.2) for small m are

$$\Phi^{\text{stand}}_{1,1} = 0, \quad \Phi^{\text{stand}}_{1,2} = \frac{1}{24}\mathcal{F}_2\,, \quad \Phi^{\text{stand}}_{2,0} = \frac{1}{12}E_2\,, \quad \Phi^{\text{stand}}_{2,1} = \frac{1}{144}E_4\,A - 2\,\mathcal{H}\,, \tag{9.8}$$

and we see that this choice is a good one in the first three cases (indeed, in these cases there *is* no choice!) but that, as we have already observed, a better choice of φ in the fourth case would have been the function $\varphi^{\text{opt}}_{2,1} = \varphi^{\text{stand}}_{2,1} - \frac{1}{144}E_4 A$, with mock part $\Phi^{\text{opt}}_{2,1} = -2\mathcal{H}$, because it has no terms $q^n y^r$ with discriminant $\Delta = 4n - r^2$ smaller than zero and (consequently) has Fourier coefficients that grow polynomially in Δ (actually, like $\Delta^{1/2+\varepsilon}$) rather than exponentially in $\sqrt{\Delta}$. Our next main objective, to which we devote the next subsection, is therefore to replace our initial choice of $\varphi_{k,m}$ as given by (9.1) or (9.2) by an optimal choice $\varphi^{\text{opt}}_{k,m}$, where "optimal" means "with the negative discriminants $d = 4mn - r^2$ that occur being as little negative as possible" or, equivalently, "with Fourier coefficients growing as slowly as possible." This choice turns out to have Fourier coefficients of very much smaller growth than those of our initial choice $\varphi^{\text{stand}}_{k,m}$ in all cases, and to be unique in many cases.

9.2 Choosing the function φ for weight 2 and small index

We now consider in more detail the meromorphic Jacobi forms of weight 2 and index m with a double pole at the origin introduced in §9.1. Any such form will have the form

$$\varphi_{2,m} = \frac{\psi_{0,m+1}}{12^{m+1}A}\,, \qquad \psi_{0,m+1} \in B^{m+1} + A\cdot\widetilde{J}_{2,m} \subset \widetilde{J}_{0,m+1}\,. \tag{9.9}$$

For each m, we want to choose a meromorphic Jacobi form $\varphi^{\text{opt}}_{2,m}$ differing from $\varphi^{\text{stand}}_{2,m}$ by a weak Jacobi form of weight 2 and index m whose coefficients grow as slowly as possible. We are interested both in the form of the corresponding $\psi_{0,m+1} = \psi^{\text{opt}}_{0,m+1}$ as a polynomial in A and B with modular form coefficients, and in the nature of the finite part $\Phi^{\text{opt}}_{2,m} = \varphi^{\text{opt}}_{2,m} - \mathcal{A}_{2,m}$ as a mock Jacobi form. In this subsection we will look at the optimal choice for $0 \le m \le 11$ to see what phenomena occur, while in the next subsection, we report on the calculations for higher values up to about 250 and formulate the general results.

For **m=0**, we have to choose

$$\varphi^{\rm opt}_{2,0} \;=\; \varphi^{\rm stand}_{2,0} \;=\; \frac{B}{12A}\,, \qquad \psi^{\rm opt}_{0,1} \;=\; B$$

because there are no weak Jacobi forms of weight 2 and index 0. The mock part $\Phi^{\rm opt}_{2,0}$ here is $E_2(\tau)/12$, as we have already seen (Example 3 of §8.5).

For **m=1** the only freedom is the addition of a multiple of E_4A and (as recalled in §9.1) the optimal choice is

$$\varphi^{\rm opt}_{2,1} \;=\; \varphi^{\rm stand}_{2,1} \;-\; \frac{E_4A}{144}\,, \qquad \psi^{\rm opt}_{0,2} \;=\; B^2 \;-\; E_4A^2\,, \tag{9.10}$$

because then $\Phi^{\rm opt}_{2,1} \;=\; -2\mathcal{H}$ has no terms q^ny^r with $4n - r^2 < 0$ and its Fourier coefficients $-2H(4n-r^2)$ have only polynomial growth as $4n - r^2 \to \infty$.

Now we look at **m=2**. Here we can modify $12^3\,\Phi^{\rm stand}_{2,2} = B^3/A - 12^3\mathcal{A}_{2,2}$ by adding to it any linear combination of the two weak Jacobi forms E_4AB and E_6A^2. Each of these three functions has Fourier coefficients of the form $c(n,r) = C_\varphi(8n-r^2)$ (because the (n,r)-coefficient of a Jacobi form of prime or prime power index m and even weight always depends only on the discriminant $4mn - r^2$), with the first few given by

Δ	-4	-1	0	4	7	8	12	15	16
$C(12^3\Phi^{\rm stand}_{2,2};\Delta)$	1	32	366	528	1056	-10144	-14088	92832	-181068
$C(E_4AB;\Delta)$	1	8	-18	144	2232	-4768	-22536	96264	-151884
$C(E_6A^2;\Delta)$	1	-4	6	-480	1956	-2944	-28488	96252	-139452

It follows from this table that the linear combination

$$\varphi^{\rm opt}_{2,2} \;=\; \varphi^{\rm stand}_{2,2} \;-\; \frac{1}{576}\,E_4AB \;+\; \frac{1}{864}E_6A^2 \;=\; \frac{B^3 \;-\; 3E_4A^2B \;+\; 2E_6A^3}{12^3\,A} \tag{9.11}$$

has a mock Jacobi part $\Phi^{\rm opt}_{2,2} = \varphi^{\rm opt}_{2,2} - \mathcal{A}_{2,2}$ with no negative terms and much smaller coefficients:

d	-4	-1	0	4	7	8	12	15	16
$C(\Phi^{\rm opt}_{2,2};\Delta)$	0	0	$1/4$	$-1/2$	-1	-1	-2	-2	$-5/2$

On inspection of these numbers and the next few values, we recognize them as simple linear combinations of Hurwitz class numbers, namely:

$$C(\Phi^{\rm opt}_{2,2};\Delta) = \begin{cases} -H(\Delta) & \text{if } \Delta \equiv 7 \pmod 8\,, \\ -H(\Delta) - 2H(\Delta/4) & \text{if } \Delta \equiv 0 \pmod 4\,, \end{cases}$$

which says that $\Phi^{\rm opt}_{2,2}$ is simply $-\mathcal{H}|V_2$, with $\mathcal{H}$ as in (7.25) and V_2 as in (4.37). (Note, by the way, the similarity between (9.11) and (4.33). Together they say that $\varphi^{\rm opt}_{2,2} = (C/2A)^2$.)

The cases **m=3**, **m=4**, **m=5**, **m=7**, **m=8**, **m=9** and **m=11** are similar to the case $m = 2$. For each of these values of m the coefficient of $q^n y^r$ in $\Phi^{\rm stand}_{2,m}$ depends only on $\Delta = 4nm - r^2$, the number of negative Δ for which this coefficient is non-zero equals the dimension of the space of weak Jacobi forms of weight 2 and index m, and we can subtract a unique weak Jacobi form from $\varphi^{\rm stand}_{2,m}$ to obtain a meromorphic Jacobi form $\varphi^{\rm opt}_{2,m}$ whose finite part is a strongly holomorphic mock Jacobi form with very small Fourier coefficients. For example, for $m = 3$ the optimal choice of $\varphi^{\rm opt}_{2,m}$ is $\varphi^{\rm opt}_{2,3} = \psi^{\rm opt}_{0,4}/12^4 A$ with

$$\psi^{\rm opt}_{0,4} \;=\; B^4 \,-\, 6E_4A^2B^2 \,+\, 8E_6A^3B \,-\, 3E_4^2A^4 \tag{9.12}$$

and the first few Fourier coefficients of $12^4\,\Phi^{\rm stand}_{2,3}$ and $\Phi^{\rm opt}_{2,3}$ are given by

Δ	-9	-4	-1	0	3	8	11	12	15
$12^4\,C(\Phi^{\rm stand}_{2,3};\Delta)$	1	42	687	5452	1104	8088	-1488	-139908	-19629
$C(\Phi^{\rm opt}_{2,3};\Delta)$	0	0	0	$1/3$	$-1/3$	-1	-1	$-4/3$	-2

Again we recognize the coefficients $C(\Phi^{\rm opt}_{2,3};\Delta)$ as $-H(\Delta)$ if $9\nmid\Delta$ and $-H(\Delta)-3H(\Delta/9)$ if $9\,|\,\Delta$, so that just as for $m = 2$ we find that the mock part of $\varphi^{\rm opt}_{2,3}$ equals $-\mathcal{F}_1|V_3$. The same thing also happens for $m = 5$, 7 and 11, suggesting that for prime values of m we can always choose

$$\Phi^{\rm opt}_{2,p} \;=\; -\,\mathcal{H}|V_p \qquad (p\ \text{prime}). \tag{9.13}$$

This will be proved in §10. For the prime-power values $m = 4$, 8 and 9 this formula no longer holds, but the coefficients of $\Phi^{\rm opt}_{2,m}$ are still simple linear combinations of Hurwitz-Kronecker class numbers and we find the expressions

$$\Phi^{\rm opt}_{2,4} = -\mathcal{H}|V_4 + 2\mathcal{H}|U_2\,, \quad \Phi^{\rm opt}_{2,8} = -\mathcal{H}|V_8 + 2\mathcal{H}|U_2V_2\,, \quad \Phi^{\rm opt}_{2,9} = -\mathcal{H}|V_9 + 3\mathcal{H}|U_3\,,$$

where U_t is the Hecke-like operator defined in §4.4 that multiplies the index of a Jacobi form (or mock Jacobi form) by t^2. This suggests that for prime power values of m we can choose

$$\Phi^{\rm opt}_{2,m} \;=\; -2\,\mathcal{H}|\,\mathcal{V}^{(1)}_{2,m} \qquad (m\ \text{a prime power}) \tag{9.14}$$

where $\mathcal{V}^{(1)}_{k,t}$ for $t \in \mathbb{N}$ is the Hecke-like operator from Jacobi (or weakly holomorphic Jacobi, or mock Jacobi) forms of weight k and index 1 to forms of weight k and index t defined in (4.38). Formula (9.14) will also be proved in §10.

The data for the values discussed so far ($0 \le m \le 11$, $m \ne 6$, 10) is summarized in the table below, which expresses the weak Jacobi form $\psi^{\rm opt}_{0,m+1} = 12^{m+1}A\,\varphi^{\rm opt}_{2,m}$ for each of these values of m as a polynomial in A and B. In this table we notice many regularities, e.g., the coefficients of $E_4A^2B^{m-2}$, $E_6A^3B^{m-3}$ and $E_4^2A^4B^{m-4}$ in $\psi^{\rm opt}_{0,m}$ are always given by $-\binom{m}{2}$, $2\binom{m}{3}$ and $-3\binom{m}{4}$, respectively, and more generally, if we write $\psi^{\rm opt}_{0,m}$ as $\sum_{i=0}^{m} f_{m,i}\, A^i\, B^{m-i}$ with $f_{m,i} = f_{m,i}(\tau) \in M_{2i}$, $f_{m,0} = 1$, then the constant terms $f_{m,i}(\infty)$ of the modular forms $f_{m,i}$ (which can be read off from the table by setting $E_4 = E_6 = 1$ and $D = 0$) are given in each case by $f_{m,i}(\infty) = (-1)^{i-1}(i-1)\binom{m}{i}$ or equivalently by the generating function

$$\sum_{i=0}^{m} f_{m,i}(\infty)\, X^{m-i} \;=\; (X-1)^m \,+\, m\,(X-1)^{m-1} \;=\; (X-1)^{m-1}(X+m-1)\,, \qquad (9.15)$$

e.g. $X^8 - 28X^6 + 112X^5 - 210X^4 + 224X^3 - 140X^2 + 48X - 7 \,=\, (X-1)^7(X+7)$. This formula has a simple interpretation: the constant term with respect to q of $\sum f_{m,i}\, A^i\, B^{m-i}$ is $\sum f_{m,i}(\infty)(y^{-1} - 2 + y)^i(y^{-1} + 10 + y)^{m-i}$ and this Laurent polynomial—subject to the condition $f_{m,1}(\infty) = 0$, which comes from the fact that there are no modular forms of weight 2 on $SL(2,\mathbb{Z})$—has minimal growth $\mathrm{O}\big(y + y^{-1}\big)$ precisely for the coefficients defined by (9.15).

Table 2: Coefficients of $\psi^{\rm opt}_{0,m}$ in terms of the standard basis. Here $D := 2^{11}3^3\Delta$.

For **m=6** several new things happen, all connected with the fact that 6 is the first value of m having more than one prime factor. First of all, the formula (9.14), which worked for prime powers, now fails: $-2\mathcal{H}|\mathcal{V}_{2,6}^{(1)}$ is not a possible choice for $\Phi_{2,6}$. The reason is that, as we will see later in general, the form $\mathcal{H}|\mathcal{V}_{2,m}^{(1)}$ (for any m) is invariant under all Atkin-Lehner involutions, but $\Phi_{2,m}$ is not when m is not a prime power. The expression $-2\mathcal{H}|\mathcal{V}_{2,6}^{(1)}$ does, however, give the optimal choice of the eigencomponent $\Phi_{2,6}^{++}$ of $\Phi_{2,6}$ with eigenvalues $W_2 = W_3 = +1$. The other eigencomponent, corresponding to $W_2 = W_3 = -1$, is obtained by subtracting a multiple of the non-weak Jacobi form $\varphi_{2,6}^{-}$ given in (4.48) from $\pi_2^{-}(\Phi_{2,6}^{\text{opt}})$ (which is weakly holomorphic but not weak), and turns out to be simply a multiple of the mock Jacobi form $\mathcal{F}_6$ defined in §7.2 (Example 3), giving as our first choice of the "optimal" mock modular form

$$\Phi_{2,6}^{\text{I}} \;=\; -2\,\mathcal{H}\,|\,\mathcal{V}_{2,6}^{(1)} \;-\; \frac{1}{24}\,\mathcal{F}_6\;. \tag{9.16}$$

The second new phenomenon for $m = 6$ is that requiring the order of the poles to be as small as possible no longer fixes a unique optimal choice. The function $\Phi_{2,6}^{\text{I}}$ defined above has an even part that is strongly holomorphic (because $\mathcal{H}$ is) and an odd part that has discriminant $\Delta \geq -1$ (because $C^{(6)}(\Delta) = 0$ for $\Delta < -1$), but we can change this choice without disturbing the discriminant bound $\Delta \geq -1$ by adding to it an arbitrary multiple of the function

$$\mathcal{K}_6 = \frac{E_4AB^5 - 5E_6A^2B^4 + 10E_4^2A^3B^3 - 10E_4E_6A^4B^2 + (5E_4^3 - \frac{1}{4}D)A^5B - E_4^2E_6A^5}{12^5} \tag{9.17}$$

which is (up to a scalar factor, fixed here by requiring $\mathcal{K}_6 = y - 2 + y^{-1} + \mathrm{O}(q)$) the unique Jacobi form of weight 2 and index 6 satisfying the same discriminant bound.

Two particularly nice choices besides the function $\Phi_{2,6}^{\text{I}}$ are the functions

$$\Phi_{2,6}^{\text{II}} \;=\; \Phi_{2,6}^{\text{I}} \;-\; \frac{1}{24}\,\mathcal{K}_6 \qquad \Phi_{2,6}^{\text{III}} \;=\; \Phi_{2,6}^{\text{I}} \;+\; \frac{1}{4}\,\mathcal{K}_6 \tag{9.18}$$

The special properties of these two choices are that $\Phi_{2,6}^{\text{II}}$ is the unique choice with $c(\Phi; 0, 1) = 0$ and (hence) has the form $12^{-7}\sum_{i=0}^{7} f_{7,i}A^{i-1}B^{7-i}$ with $f_{7,i}$ satisfying (9.15), while $\Phi_{2,6}^{\text{III}}$ is the unique choice for which $c(n,r) = 0$ whenever $24n = r^2$. (This last choice is from some points of view the most canonical one.) Each of these three special choices, as we shall see below, has analogues for all m, although in general none of them is canonical, since for large m we can change them by adding cusp forms without affecting their defining properties and we do not know any criterion that selects a unique form.

The following table, which gives the first few Fourier coefficients $C(\Phi; \Delta,\, r \pmod{12})$ for the Jacobi form $\mathcal{K}_6$ and each of the five mock Jacobi forms $-2\mathcal{H}|\mathcal{V}_{2,6}^{(1)}$, $\mathcal{F}_6$, $\Phi_{2,6}^{\text{I}}$, $12\Phi_{2,6}^{\text{II}}$ and $\Phi_{2,6}^{\text{III}}$, summarizes the above discussion. In this table we have set in boldface the Fourier coefficients $C(\Delta, r)$ whose special properties determine the choice of Φ (namely, $C(-1,\pm1) + C(-1,\pm5) = 0$ for Φ^{I}, $C(-1,\pm1) = 0$ for Φ^{II}, and $C(0,0) = 0$ for Φ^{III}). We mention in passing

Δ	-1	-1	0	8	12	15	20	23	23	24	32	36	39
$r \pmod{12}$	±1	±5	0	±4	6	±3	±2	±1	±5	0	±4	6	±3
$\mathcal{K}_6$	1	1	-2	10	28	10	-12	13	13	-44	58	104	2
$-2\mathcal{H}\,\vert\,\mathcal{V}_{2,6}$	0	0	$\frac{1}{2}$	$-\frac{1}{2}$	-1	-1	-1	$-\frac{3}{2}$	$-\frac{3}{2}$	-1	$-\frac{5}{2}$	-2	-2
$\mathcal{F}_6$	-1	1	0	0	0	0	0	35	-35	0	0	0	0
$\Phi^{\rm I}_{2,6}$	$\boldsymbol{\frac{1}{24}}$	$-\boldsymbol{\frac{1}{24}}$	$\frac{1}{2}$	$-\frac{1}{2}$	-1	-1	-1	$-\frac{71}{24}$	$-\frac{1}{24}$	-1	$-\frac{5}{2}$	-2	-2
$12\,\Phi^{\rm II}_{2,6}$	$\mathbf{0}$	-1	7	-11	-26	-17	-6	-42	-7	10	-59	-76	-25
$\Phi^{\rm III}_{2,6}$	$\frac{7}{24}$	$\frac{5}{24}$	$\mathbf{0}$	2	6	$\frac{3}{2}$	-4	$\frac{7}{24}$	$\frac{77}{24}$	-12	12	24	$-\frac{3}{2}$

Table 3: Jacobi and mock Jacobi forms of weight 2 and index 6

that the function $\psi^{\rm I}_{0,7} = 12^7 A\varphi^{\rm I}_{2,6}$ corresponding to (9.16) is precisely equal to B times $\psi^{\rm opt}_{0,6}$ as given in Table 2. We do not know if this has any special significance. It may be connected with the fact that $\psi^{\rm opt}_{0,6}$, which is equal to the quotient $\vartheta_1(\tau,4z)/\vartheta_1(\tau,2z)$ (Watson quintuple product identity), is a (-1)–eigenvector of the involution $W_2 = W_3$ on $\widetilde{J}_{0,6}$.

For **m=10** the situation is similar. Again, we can achieve $\Delta \geq -1$ but not uniquely because there is a weak Jacobi form $\mathcal{K}_{10} \in \widetilde{J}_{2,10}$ (unique up to a normalizing factor, which we fix in the same way as before) satisfying the same discriminant bound and we can change $\varphi_{2,10}$ an arbitrary multiple of $\mathcal{K}_{10}$. We again have three distinguished choices

$$\varphi^{\rm II}_{2,10} \;=\; \frac{\psi^{\rm II}_{0,11}}{12^{11}A}\,, \qquad \varphi^{\rm I}_{2,10} \;=\; \varphi^{\rm II}_{2,10} + \frac{1}{12}\mathcal{K}_{10} \qquad \varphi^{\rm III}_{2,10} \;=\; \varphi^{\rm I}_{2,10} + \frac{3}{8}\mathcal{K}_{10}\,, \tag{9.19}$$

where $\psi^{\rm II}_{0,11} \in \widetilde{J}_{0,11}$ is given (with $D = 32(E_4^3 - E_6^2) = 2^{11}3^3\Delta$ as in Table 2) by

$$\begin{aligned}\Psi^{\rm II}_{11} = {}& B^{11} - 55E_4A^2B^9 + 330E_6A^3B^8 - 990E_4^2A^4B^7 + 1848E_4E_6A^5B^6 - (2310E_4^3 - 111D)A^6B^5\\ &+1980E_4^2E_6A^7B^4 - (1155E_4^4 + 120E_4D)A^8B^3 + (440E_4^3E_6 + 20E_6D)A^9B^2\\ &-(99E_4^5 - 117E_4^2D)A^{10}B + (10E_4^4E_6 - 56E_4E_6D)A^{11}\end{aligned} \tag{9.20}$$

and is the unique choice satisfying (9.15), $\Phi^{\rm III}_{2,10}$ is the unique choice with no $\Delta = 0$ coefficients, and $\Phi^{\rm I}_{2,10}$ is the unique choice whose invariant part under W_2 (or W_5) is strongly holomorphic. Explicitly, we have

$$\Phi^{\rm I}_{2,10} \;=\; -\,2\,\mathcal{H}|\mathcal{V}^{(1)}_{2,10} - \frac{1}{12}\mathcal{F}_{10} \tag{9.21}$$

where $\mathcal{F}_{10}$ is a mock Jacobi form of weight 2 and index 10 with Fourier coefficients given by

$$c(\mathcal{F}_{10};n,r) = \begin{cases} \;\;C^{(10)}(40n - r^2) & r \equiv \pm1 \pmod{20} \text{ or } r \equiv \pm3 \pmod{20}\\ -\,C^{(10)}(40n - r^2) & r \equiv \pm7 \pmod{20} \text{ or } r \equiv \pm9 \pmod{20}\end{cases} \tag{9.22}$$

for a function $C^{10}(\Delta)$ whose first few values are

Δ	-1	31	39	71	79	111	119	151	159	191	199	231	239
$C^{(10)}(\Delta)$	-1	9	21	35	63	57	112	126	207	154	306	315	511

,

or equivalently, where $\mathcal{F}_{10}$ has a theta expansion of the form

$$\mathcal{F}_{10}(\tau,z) \;=\; \sum_{\substack{\ell \ (\mathrm{mod}\ 20)\\ (\ell,10)=1}} h_\ell(\tau)\,\vartheta_{10,\ell}(\tau,z) \tag{9.23}$$

with mock modular forms $h_\ell = h_\ell(\tau)$ having expansions beginning

$$h_1 \;=\; -h_9 \;=\; -h_{11} \;=\; h_{19} \;=\; q^{-1/40}\left(-1 \,+\, 21q \,+\, 63q^2 \,+\, 112q^3 \,+\, \cdots\right), \tag{9.24}$$

$$h_3 \;=\; -h_7 \;=\; -h_{13} \;=\; h_{17} \;=\; q^{31/40}\left(9 \,+\, 35q \,+\, 57q^2 \,+\, 126q^3 \cdots\right). \tag{9.25}$$

9.3 Further data and formulation of main results for the weight 2 family

In §9.2, we found that the functions $\Phi_{2,m}$ for $m \le 11$ could all be obtained, using the Hecke-like operators from §4.4, from just three functions $\mathcal{H}$, $\mathcal{F}_6$ and $\mathcal{F}_{10}$. Continuing, we find that for $\mathbf{m = 12}$ the same statement holds: the $(+1,+1)$ eigencomponent of this form with respect to the involutions W_4 and W_3 can be chosen to be $-2\mathcal{H}|\mathcal{V}^{(1)}_{2,12}$ and the $(-1,-1)$ eigencomponent can be chosen to be $\frac{1}{12}\mathcal{F}_6|\mathcal{V}^{(6)}_{2,2}$, with $\mathcal{V}^{(M)}_{k,t}$ as in (4.38) (so $V^{(1)}_{2,12} = \frac{1}{4}(V_{12} - 2V_2U_3)$ and $\mathcal{V}^{(6)}_{2,2} = \frac{1}{2}V_2$). Thus

$$\Phi_{2,12} \;=\; -2\mathcal{H}\,|\,\mathcal{V}^{(1)}_{2,12} \,+\, \frac{1}{12}\,\mathcal{F}_6\,|\,\mathcal{V}^{(6)}_{2,2} \tag{9.26}$$

is a possible choice for $\Phi_{2,12}$. Similarly, for $\mathbf{m = 18}$ and $\mathbf{m = 24}$ we can take the functions

$$\Phi_{2,18} \;=\; -2\mathcal{H}\,|\,\mathcal{V}^{(1)}_{2,18} \,+\, \frac{1}{24}\,\mathcal{F}_6\,|\,\mathcal{V}^{(6)}_{2,3}\,, \qquad \Phi_{2,24} \;=\; -2\mathcal{H}\,|\,\mathcal{V}^{(1)}_{2,24} \,+\, \frac{1}{24}\,\mathcal{F}_6\,|\,\mathcal{V}^{(6)}_{2,4} \tag{9.27}$$

as our representatives of the coset $\Phi^{\text{stand}}_{2,m} + \widetilde{J}_{2,m}$.

On the other hand, the indices $\mathbf{m = 14}$ and $\mathbf{m = 15}$ are similar to the indices $m = 6$ and $m = 10$ looked at previously: here we find optimal mock Jacobi forms of the form

$$\Phi_{2,14} \;=\; -2\mathcal{H}\,|\,\mathcal{V}^{(1)}_{2,14} \,-\, \frac{1}{8}\,\mathcal{F}_{14}\,, \qquad \Phi_{2,15} \;=\; -2\mathcal{H}\,|\,\mathcal{V}^{(1)}_{2,15} \,-\, \frac{1}{6}\,\mathcal{F}_{15}\,, \tag{9.28}$$

where $\mathcal{F}_{14}$ and $\mathcal{F}_{15}$ are forms anti-invariant under W_p $(p|m)$ with Fourier expansions of the form

$$c(\mathcal{F}_{14};n,r) = \begin{cases} \;\;C^{(14)}(56n - r^2) & \text{for } r \equiv \pm1,\ \pm3 \text{ or } \pm5 \pmod{28}, \\ -\,C^{(14)}(56n - r^2) & \text{for } r \equiv \pm9,\ \pm11, \text{ or } \pm13 \pmod{28}, \end{cases} \tag{9.29}$$

$$c(\mathcal{F}_{15};n,r) = \begin{cases} \;\;C^{(15)}(60n - r^2) & \text{for } r \equiv \pm1,\ \pm2,\ \pm4, \text{ or } \pm7 \pmod{30}, \\ -\,C^{(15)}(60n - r^2) & \text{for } r \equiv \pm8,\ \pm11,\ \pm13, \text{ or } \pm14 \pmod{30}, \end{cases} \tag{9.30}$$

with coefficients $C^{14}(\Delta)$ and $C^{15}(\Delta)$ given for small Δ by

Δ	-1	31	47	55	87	103	111	143	159	167	199	215	223
$C^{(14)}(\Delta)$	-1	3	10	15	15	30	42	20	51	65	51	85	120

,

Δ	-1	11	44	56	59	71	104	116	119	131	164	176	179
$C^{(15)}(\Delta)$	-1	2	10	4	14	9	28	24	29	26	40	28	54

.

This pattern continues: as we continue to higher values, we find that for each index M which is a product of an even number of distinct primes (i.e., for which $\mu(M)=1$, where $\mu(\,\cdot\,)$ denotes the Möbius function), we need to introduce a new function $\mathcal{Q}_M$ that is anti-invariant under W_p for all p dividing M, but that these functions and their images under Hecke-like operators then suffice to give possible choices for our special mock Jacobi forms in all indices, in the sense that the function

$$\Phi_{2,m} \;=\; \frac{1}{2^{\omega(m)-1}} \sum_{\substack{M|m\\ \mu(M)\,=\,+1}} \mathcal{Q}_M \,|\, \mathcal{V}^{(M)}_{2,\,m/M} \qquad (\,\omega(m) := \#\{p \mid p \text{ prime},\, p|M\}\,) \tag{9.31}$$

belongs to the coset $\Phi^{\text{stand}}_{k,m} + \widetilde{J}_{2,m}$ for all $m \geq 1$. (The factor $2^{1-\omega(m)}$ will be explained below.) In fact more is true. The functions $\mathcal{Q}_M$ in (9.31) are simply the $(-1,\dots,-1)$ eigencomponents of $\Phi_{2,M}$ for some choice of these latter functions within their defining cosets, and the various terms in (9.31) are the eigencomponents of $\Phi_{2,m}$ for the involutions W_{m_1} $(m_1\|m)$. In other words, we have the following theorem:

Theorem 9.1. *For any choice of the mock Jacobi forms $\Phi_{2,m} \in \Phi^{\text{stand}}_{2,m} + \widetilde{J}_{2,m}$ $(m \in \mathbb{N})$, the eigencomponents $\Phi^{\varepsilon_1,\dots,\varepsilon_r}_{2,m}$ $(m = \prod_i p_i^{\nu_i},\ \varepsilon_i = \pm 1,\ \prod \varepsilon_i = +1)$ with respect to the decomposition[19] (4.41) are given by*

$$\frac{1}{2}\Phi_{2,m}\,\Big|\,\prod_{i=1}^{r}\big(1+\varepsilon_i W_{p_i^{\nu_i}}\big) \;=\; \mathcal{Q}_M \,|\, \mathcal{V}^{(M)}_{2,m/M} \quad \big(\mathit{mod}\ (J^{!}_{2,m})^{\varepsilon_1,\dots,\varepsilon_r}\big)\,, \tag{9.32}$$

where M is the product of the p_i with $\varepsilon_i = -1$, $\mathcal{Q}_M$ is defined by

$$\mathcal{Q}_M \;=\; \frac{1}{2}\Phi_{2,M}\,\Big|\,\prod_{p|M}\big(1-W_p\big) \;=\; 2^{\omega(M)-1}\,\Phi^{-,\dots,-}_{2,M} \qquad (\mu(M)\;=\;+1), \tag{9.33}$$

and $\mathcal{V}^{(M)}_{2,m/M}$ is the Hecke-like operator defined in (4.38). In particular, the decomposition (9.31) is always true modulo $\widetilde{J}_{2,m}$, and if we choose the functions $\Phi_{2,M}$ and consequently $\mathcal{Q}_M$ arbitrarily for all M with $\mu(M)=1$, then the function defined by (9.31) gives an admissible choice of $\Phi_{2,m}$ for all indices $m \geq 1$.

---

[19] or rather, its analogue for elliptic forms

Examples. The functions $\mathcal{Q}_M$ for the first few values of M with $\mu(M) = 1$ are

$$\mathcal{Q}_1 = -\mathcal{H}\,, \quad \mathcal{Q}_6 = -\frac{\mathcal{F}_6}{12}\,, \quad \mathcal{Q}_{10} = -\frac{\mathcal{F}_{10}}{6}\,, \quad \mathcal{Q}_{14} = -\frac{\mathcal{F}_{14}}{4}\,, \quad \mathcal{Q}_{15} = -\frac{\mathcal{F}_{15}}{3}\,, \quad \dots\,, \tag{9.34}$$

where $\mathcal{H}, \mathcal{F}_6, \dots, \mathcal{F}_{15}$ are the functions introduced in §7.2, §9.2, and this subsection. (The reasons for the various normalizations, and for having two symbols $\mathcal{F}_M$ and $\mathcal{Q}_M$ to denote proportional functions, will be discussed later.)

We will prove Theorem 9.1 towards the end of this section by calculating the shadows of the mock Jacobi forms on the two sides of (9.32), since two mock Jacobi forms differ by a true Jacobi form if and only if they have the same shadow.

Remarks. 1. We wrote $\big(J^!_{2,m}\big)^{\varepsilon_1,\dots,\varepsilon_r}$ rather than $\widetilde{J}^{\varepsilon_1,\dots,\varepsilon_r}_{2,m}$ in the theorem because of the fact mentioned in §4.4 that the involutions W_{m_1} do not preserve the space of weak Jacobi forms (or weak elliptic forms), so that the left-hand side of eq. (9.32) for an arbitrary choice of $\Phi_{2,m}$ may contain monomials $q^n y^r$ with $n < 0$. In fact, it will follow from the results given below that the functions $\Phi_{2,M}$ can be chosen in such a way that the eigencomponents $\Phi^{-,\dots,-}_{2,M}$ do not contain any negative powers of q, in which case the expression on the right-hand side of (9.31) really does lie in $\Phi^{\text{stand}}_{k,m} + \widetilde{J}_{2,m}$ as asserted, and not merely in $\Phi^{\text{stand}}_{k,m} + J^!_{2,m}$.
2. An exactly similar statement is true for the functions $\Phi_{1,m}$, except that in that case we have $\prod_i \varepsilon_i = -1$ (because in odd weight W_m acts as multiplication by -1), so that the M that occur in the decomposition of $\Phi_{1,m}$ are the divisors of m with $\mu(M) = -1$, and the functions $\mathcal{Q}_M$ that occur in the decomposition of $\Phi_{1,M}$ are defined by

$$\mathcal{Q}_M \;=\; \frac{1}{2}\,\Phi_{1,M}\Big|\prod_{p|M}\big(1 - W_p\big) \;=\; 2^{\omega(M)-1}\,\Phi^{-,\dots,-}_{2,M} \qquad (\mu(M) \;=\; -1) \tag{9.35}$$

instead of equation (9.33). The reason for the factor $2^{\omega(m)-1}$ in these two equations is now apparent: it is the minimal factor making $\mathcal{Q}_M$ an integral linear combination of images of $\Phi_{k,m}$ under Atkin-Lehner involutions. (We could remove one factor 2 because for each decomposition $M = M_1M_2$, the two terms $\mu(M_1)\Phi_{k,m}|W_{M_1}$ and $\mu(M_2)\Phi_{k,m}|W_{M_2}$ are equal.)

Theorem 9.1 explains the first part of our observations, those connected with the eigencomponent decomposition of the mock Jacobi forms $\Phi_{2,m}$ and the fact that the collection of all of these functions can be expressed in terms of the special functions (9.34) and their images under Hecke-like operators. But it does not say anything about the orders of the poles of the functions in question, which was our original criterion for optimality. On the other hand, from the tables of Fourier coefficients of the functions $\mathcal{Q}_1, \dots, \mathcal{Q}_{15}$ that we have given we see that, although none of these functions except $\mathcal{Q}_1$ is strongly holomorphic, each of them satisfies the only slightly weaker discriminant bound $\Delta := 4mn - r^2 \geq -1$. This property will turn out to play a prominent role. We will call Jacobi or elliptic forms satisfying it **forms with optimal**

growth[20], because their Fourier coefficients grow more slowly than forms that do not obey this discriminant bound. We observe that any Jacobi or elliptic form having optimal growth is automatically a weak form, since $4nm - r^2 \geq -1$ implies $n \geq 0$.

As we continued our computations to higher values of M, we were surprised to find that this "optimal growth" property continued to hold for each M of the form pq (p and q distinct primes) up to 200. It followed that the full function $\Phi_{2,M}$ could also be chosen to have optimal growth in these cases, since $\Phi_{2,M} \;=\; \mathcal{Q}_1 | \mathcal{V}^{(1)}_{2,M} + \mathcal{Q}_M$ and the image of the strongly holomorphic form $\mathcal{Q}_1$ under $\mathcal{V}^{(1)}_{2,M}$ is strongly holomorphic. This made it particularly interesting to look at the case $\mathbf{m = 210}$, the first product of four distinct primes, because in this case, even if the function $\mathcal{Q}_{210} = \Phi^{----}_{2,210}$ can be chosen to be have optimal growth, then the six middle terms in the decomposition (9.31), which here takes the form

$$\begin{aligned} 8\,\Phi_{2,210} \;&=\; \mathcal{Q}_1 \,|\, \mathcal{V}^{(1)}_{2,210} \,+\, \mathcal{Q}_6 \,|\, \mathcal{V}^{(6)}_{2,35} \,+\, \mathcal{Q}_{10} \,|\, \mathcal{V}^{(10)}_{2,21} \,+\, \mathcal{Q}_{14} \,|\, \mathcal{V}^{(14)}_{2,15} \\ &\quad +\, \mathcal{Q}_{15} \,|\, \mathcal{V}^{(15)}_{2,14} \,+\, \mathcal{Q}_{21} \,|\, \mathcal{V}^{(21)}_{2,10} \,+\, \mathcal{Q}_{35} \,|\, \mathcal{V}^{(35)}_{2,6} \,+\, \mathcal{Q}_{210}\,, \end{aligned} \tag{9.36}$$

will not be. (Even if $\mathcal{Q}_M$ is chosen to have optimal growth, its image under the operator $\mathcal{V}^M_{2,t}$ will in general satisfy only $\Delta \geq -t^2$. For M of the form pq we had no problems with this because $\mathcal{Q}_1$, and hence also its image under $\mathcal{V}^{(1)}_{2,M}$, is actually holomorphic.) The corresponding computation was somewhat forbidding since the space $\widetilde{J}_{2,210}$ of forms by which we can change the initial choice $\Phi^{\text{stand}}_{2,210}$ has dimension 3815, and the conditions $C(\Delta, r) = 0$ for $\Delta < -1$ give 3813 linear constraints, so that we have to find the kernel of a roughly square matrix of size nearly 4000. Moreover, the coefficients of this matrix are gigantic, so that we have to work modulo some large prime. Nevertheless, this computation could be carried out (using PARI/GP), and it turned out that the function $\mathcal{Q}_{210}$ could again be chosen to have optimal growth! This solution is given by $\mathcal{Q}_{210} \;=\; -\mathcal{F}_{210}$, where $\mathcal{F}_{210} = \sum_{\ell \pmod{420}} h_\ell\, \vartheta_{210,\ell}$ with the Fourier coefficients of the mock theta functions h_ℓ given in Table 4. In this table, we have listed the values of ℓ with $(\ell, 210) = 1$ and $0 \leq \ell < 210$ (since $h_{420n \pm \ell} = h_\ell$ and $h_\ell = 0$ for $(\ell, 210) > 1$) in groups of 8, with $h_\ell = h_{\ell_0}$ for the first four and $h_\ell = -h_{\ell_0}$ for the second four, where ℓ_0 (shown in boldface) belongs to $\{1, 11, 13, 17, 19, 23\}$ and $h_{\ell_0} \;=\; \sum_{n \geq 0} C(n)\, q^{n - \ell_0^2/840}$. Thus, the third line of the table means that $h_{\pm 13} = h_{\pm 43} = \cdots = -h_{\pm 167} = -h_{\pm 197} \;=\; q^{-169/840}\big(6q + 17q^2 + 17q^3 + \ldots\big)$. A striking property of these coefficients is that they are so small: for instance, the largest value of $c(n, \ell)$ in the table is $c(12, 1) = 121$, with corresponding discriminant $\Delta = 4 \cdot 210 \cdot 12 - 1^2 = 10079$, while for the Mathieu form $h^{(2)}$ the table following eq. (7.31) gave the much larger coefficient 132825

---

[20] An alternative name would be "forms with only simple poles" because the forms $h_\ell(\tau) = \sum_\Delta C(\Delta, \ell)\, q^{\Delta/4m}$ have no singularity worse than $q^{-1/4m}$ as $q \to 0$, i.e., they have at most simple poles with respect to the local parameter $q^{1/4m}$ at $\tau = i\infty$. However, this terminology would be dangerous because it could also suggest simple poles with respect to z. Another reasonable name would be "nearly holomorphic," but this terminology also carries a risk of confusion since "almost holomorphic" is already a standard notation for modular forms which are polynomials in $1/\tau_2$ with holomorphic coefficients.

Table 4: Fourier coefficients of the function $\mathcal{F}_{210}$

for the much smaller discriminant $4 \cdot 2 \cdot 9 - 1^2 = 71$. This behavior is a direct consequence of the "optimal growth" property together with the fact that the index is large (cf. Theorem 9.3 below and the discussion in §9.5).

In fact, in this example even more happens: not only the function $\mathcal{Q}_{210} = \Phi_{2,210}^{----}$, but the whole function $\Phi_{2,M}$ (and hence each of its eigencomponents $\Phi_{2,210}^{\pm\pm\pm\pm}$) can be chosen to have optimal growth. It turns out that this statement holds for all square-free indices m, whether they have an even or an odd number of prime factors. If m is not square-free, then this is not true in general,[21] but it becomes true after a very small modification of the functions in question:

Theorem 9.2. *The functions* $\{\Phi_{2,m}\}_{m\geq 1}$ *can be chosen to have the form*

$$\Phi_{2,m}(\tau, z) \;=\; \sum_{d^2|m} \Phi^0_{2,m/d^2}(\tau,\, dz) \tag{9.37}$$

where $\{\Phi^0_{2,m}\}_{m\geq 1}$ *are primitive mock Jacobi forms having optimal growth.*

Corollary. *The functions* $\{\mathcal{Q}_M\}_{M>1,\,\mu(M)=1}$ *can be chosen to have optimal growth.*

(Here we have excluded the case $M = 1$ because the function $\mathcal{Q}_1 = -\mathcal{H}$ has already been chosen to have no poles at all.) Tables of Fourier coefficients of the functions $\mathcal{Q}_M$ appearing in the corollary for $M \leq 50$ are given in Appendix A.1.

If we denote by $\mathcal{E}_m^{\mathrm{OG}}$ the space of elliptic forms of index m (cf. §4.4) having optimal growth, then we have the sequence of inclusions

$$\mathcal{E}^0_m \;\subset\; \mathcal{E}_m \;\subset\; \mathcal{E}^{\mathrm{OG}}_m \;\subset\; \widetilde{\mathcal{E}}_m \;\subset\; \mathcal{E}^!_m \qquad \bigl(\varphi \in \mathcal{E}^{\mathrm{OG}}_m \underset{\mathrm{DEF}}{\iff} C_\varphi(\Delta, \ell) = 0 \text{ if } \Delta < -1\bigr)$$

of spaces of different types of elliptic forms (cusp, holomorphic, optimal growth, weak, weakly holomorphic) with different orders of growth. Theorem 9.2 says that we can represent all of our functions in terms of new, “primitive,” forms $\Phi^0_m \in \mathcal{E}^{\mathrm{OG}}_m$ for all m. The function Φ^0_m is unique up to the addition of an element of the space $J^{\mathrm{OG}}_{2,m} = \mathcal{E}^{\mathrm{OG}}_m \cap \widetilde{J}_{2,m}$ of Jacobi forms of weight 2 and index m of optimal growth. We will study this latter space in the next subsection.

---

[21] It is true if and only if m is the product of a square-free number and a prime power.

Theorem 9.2 has an immediate consequence for the growth of the Fourier coefficients of the optimal choice of $\Phi_{2,m}$, since the Hardy-Ramanujan circle method implies that the Fourier coefficients of a weakly holomorphic Jacobi (or mock Jacobi) form grow asymptotically like $e^{\pi\sqrt{\Delta|\Delta_0|}/m}$, where Δ_0 is the minimal value of the discriminants occurring in the form. We give a more precise version of this statement in the special case of forms of weight 2 having optimal growth.

Theorem 9.3. *Let φ be a weak or mock Jacobi form of weight 2 and index m with optimal growth. Then the Fourier coefficients of φ satisfy the asymptotic formula*

$$C_\varphi(\Delta, r) \;=\; \kappa_r \, e^{\pi\sqrt{\Delta}/m} \;+\; O\big(e^{\pi\sqrt{\Delta}/2m}\big) \tag{9.38}$$

as $\Delta \to \infty$, where the coefficient $\kappa_r = \kappa(\varphi; r)$ is given by

$$\kappa_r \;=\; -\sum_{\substack{\ell \ (\mathrm{mod}\ 2m) \\ \ell^2 \equiv 1 \ (\mathrm{mod}\ 4m)}} C_\varphi(-1, \ell)\, \cos\Big(\frac{\pi \ell r}{m}\Big)\,. \tag{9.39}$$

Proof. We only sketch the proof, since it is a standard application of the circle method. We write the coefficient $c_\varphi(\Delta, r)$ as a Fourier integral $\int_{-\frac{1}{2}+i\varepsilon}^{\frac{1}{2}+i\varepsilon} h_r(\tau)\, \mathbf{e}(-\Delta\tau/4m)\, d\tau$, with h_ℓ defined by (4.9) and (4.10). Its value is unchanged if we replace $h_r(\tau)$ by its completion $\widehat{h}_r(\tau)$, since they differ only by terms with negative discriminant The main contribution to the integral comes from a neighbourhood of $\tau = 0$, where we can estimate $\widehat{h}_r(\tau)$ to high accuracy as

$$\widehat{h}_r(\tau) \;=\; -\frac{(i/\tau)^{3/2}}{\sqrt{2m}} \sum_{\ell \ (\mathrm{mod}\ 2m)} \mathbf{e}\Big(\frac{r\ell}{2m}\Big)\, \widehat{h}_\ell\Big(-\frac{1}{\tau}\Big) \;=\; -\frac{\kappa_r}{\sqrt{2m}}\, (i/\tau)^{3/2}\, \mathbf{e}\Big(\frac{1}{4m\tau}\Big) \;+\; \mathrm{O}\big(\tau^{1/2}\big)\,,$$

the first equation holding by the S-transformation equation ([57], p. 59) and the second because the “optimal growth” assumption implies that $\widehat{h}_\ell(-1/\tau) = C_\varphi(-1, \ell)\, \mathbf{e}(1/4m\tau) + \mathrm{O}(1)$ as $\tau \to 0$ and the contribution from the Eichler integral of the shadow of $\widehat{h}_\ell$ is at most $\mathrm{O}(1/\tau)$. The rest follows by a standard calculation, the only point worthy of note being that since the h_ℓ's have weight 3/2 the Bessel functions that typically arise in the circle method are simple exponentials here. ☐

It is interesting to compare the statement of Theorem 9.3 with the tables given in the Appendix. This will be discussed in more detail in §9.5.

9.4 Optimal choice of the function $\Phi_{2,m}$

As we already saw, Theorem 9.2 fixes the choice of the mock Jacobi form $\Phi^0_{2,m}$ up to the addition of an element of the space $J^{\rm OG}_{2,m}$ of Jacobi forms of weight 2 and index m having optimal growth. The structure of this latter space is described by the following theorem, proved in §10.

Theorem 9.4. *The quotient $J^{\rm OG}_{2,m}/J_{2,m}$ has dimension 1 for every m. An element $\mathcal{K}_m \in J^{\rm OG}_{2,m}$ representing a non-trivial element of this quotient space can be chosen to satisfy*

$$\mathcal{K}_m(\tau,z) \;=\; y \,-\, 2 \,+\, y^{-1} \,+\, O(q) \quad \in\, \mathbb{C}[y,y^{-1}][[q]]\,,$$

and then has polar coefficients given by

$$C(\mathcal{K}_m;\,\Delta,\,r) \;=\; \begin{cases} 1 & \textit{if}\ \Delta=-1,\ r^2\equiv 1 \pmod{4m}\,, \\ 0 & \textit{if}\ \Delta<-1\,. \end{cases} \tag{9.40}$$

The function $\mathcal{K}_m$ can be chosen to be primitive and invariant under all the operators W_{m_1} $(m_1\|m)$.

The choice of $\mathcal{K}_m$ described in the theorem is unique up to the addition of a primitive holomorphic Jacobi form invariant under all W_m operators. This first occurs for $m=25$, so $\mathcal{K}_m$ is unique for small values of m. Because of Theorem 9.4, the function Φ^0_m has only a very small amount of choice: we can change it without disturbing the "optimal growth" property by adding an arbitrary multiple of $\mathcal{K}_m$ and an arbitrary holomorphic Jacobi form, but this is the only freedom we have. In particular, we have three special choices of "optimal" $\Phi^0_{2,m}$, each unique for $m<25$, corresponding to the three that we already encountered for $m=6$ and $m=10$ in §9.2:

(I) The $(+,\cdots,+)$-eigencomponent of $\Phi^{0,\rm I}_{2,m}$ is strongly holomorphic.

(II) $\Phi^{0,\rm II}_{2,m}$ has $c(0,1)=0$.

(III) $\Phi^{0,\rm III}_{2,m}$ has $c(0,0)=0$.

Each of these three choices has certain advantages over the other ones. In case (I) we can choose $\Phi^{0,\rm I}_{2,m}$ within its class modulo $J^0_{2,m}$ so that its $(+,\cdots,+)$-eigencomponent is precisely equal to $2^{1-\omega(m)}\mathcal{Q}_1|\mathcal{V}^{(1)}_{2,m}$ and hence has Fourier coefficients expressible in terms of class numbers, like in the examples for small m that we already saw. Also, $\Phi^{0,\rm I}_{2,m}$ is strongly holomorphic when m is a prime power, so that this is certainly the best of the three choices in that special case. The function occurring in (II) has a Fourier expansion beginning $\frac{1}{12}(m+1)+O(q)$, and the corresponding $\psi^{0,\rm II}_{m+1}$ satisfies (9.15) and belongs to the family of the weight zero, index m Jacobi forms discussed in [66]. The choice (III) looks at first sight like the least natural of the three, since it might seem strange to insist on killing a $\Delta = 0$ term when there are $\Delta = -1$ terms that are more singular, but in fact it is the nicest in some ways, since it can be further improved by the addition of a holomorphic Jacobi form to have *all* of its $\Delta = 0$ coefficients equal to zero, and its polar coefficients are then given by an elegant formula, which we now state.

Theorem 9.5. *The mock Jacobi form $\Phi^{0,\mathrm{III}}_{2,m}$ in Theorem 9.2 can be chosen, uniquely up to the addition of a Jacobi cusp form of weight 2 and index m, so that all its Fourier coefficients with $\Delta = 0$ vanish. Its polar coefficients are then given by*

$$C(\Phi^{0,\mathrm{III}}_{2,m}; -1, r) \;=\; \frac{1}{24}\sum_{d^2|m} \mu(d)\,\Bigl(\bigl(\frac{r-1}{2}, \frac{m}{d^2}\bigr) \,+\, \bigl(\frac{r+1}{2}, \frac{m}{d^2}\bigr)\Bigr) \quad \textit{for } r^2 \equiv 1 \pmod{4m}. \tag{9.41}$$

Moreover, the function $\Phi^{0,\mathrm{III}}_{2,m}$ can be chosen to be primitive without affecting these properties.

This also gives a multiplicative formula for the polar coefficients of all eigencomponents of $\Phi^{0,\mathrm{III}}_{2,m}$:

Corollary. *Write $m = \prod_{i=1}^{s} P_i$, where $P_i = p_i^{\nu_i}$ with distinct primes p_i and exponents $\nu_i \ge 1$. Then for any $\varepsilon_i \in \{\pm 1\}$ with $\varepsilon_1 \cdots \varepsilon_s = 1$, we have*

$$C\Bigl(\Phi^{0,\mathrm{III}}_{2,m}\,\Big|\,\prod_{i=1}^{s}\bigl(1 + \varepsilon_i W_{P_i}\bigr);\, -1,\, r\Bigr) \;=\; \frac{\pm 1}{12}\prod_{i=1}^{s}\begin{cases}(p_i + \varepsilon_i) & \textit{if } \nu_i = 1,\\ (p_i^{\nu_i} - p_i^{\nu_i - 2}) & \textit{if } \nu_i \ge 2,\end{cases} \tag{9.42}$$

where the sign is the product of the ε_i for all i for which $r \equiv -1 \pmod{2P_i}$. In particular, for the functions $\mathcal{Q}_M$ ($M > 1$, $\mu(M) = 1$), chosen by the Corollary to Theorem 9.2 to have optimal growth, the Fourier coefficients with non-positive discriminant are given by

$$C(\mathcal{Q}_M; \Delta, r) \;=\; \begin{cases} \quad 0 & \textit{if } \Delta = 0\,,\\ \pm\dfrac{\varphi(M)}{24} & \textit{if } \Delta \;=\; -1\,,\end{cases} \tag{9.43}$$

where in the second line $r^2 \equiv 1 \pmod{4M}$ and the sign is determined by $\mu((\frac{r+1}{2}, M)) = \pm 1$.

The final statement of the corollary can be compared with the examples in (9.34), in which each of the $\mathcal{F}_M$'s occurring (for $M > 1$) was normalized with $C(\mathcal{F}_M; -1, 1) = -1$, and the numerical factor relating $\mathcal{Q}_M$ and $\mathcal{F}_M$ equals $-\varphi(M)/24$ in each case. To give a feeling for the nature of these functions in general, and as an illustration of the formulas in Theorem 9.5 and its corollary, we give in Table 5 below the first few Fourier coefficients $C(\Phi; \Delta, \ell)$ for these and some related functions Φ for $m = 25$ (the first index where $J_{2,m} \neq \{0\}$ and hence $\mathcal{K}_m$ is not unique), $m = 37$ (the first index where $J^0_{2,m} \neq \{0\}$ and hence $\Phi^{0,\mathrm{III}}_{2,m}$ is not unique), $m = 50$ (the first case where (9.42) is non-trivial), and $m = 91$ (the first case where where $J^{0,--}_{2,m} \neq \{0\}$ and hence $\mathcal{Q}_m$ is not unique). The free coefficients "a", "b" and "c" in the table arise because

Table 5: Examples of non-unique Jacobi and mock Jacobi forms

$\dim J_{2,25} = \dim J^0_{2,37} = \dim J_{2,50} = \dim J^0_{2,91} = 1$. In the case of $m = 91$ we show the two ℓ-values corresponding to each value of Δ in the format $\ell\,/\,\ell^*$ and give in the following line the Fourier coefficient $C(\mathcal{Q}_{91};\Delta,\ell) = -C(\mathcal{Q}_{91};\Delta,\ell^*)$. In the cases of $m = 25$ and $m = 37$, we have given the (non-unique) holomorphic mock Jacobi form $\Phi^{0,\mathrm{I}}_{2,2m}$ as well as $\Phi^{0,\mathrm{III}}_{2,2m}$.

In summary, the "optimal growth" property of $\Phi^0_{2,m}$ and the near-uniqueness of the Jacobi form $\mathcal{K}_m$ have permitted us to pin down both of these functions in many cases, but there still remains an additive ambiguity whenever there are Jacobi cusp forms. We do not know how to resolve this ambiguity in general, and state this as an open problem:

Question: Is there a canonical choice of the forms $\mathcal{K}_m$ and $\mathcal{Q}_M$ for all positive integers m and all positive square-free integers M?

Should the answer to either of these questions be positive, the corresponding forms would be of considerable interest. In particular, one can speculate that the canonical choice of $\mathcal{Q}_M$, if it exists, might be canonically associated to the quaternion algebra of discriminant M, since there is a natural bijection between positive square-free integers and quaternion algebras over $\mathbb{Q}$, with the latter being indefinite or indefinite according as $\mu(M)=1$ (corresponding to our $k=2$ forms and to mock theta functions of weight 3/2) or $\mu(M)=-1$ (corresponding to $k=1$ and to mock theta functions of weight 1/2).

We end this subsection by describing one possible approach to answering the above question that we tried. This approach was not successful in the sense that, although it did produce a specific choice for $\mathcal{K}_m$ and $\Phi^0_{2,m}$ (or $\Phi^0_{1,m}$), these did not seem to have arithmetic coefficients and therefore had to be rejected, but the method of calculation involves a result that is of interest in its own right and may be useful in other contexts. The idea is to fix the choice of the Jacobi forms (or mock Jacobi forms) in question by demanding that they (or their completions) be orthogonal to Jacobi cusp forms with respect to the Petersson scalar product. (As an analogy, imagine that one wanted to determine the position of $E_{12}=1+\cdots$ in $M_{12}=\mathbb{C}\,E_4^3+\mathbb{C}\,\Delta$ but did not know how to compute the Fourier expansion of $\sum(m\tau+n)^{-12}$. Then one could simply write $E_{12}=E_4^3+a\Delta$ and use the orthogonality of Eisenstein series and cusp forms to compute the number $a=-432000/691$ numerically as $-(E_4^3,\Delta)/(\Delta,\Delta)$, where $(\;,\;)$ denotes the Petersson scalar product.) To apply this idea, we need a good way to compute the Petersson scalar product of Jacobi forms. This is the result of independent interest referred to above. For simplicity, we state it only in the case $k=2$.

Theorem 9.6. *Let φ_1 and φ_2 be two Jacobi cusp forms of weight 2 and index m, and set*

$$A(\Delta)\;=\sum_{\ell\;(\mathrm{mod}\;4m)} C_{\varphi_1}(\Delta,\ell)\,\overline{C_{\varphi_2}(\Delta,\ell)}\,,\qquad H(t)\;=\;\sum_{\Delta=1}^{\infty}\frac{A(\Delta)/\sqrt{\Delta}}{\exp(2\pi\sqrt{t\Delta/m})\;-\;1}\;. \tag{9.44}$$

Then the function $\dfrac{tH(t)-H(1/t)}{t-1}$ $(t\neq 1)$ has a constant value c_H which is proportional[22] *to the Petersson scalar product (φ_1,φ_2).*

Sketch of proof: We refer to [57] for the definition of (φ_1,φ_2) (eq. (13), p. 27) and for its expression as a simple multiple of $\sum_\ell(h_\ell^{(1)},h_\ell^{(2)})$, where $h_\ell^{(1)}$ and $h_\ell^{(2)}$ are the coefficients in the theta expansions of φ_1 and φ_2 (Theorem 5.3, p. 61). Calculating these weight 3/2 scalar products by the Rankin-Selberg method as explained in §3.1, we find that (φ_1,φ_2) can be expressed as a simple multiple of the residue at $s=3/2$ of the Dirichlet series $L(s)=\sum_{\Delta>0}A(\Delta)\Delta^{-s}$. The Rankin-Selberg method also shows that the function $\widetilde{L}(s)=2\,(2\pi)^{-s}m^s\,\Gamma(2s)\,\zeta(2s)\,L(s+\frac{1}{2})$ has a meromorphic continuation to all s, with poles only at $s=0$ and $s=1$, and is invariant under $s\to 1-s$. But $\widetilde{L}(s)$ is simply the Mellin transform of $H(t)$, so this implies the proposition by a standard argument. ☐

A rather surprising aspect of this theorem is that it is actually *easier* to compute Petersson scalar products for Jacobi forms than it is for ordinary modular forms of integral weight. In that case the analogue of $H(t)$ would have an infinite sum of K-Bessel functions multiplying each coefficient $A(\Delta)$, whereas here the Bessel functions are replaced by simple exponentials (because the modular forms $h_\ell^{(i)}$ have half-integral weight, so that the usual gamma factor $\Gamma(s)\Gamma(k+s-1)$ in the Rankin-Selberg method becomes a single gamma function $\Gamma(2s)$) and at the same time the infinite sum becomes a geometric series that can be summed explicitly.

---

[22] The exact constant of proportionality plays no role for our purposes, since we will only be concerned with ratios of Petersson scalar products. If the scalar product is normalized as in [57], its value is 1/2.

To apply the proposition to our situation in the case of $\mathcal{K}_{37}$, we start with an initial choice (like the one given in Table 5) and replace it by $\mathcal{K}_{37} + a\varphi_{37}$, where φ_{37} is the generator of $J^0_{2,37}$ (normalized by $C(\varphi_{37}\,;3,21) = 1$) and where $a \in \mathbb{R}$ is chosen to make this function orthogonal to φ_{37}, i.e., $a = -(\mathcal{K}_{37}, \varphi_{37})/(\varphi_{37}, \varphi_{37})$, in the hope that this a will be an integer or simple rational number. (Of course $\mathcal{K}_{37}$ is not a cusp form, but the integral defining the Petersson scalar product still converges,[23] the sum defining $H(t)$ converges for $t > \frac{1}{148}$ by Theorem 9.3, and Theorem 9.6 still holds.[24]) The numerical calculation for the case $\varphi_1 = \varphi_2 = \varphi_{37}$ gives the value $c_H = c_1 = -0.95284748097797917403$ (a value that can be checked independently, since up to a factor $-\pi$ it must be equal to the even period of the elliptic curve $y^2 - y = x^3 - x$, as calculated by GP-PARI as `ellinit`([0,0,1,-1,0])[15]). The corresponding number for $\varphi_1 = \varphi_{37}$ and $\varphi_2 = \mathcal{K}_{37}$ (with $\mathcal{K}_{37}$ chosen as in Table 5, with $a = 0$) is $c_2 = 0.26847600706319893417$, which is not a simple multiple of c_1, but when we calculate again with $\varphi_2 = \Phi^{0,\mathrm{III}}_{2,37}$ (again as in Table 5, with $b = 0$) we find a value $c_3 = 0.107471184190738587618$ that is related to the two previous values by $12c_3 - 19c_2 = 4c_1$ numerically to high precision. Thus in this case we have indeed found a form orthogonal to cusp forms and with rational coefficients. This at first looks promising, but in fact has a simple and disappointing explanation: the linear combination $\Phi^{0,\mathrm{III}}_{2,37} - \frac{19}{12}\mathcal{K}_{37} - \frac{1}{3}\varphi_{37} = \Phi^{0,\mathrm{I}}_{2,37} - \frac{1}{3}\varphi_{37}$ is nothing other than $\mathcal{Q}_1|V_{37}$ (as one can see in Table 5, where setting $c = -\frac{1}{3}$ gives entries equal to $-H(\Delta)$), and since the function $\mathcal{Q}_1 = -\mathcal{H}$ is constructed from an Eisenstein series, albeit a non-holomorphic one, it is automatically orthogonal to all cusp forms. And indeed, when we look at the case of $\mathcal{Q}_{91}$ and $\varphi_{91} \in J^{0,--}_{2,91}$, where there are no Eisenstein series in sight, then the calculation of the quotient $(\widehat{\mathcal{Q}}_{91}, \varphi_{91})/(\varphi_{91}, \varphi_{91})$ failed to yield a simple number. (The non-holomorphy of $\widehat{\mathcal{Q}}_{91}$ does not affect the application of Theorem 9.6, since its non-holomorphic part has Fourier coefficients only for $\Delta < 0$, where the coefficients of φ_{91} vanish.) As an incidental remark, we mention that the cusp form φ_{37}, whose first few

---

[23] The precise condition needed for the convergence of the Petersson scalar product of two weakly holomorphic Jacobi forms φ_1 and φ_2 is that $\mathrm{ord}_\infty(h_\ell^{(1)}) + \mathrm{ord}_\infty(h_\ell^{(2)}) > 0$ for all $\ell \in \mathbb{Z}/2m\mathbb{Z}$. This is amply satisfied in the case $\varphi_1 = \varphi_{37}$, $\varphi_2 = \mathcal{K}_{37}$, since the only negative value of $\mathrm{ord}_\infty(h_\ell^{(2)})$ is $-1/148$ for $\ell \equiv \pm 1 \pmod{74}$, and there $\mathrm{ord}_\infty(h_\ell^{(1)}) = 147/148$.

[24] The proof given above breaks down, since the numbers $A(\Delta)$ grow exponentially in $\sqrt{\Delta}$, so that the Dirichlet series $\sum_\Delta A(\Delta)/\Delta^s$ does not converge for any value of s, but the function $f(y) = y^{3/2}\sum_\Delta A(\Delta)e^{-\pi\Delta y/m}$, which is the constant term of an $SL(2,\mathbb{Z})$-invariant function that is small at infinity, still has a Mellin transform with a meromorphic continuation to all s, and if we define $\widetilde{L}(s)$ as the product of this Mellin transform with $\pi^{-s}\Gamma(s)\zeta(2s)$, then $\widetilde{L}(s)$ has the same analytic properties as before and its inverse Mellin transform $H(t)$ is still given by the sum in (9.44) for t sufficiently large and satisfies the same functional equation.

Fourier coefficients were obtained only with difficulty in [57] (pp. 118–120 and 145), can now be obtained very easily using the "theta blocks" of [69] as

$$\varphi_{37}(\tau,z) \;=\; \frac{1}{\eta(\tau)^6}\prod_{i=1}^{10}\vartheta(\tau,a_iz)\,, \qquad (a_1,\dots,a_{10}) \;=\; (1,1,1,2,2,2,3,3,4,5)\,,$$

and similarly $\varphi_{2,91}$ can be obtained easily as the difference of the two similarly defined theta blocks for the 10-tuples $(a_1,\dots,a_{10}) = (1,1,2,3,4,4,5,5,6,7)$ and $(1,1,2,2,3,3,4,5,7,8)$.

9.5 Observations on the weight one family, integrality, and positivity

In the last two subsections we discussed experimental properties of the family of weight 2 mock Jacobi forms that were introduced in §9.1 and formulated a number of general results that will be proved in §10. In this subsection we report on the experimental data for the weight 1 family and discuss various properties of both families that play a role in connection with other investigations in mathematics and physics (like "Umbral Moonshine") or that seem to be of independent interest.

The discussion of the weight 1 family is quite different in nature from that of the weight 2 case, because here there do not seem to be general structural results as there were there, but only a small number of special functions for small values of the index having nice properties. In particular, the analogue of Theorem 9.2 no longer holds, and we find instead that (at least up to $m = 100$, and presumably for all m) the appropriately defined primitive mock Jacobi forms $\Phi^0_{1,m}$ can be chosen to have optimal growth only for the indices

$$m \;=\; 2,\ 3,\ 4,\ 5,\ 6,\ 7,\ 8,\ 9,\ 10,\ 12,\ 13,\ 16,\ 18,\ 25\,. \tag{9.45}$$

Similarly, although the analogue of Theorem 9.1 is still valid in the weight 1 case (now with the special mock Jacobi forms $\mathcal{Q}_M$ labelled by square-free integers M having an odd rather than an even number of prime factors), the functions $\mathcal{Q}_M$ can apparently be chosen to have optimal growth only for

$$M \;=\; 2,\ 3,\ 5,\ 7,\ 13,\ 30,\ 42,\ 70,\ 78\,. \tag{9.46}$$

(This list has a precise mathematical interpretation; see *3.* below.) Thus here a small number of special examples is singled out. Interestingly enough, these turn out to include essentially all of the special mock theta functions that have been studied in the literature in the past.

For convenience, we divide up our discussion into several topics.

1. Optimal choices for the weight one family

As in the weight 2 case, we begin our discussion by looking at small values of m. We will consider the original forms $\Phi_{1,m}$ first, starting with the "standard" choices (9.2) and trying to modify them by the addition of weak Jacobi forms to attain the property of having optimal growth. Actually, it is better to look at the primitive mock Jacobi forms, now defined by

$$\Phi^0_{1,m} \;\equiv\; \sum_{d^2|m} \frac{\mu(d)}{d}\, \Phi_{1,m/d^2}|U_d\,, \qquad \Phi_{1,m} \;\equiv\; \sum_{d^2|m} \frac{1}{d}\, \Phi^0_{1,m/d^2}|U_d \qquad (\mathrm{mod}\ \widetilde{J}_{1,m})\,, \tag{9.47}$$

instead of (9.37) and (10.52), for the same reason for which we introduced the functions $\Phi^0_{2,m}$ in §9.3: residue arguments similar to those that we will give in §10 for the weight 2 case show here that $\Phi_{1,m}$ can never have optimal growth unless it agrees with $\Phi^0_{1,m}$ (which happens if and only if m is square-free or the square of a prime number), so that the latter class is certain to be more productive. Finally, we will look at the forms $\mathcal{Q}_M$ where M is a product of an odd number of distinct prime factors, since according to Theorem 9.1 all of the forms $\Phi_{1,m}$ can be constructed from these. Unlike the situation for $k = 2$, here we do not have to worry about any choices, because of the following theorem (to be compared with Lemma 2.3 of [25] and to be proved, like all its companions, in §10) and corollary. The only issue is therefore whether the "optimal growth" condition can be fulfilled at all.

Theorem 9.7. *There are no weight one weak Jacobi forms of optimal growth.*

Corollary. *If any of the mock Jacobi forms $\Phi_{1,m}$, $\Phi^0_{1,m}$, or $\mathcal{Q}_M$ ($\mu(M) = -1$) can be chosen to have optimal growth, then that choice is unique.*

We now look at some small individual indices. For **m=1** there is nothing to discuss, since the function $\Phi^{\mathrm{st}}_{1,1} = (C/2A)^{\mathrm{F}}$ vanishes identically, as already explained in §8.5 (Example 1). (This, by the way, is the reason why $\Phi_{1,m} = \Phi^0_{1,m}$ when m is the square of a prime.) The case of **m=2** has also already been treated in the same place (Example 2), where we saw that

$$\varphi^{\mathrm{opt}}_{1,2} \;=\; \frac{B}{24\,A}\,C\,, \qquad \Phi^{\mathrm{opt}}_{1,2} \;=\; -\frac{1}{24}\,\mathcal{F}_2\,, \tag{9.48}$$

with $\mathcal{F}_2$ the mock modular form defined in §7 and related to the Mathieu moonshine story. For **m=3**, we find that the (unique) choice of $\Phi_{1,m}$ having optimal growth is given by

$$\varphi^{\mathrm{opt}}_{1,3} \;=\; \frac{B^2 - E_4A^2}{288A}\,C\,, \qquad \Phi^{\mathrm{opt}}_{1,3} \;=\; \varphi^{\mathrm{opt}}_{1,3} \;-\; \mathcal{A}_{1,3} \;=\; \frac{1}{12}\,\mathcal{F}_3\,, \tag{9.49}$$

where the normalizing factor 1/12 has been chosen to give $\mathcal{F}_3$ integral Fourier coefficients. These coefficients are determined by virtue of their periodicity and oddness by the values $C^{(3)}(\Delta) = C(\mathcal{F}_3; \Delta, r)$ for $r \in \{1, 2\}$, the first few values of $C^{(3)}(\Delta)$ being given by

Δ	-1	8	11	20	23	32	35	44	47	56	59
$C^{(3)}(\Delta)$	-1	10	16	44	55	110	144	280	330	572	704

.

(A more extensive table of these coefficients, listed separately for the two values $r = 1$ and $r = 2$, is given in Appendix A.2, where we also give the corresponding values for the other forms treated here, so that we no longer will give tables of coefficients in the text.) For **m=4** and **m=5**, the functions $\Phi_{1,m}$ can again be chosen (of course uniquely, by the corollary above) to have optimal growth, the corresponding meromorphic Jacobi forms $\varphi^{\text{opt}}_{1,4}$ and $\varphi^{\text{opt}}_{1,5}$ being given by

$$\frac{B^3 - 3E_4A^2B + 2E_6A^3}{2\cdot 12^2\,A}\,C \quad \text{and} \quad \frac{B^4 - 6E_4A^2B^2 + 8E_6A^3B - 3E_4^2A^4}{2\cdot 12^3\,A}\,C\,, \tag{9.50}$$

respectively. Note that in the case of $m = 4$, according to the decomposition result given in Theorem 9.1, we could also make the choice $\mathcal{Q}_2|\mathcal{V}^{(2)}_{1,2}$ for the function $\Phi_{1,4}$, but then it would have the worse discriminant bound $\Delta_{\min} = -4$. We also observe that, although 4 is not square-free, we do not have to distinguish between $\Phi_{1,m}$ and $\Phi^0_{1,m}$ here, because they differ by the function $\Phi^0_{1,1}|U_2$ and the function $\Phi_{1,1}$ vanishes identically.

It is now very striking that the numerators of the fractions in (9.49) and (9.50) are the *same* as the expressions that we already saw in eqs. (9.10), (9.11) and (9.12) in §9.2, meaning that for these values of m we have

$$\varphi^{\text{opt}}_{1,m} \;=\; \frac{C}{A}\,\psi^{\text{opt}}_{0,m-1} \;=\; C\,\varphi^{\text{opt}}_{2,m-2} \tag{9.51}$$

with the same weight 0 weak Jacobi modular forms $\psi^{\text{opt}}_{0,m-1}$ as were tabulated in Table 2. The same thing happens for several other small values of the index. We do not know the deeper reason (if any) for this coincidence, but merely remark that the weight 0 weak Jacobi forms obtained from the weight 1 meromorphic Jacobi forms in our family by dividing by C also play a prominent role in the recent work of Cheng, Duncan and Harvey [25] on "umbral moonshine," and also that the the forms $\psi^{\text{opt}}_{0,m}$ occur in a somewhat different context in earlier work of Gritsenko[66] related to Borcherds products, as was already mentioned in §9.3 when we introduced the "second standard choice" $\Phi^{0,\text{II}}_{2,m}$ of the primitive mock Jacobi form $\Phi^0_{2,m}$.

Continuing to larger values, we look first at primes, since for m prime the three functions of interest $\Phi_{1,m}$, $\Phi^0_{1,m}$ and $\mathcal{Q}_m$ all coincide. For **m=7** we find that $\mathcal{Q}_7 = \Phi^{\text{opt}}_{1,7}$ again has optimal growth and again satisfies (9.51) with $\varphi^{\text{opt}}_{0,6}$ as given in Table 2. However, for **m=11** the function $\mathcal{Q}_M$ *cannot* be chosen to be of optimal growth; the best possible choice, shown in the table A.3 in the appendix, has minimal discriminant -4. For **m=13** the function $\mathcal{Q}_{13}$ again has optimal growth and is again given by (9.51), but for larger primes this never seems to happen again, the minimal value of Δ for the optimal choices of $\mathcal{Q}_M$ for the first few prime indices being given by

M	2	3	5	7	11	13	17	19	23	29	31	37
$\Delta_{\min}$	1	1	1	1	4	1	4	4	8	5	8	4

The next simplest case is $m = p^2$, since here $\Phi_{1,m}$ is still primitive. For **m=9** and **m=25** this function can be chosen to have optimal growth, but apparently not after that. The following case to look at is $m = p^\nu$ with $\nu \geq 2$, since here the eigendecomposition (9.31) of $\Phi_{1,m}$ is trivial. (The eigenvalue of W_m must be -1 because the weight is odd, so $\Phi_{1,m} = \Phi^-_{1,m} = \mathcal{Q}_p|\mathcal{V}^{(p)}_{p^{\nu-1}}$.) Here we find optimal growth only for **m=8** and **m=16**. Next, for M square-free but not prime, where the decomposition (9.2) is trivial, the only two cases giving optimal growth seem to be **m=6** and **m=10**. And finally, for M neither square-free nor a power of a prime we also find two examples **m=12** and **m=18**. Altogether this leads to the list (9.45) given above. The first few coefficients of the forms $\Phi^0_{1,m}$ for all of these values of m are tabulated in Appendix A.2.

However, this is not the end of the story. If $\Phi_{1,m}$ has optimal growth for some m, then of course all of its eigencomponents with respect to the Atkin-Lehner operators also do, but the converse is not true, so there still can be further square-free values of M for which the function $\mathcal{Q}_M = 2^{1-\omega(M)}\,\Phi^{-,\ldots,-}_{1,M}$ has optimal growth, and this indeed happens. Since primes have already been treated and products of five or more primes are beyond the range of our ability to compute, we should consider products of three primes. Here we find four examples, for the indices

$$30 \;=\; 2\cdot 3\cdot 5\,, \qquad 42 \;=\; 2\cdot 3\cdot 7\,, \qquad 70 \;=\; 2\cdot 5\cdot 7\,, \qquad 78 \;=\; 2\cdot 3\cdot 13\,,$$

but for no other values less than 200 (and probably for no other values at all), giving the list (9.46). Again the Fourier coefficients of the corresponding forms, as well as those for all other $M < 150$ of the form $p_1p_2p_3$, have been listed in the appendix (part A.3). These examples are of particular interest, for a reason to which we now turn.

2. Relationship to classical mock theta functions

Recall from §7.1 that a mock modular form is called a mock theta function if its shadow is a unary theta series, and that this definition really does include all of Ramanujan's original mock theta functions that began the whole story. The theta expansion coefficients $h_\ell(\tau)$ of our special mock Jacobi forms $\Phi_{1,m}$ and $\Phi_{2,m}$ are always mock theta functions, since their shadows are multiples of the unary theta series $\varphi^1_{m,\ell}$ and $\varphi^0_{m,\ell}$, respectively. In fact, it turns out that many of our examples actually coincide with the mock theta functions studied by Ramanujan and his successors. This is the "particular interest" just mentioned.

Let us consider first the case **m=30**, the first of our $\mathcal{Q}_M$ examples with composite M. Because it is so highly composite, there are very few orbits of the group of Atkin-Lehner involutions on the group of residue classes modulo $2m$ and hence very few components in the theta decomposition of $\mathcal{Q}_{30}$. In fact there are only two, so that up to sign we get only two distinct coefficients h_1 and h_7 and $\mathcal{Q}_{30}$ has a decomposition

$$\begin{aligned} -3\,\mathcal{Q}_{30} \;=\;& h_1\left(\vartheta_{30,1}+\vartheta_{30,11}+\vartheta_{30,19}+\vartheta_{30,29}-\vartheta_{30,31}-\vartheta_{30,41}-\vartheta_{30,49}-\vartheta_{30,59}\right)\\ &+\; h_7\left(\vartheta_{30,7}+\vartheta_{30,13}+\vartheta_{30,17}+\vartheta_{30,23}-\vartheta_{30,37}-\vartheta_{30,43}-\vartheta_{30,47}-\vartheta_{30,53}\right). \end{aligned}$$

(The normalizing factor -3 is included for convenience: the function $-3\mathcal{Q}_{30}$ is the function $\mathcal{F}_{30}$ defined in 9.52 below.) The mock theta functions h_1 and h_7 have Fourier expansions beginning

$$\begin{aligned} h_1(\tau) &= q^{-1/120}\,(-1 + q + q^2 + 2q^3 + q^4 + 3q^5 + \cdots)\,, \\ h_7(\tau) &= q^{71/120}\,(1 + 2q + 2q^2 + 3q^3 + 3q^4 + 4q^5 + \cdots)\,. \end{aligned}$$

These expansions are easily recognized: up to trivial modifications they are two of the "mock theta functions of order 5" in the original letter of Ramanujan to Hardy, namely

$$\begin{aligned} 2 + q^{1/120}\,h_1(\tau) &= \chi_1(q) = \sum_{n=0}^{\infty} \frac{q^n}{(1-q^{n+1})\cdots(1-q^{2n})}\,, \\ q^{-71/120}\,h_2(\tau) &= \chi_2(q) = \sum_{n=0}^{\infty} \frac{q^n}{(1-q^{n+1})\cdots(1-q^{2n+1})}\,. \end{aligned}$$

(Actually, Ramanujan gave five pairs of mock theta functions of "order 5" in his letter, any two differing from one another by weakly holomorphic modular forms, but it was pointed out in [129] that of the five associated pairs of mock modular forms only $(q^{-1/120}(2-\chi_1(q)),\, q^{71/120}\chi_2(q))$ has the property that its completion transforms as a vector-valued modular form for the full modular group.) For **m=42**, exactly the same thing happens, and the three distinct components h_1, h_5 and h_{11} of $\mathcal{Q}_{42}$, whose initial coefficients are tabulated in Appendix A.3, turn out to be, up to powers of q and signs, identical with Ramanujan's three "order 7" mock theta functions $\mathcal{F}_{7,i}$ ($i = 1, 2, 3$) that were given as our first examples of mock modular forms in §7.1. What's more, this behavior continues: in [129] it was mentioned that one could construct mock theta functions of arbitrary prime[25] "order" p generalizing these two examples as quotients by $\eta(\tau)^3$ of certain weight 2 indefinite theta series, and an explicit example

$$M_{11,j}(\tau) = \frac{1}{\eta(\tau)^3} \sum_{\substack{m>2|n|/11 \\ n\equiv j \ (\mathrm{mod}\ 11)}} \Big(\frac{-4}{m}\Big)\Big(\frac{12}{n}\Big)\big(m\,\mathrm{sgn}(n) - \frac{n}{6}\big)\, q^{m^2/8-n^2/264} \qquad (j \in \mathbb{Z}/11\mathbb{Z})$$

was given for $p = 11$. Computing the beginnings of the Fourier expansions of these five mock theta functions (only five rather than eleven because $M_{11,j} = -M_{11,-j}$) and comparing with the table in Appendix A.3, we find perfect agreement with the coefficients in the theta expansion of $\mathcal{Q}_{66}$, the first example in that table of a form that is not of optimal growth.

This discussion thus clarifies the precise mathematical meaning of the number designated by Ramanujan as the "order" of his mock theta functions, but which he never defined: it is indeed related to the *level* of the completions of the corresponding mock modular forms, as was clear from the results of Zwegers and other authors who have studied these functions, but it is even more closely related to the *index* of the mock Jacobi forms that have these mock theta functions as the coefficients of its theta expansion.

---

[25] actually, only $(p, 6) = 1$ is needed

Of course the above cases are not the only ones where there is a relationship between the special mock Jacobi forms $\mathcal{Q}_M$ and classically treated mock theta functions, but merely the ones where the relationship between the "order" and the index is clearest. Without giving any further details, we say only that Ramanujan's order 3 functions are related in a similar way[26] to our $\mathcal{Q}_3$ and that his order 10 functions (not given in his letter to Hardy, but contained in the so-called "Lost Notebook") are related to $\mathcal{Q}_5$. We also refer once again to the beautiful recent work of Cheng, Duncan and Harvey [25] on "umbral moonshine," in which many of these same functions are discussed in detail in connection with representations of special finite groups.

Finally, we should mention that all of Ramanujan's functions were q-hypergeometric series but that in general no q-hypergeometric expression for the theta expansion coefficients of the functions $\Phi_{k,m}$ or $\mathcal{Q}_M$ is known. This seems to be an interesting subject for further research. One could look in particular for representations of this sort for the functions $\mathcal{Q}_{13}$ and $\Phi^0_{1,25}$ as given in Table A.2, since these have particularly small and smoothly growing coefficients that suggest that such a representation, if it exists, might not be too complicated. It would also be reasonable to look at $\mathcal{Q}_{70}$ and $\mathcal{Q}_{78}$, the only two other known weight 1 examples with optimal growth.

3. Integrality of the Fourier coefficients

In Subsections 9.2 and 9.3 and above, we encountered several examples of functions $\mathcal{Q}_M$ of optimal growth that after multiplication by a suitable factor gave a function $\mathcal{F}_M$ having all or almost all of the following nice arithmetic properties:

(A) All Fourier coefficients $C(\mathcal{F}_M;\Delta,r)$ are integral.

(B) The polar Fourier coefficient $C(\mathcal{F}_M;-1,1)$ equals -1.

(C) The non-polar Fourier coefficients $C(\mathcal{F}_M;\Delta,r)$ have a sign depending only on r.

(D) $C(\mathcal{F}_M;\Delta,r)$ is always positive for $r=r_{\min}$, the smallest positive number whose square equals $-\Delta \pmod{4m}$.

In particular, for $k=2$ this occurred for $M=6$, 10, 14 and 15 (compare eqs. (7.28), (9.22), (9.29) and (9.30), which describe the coefficients $C^{(M)}(\Delta)=C(\mathcal{F}_M;\Delta,r_{\min})$ for these indices) and for $k=1$, for the values $M=2$, 3, 5, 7, 13 and 30 (with "non-negative" instead of "positive" in (C) in the case of $M=13$), as well as for the functions $\Phi^0_{1,m}$ for the prime powers $M=4$, 8, 9, 16 and 25 (again with "positive" replaced by "non-positive," and also allowing half-integral values for the Fourier coefficients with $\Delta=0$). It is natural to ask for what values of M these properties can be expected to hold. We will discuss properties (A) and (B) here and properties (C) and (D) in point *4.* below.

---

[26] but not "on the nose," for instance, our function $h_{3,1}$ differs from Ramanujan's 3rd order mock theta function $-3\,q^{1/12}f(q^2)$ by an eta product.

Clearly either (A) or (B) can always be achieved by multiplying $\mathcal{Q}_M$ by a suitable scalar factor. We define a renormalized function $\mathcal{F}_M$ in all cases by setting

$$\mathcal{F}_M(\tau, z) \;=\; -c_M\, \mathcal{Q}_M(\tau, z)\,, \tag{9.52}$$

where c_M is the unique positive rational number such that $\mathcal{F}_M$ has integer coefficients with no common factor. Then (A) is always true and (B) and (C) will hold in the optimal cases. This normalization is also convenient for the presentation of the coefficients in tables, since there are no denominators and very few minus signs. Tables of the first few Fourier coefficients of all $\mathcal{F}_M$ up to $M = 50$ in the weight 2 case (i.e., for M with $\mu(M) = 1$) and of all known $\mathcal{F}_M$ having optimal growth in the weight 1 case (i.e., for M with $\mu(M) = -1$) are given in A.1 and A.3 of the Appendix, respectively. Looking at these tables, we see that the values of M for which all three properties above hold are $M = 6$, 10, 14, 15, 21 and 26 in the case $k = 2$ and $M = 2$, 3, 5, 7, 13, 30 and 42 in the case $k = 2$, and that in the $k = 2$ case we also get $\mathcal{F}_M$ satisfying (C) but not (B) for $M = 22$ and $\mathcal{F}_M$ satisfying (B) but not (C) for $M = 35$ and 39. This list is not changed if we look at a larger range of M (we have calculated up to $M = 210$ in the weight 2 case and $M = 100$ in the weight 1 case) or Δ (in each case we have calculated about twice as many Fourier coefficients as those shown in the tables), so that it seems quite likely that it is complete.

For the weight 2 functions, the corollary of Theorem 9.41 tells us that $C(\mathcal{F}_M; -1, 1)$ will always be negative with the normalization (9.52) and that we have

$$c_M \;=\; t \cdot \mathrm{denom}\Big(\frac{\varphi(M)}{24}\Big)\,, \qquad C(\mathcal{F}_M; -1, 1) \;=\; -t \cdot \mathrm{numer}\Big(\frac{\varphi(M)}{24}\Big) \tag{9.53}$$

for some positive rational number t. In all cases we have looked at, t turned out to be an integer, and in fact usually had the value 1. For instance, the second statement is true for all values of M tabulated in Appendix A, and also for $M = 210$, where Table 4 in §9.3 shows that $c_M = 1$ and hence $t = 1$, but the table below giving all values up to $M = 100$ shows that it fails for $M = 65$ and $M = 85$.

M	6	10	14	15	21	22	26	33	34	35	38	39	46	51	55	57	58	62	65	69	74	77	82	85	86	87	91	93	94	95
c_M	12	6	4	3	2	12	2	6	3	1	4	1	12	3	3	2	6	4	2	6	2	2	3	6	4	3	1	2	12	1
$C(\mathcal{F}_M; -1, 1)$	1	1	1	1	1	5	1	5	2	1	3	1	11	4	5	3	7	5	4	11	3	5	5	16	7	7	3	5	23	3
t	1	1	1	1	1	1	1	1	1	1	1	1	1	1	1	1	1	1	2	1	1	1	1	2	1	1	1	1	1	1

If it is true that t is integral, then equation (9.53) shows that the above list of $\mathcal{F}_M$ satisfying property (B) is complete, because we can then only have $|C(\mathcal{F}_M; -1, 1)| = 1$ if $\varphi(M)$ divides 24, which in turn implies that M is at most 90 and hence within the range of our calculations. We do not know whether the integrality is true in general, but in any case $12^{M+1}t$ must be an integer, since correcting the initial choice $\Phi_{2,M}^{\text{stand}} = 12^{-M-1}B^{M+1}A^{-1} - \mathcal{A}_{2,M}$ by weak Jacobi forms cannot make its denominator any worse.

Exactly similar comments apply in the weight 1 case. Here a residue calculation similar to the ones described in the next section (but with the residue $\mathcal{R}$ as defined in (10.17) below replaced by its weight 1 analogue as defined in (10.59)) tells us that in the case of optimal growth eq. (9.43) still holds, so that we find that eq. (9.53) still holds for some postive rational number t. If this t turns out to be an integer, it again follows that property (B) can only hold if $\varphi(M)|24$, and the list of all integers M with $\mu(M) = -1$ satisfying this latter condition coincides exactly with the list (9.46). Thus, although we cannot yet prove that that list is complete, we can at least understand where it comes from.

4. Positivity of the Fourier coefficients

We now turn to properties (C) and (D). Here we can use the asymptotic formula given in Theorem 9.3 to understand the question of the signs and asymptotics of the Fourier coefficients. (We will discuss only the weight 2 case in detail, but a similar theorem and similar discussion could equally well be given for the case $k = 1$.) This theorem implies that (C) "almost holds" in the sense that for any fixed value of r the Fourier coefficients $C(\Delta, r)$ eventually have a constant sign, so that there are at most finitely many exceptions to the statement. We therefore have to consider (D) and also the question of which values of r are most likely to give rise to the exceptional signs.

For the function $\mathcal{Q}_M$ (which we remind the reader differs from $\mathcal{F}_M$ by a negative proportionality factor, so that the expected behavior (D) would now say that $C(\Delta, r)$ is always negative when $r = r_{\min}$ is the smallest positive square root of $-\Delta$), the value of the constant κ_r appearing in that theorem as given according to (9.39) and (9.43) by

$$\kappa(\mathcal{Q}_M, r) \;=\; -\frac{\varphi(M)}{24} \cdot 2 \sum_{\substack{0<\ell<M \\ \ell^2 \equiv 1 \pmod{4M}}} \mu\Big(\big(\frac{\ell+1}{2}, M\big)\Big) \cos\Big(\frac{\pi \ell r}{M}\Big)\,. \tag{9.54}$$

A similar formula applies in the weight 1 case with "cos" resplaced by "sin." In the case when M is a prime, this immediately gives the positivity of $\kappa(\mathcal{Q}_M, r_{\min})$, and in the case when M has three prime factors, the tables in A.3 show that (D) usually fails. We therefore consider the weight 2 case, where $\mu(M) = +1$.

If M (which we always assume to be larger than 1) is a product of two primes, and in particular for all $M < 330$ with $\mu(M) = 1$ except 210, the sum on the right-hand side has only two terms and reduces to simply $\cos(\pi r/M) - \cos(\pi r^*/M)$, and since $0 < r_{\min} < r^*_{\min} < 2M$ and $\cos(\pi x)$ is decreasing on the interval $[0, \pi]$, the value of $-\kappa(\mathcal{Q}_M, r_{\min})$ is indeed always strictly negative. It then follows from Theorem 9.3 that almost all $C(\mathcal{F}_M; \Delta, r_{\min})$ are positive, but there can be, and in general are, finitely many exceptions. However, for small M these are fairly rare, e.g., the following table lists all triples $(M,\ r = r_{\min},\ n)$ within the range of Appendix A for which $c(\mathcal{F}_M; n, r)$ is negative.

M	6–22	33	34	35	38	39	46
r	—	8	15	2	17	10	21
n	—	1, 5, 7	5, 11	1, 5	5, 7, 11	5	5, 7, 11, 13

(The corresponding r-values are marked with a star in the appendix, and a search up to a much larger n-limit yields no further negative coefficients for these values of M.) Here again the asymptotic formula (9.38) helps us to understand this behavior: the negative values are much more likely to occur when κ_r is small. For instance, for $M = 33$ the table

$r\ (= r_{\min})$	1	2	4	5	7	8	10	13	16	19
$\cos(\frac{\pi r}{66}) - \cos(\frac{\pi r^*}{66})$	1.58	1.31	1.71	0.94	1.71	0.49	1.58	1.31	0.94	0.49

shows that the residue classes $r_{\min} \pmod{2M}$ most likely to give some negative Fourier coefficients are 8 and 19, for which the values of κ_r (which are the same; this duplication always occurs for odd M) are minimal, and indeed the class $r = 8$ did lead to three negative coefficients. The class $r = 19$ did not contain any negative values of $c(n, r)$, but instead achieved its small initial average by the initial zeros forced by the optimal growth condition, which says that $c(n, r) = 0$ for $0 \leq n \leq (r^2 - 2)/4m$.

For values of M for more than two prime factors on the other hand, it does not have to be true that $\kappa(\mathcal{F}_M, r_{\min}) > 0$. It is true for the first such index, $M = 210$, and even in a very strong form: not only is κ_r positive for each of the six possible values of $r_{\min}$ (which are nothing other than the values ℓ_0 printed in boldface in Table 4), but of the seven "partners" of each $r_{\min}$, i.e., the seven other values of $r \in [0, 210]$ with $r^2 \equiv r^2_{\min} \pmod{840}$, the three that have the same sign of $C(\Delta, r)$ as for $C(\Delta, r_{\min})$ (i.e., which differ from $r_{\min} \pmod{2p}$ for exactly two of the four prime divisors p of 210) all belong to the first half of the interval $[0, 210]$, while the four that have the opposite sign (i.e., which differ from $r_{\min} \pmod{2p}$ for one or three of these p) belong to the second half, so that all eight terms in the sum in (9.54) are positive. The value of $\kappa(\mathcal{F}_M, r_{\min})$ is again positive for all $r_{\min}$ for the next two values $M = 330$ and $M = 390$, but for $M = 462 = 2\cdot3\cdot7\cdot11$ and $r\ (= r_{\min})\ =\ 31$ we have $\kappa(\mathcal{F}_M, r) < 0$, so that in this case all but finitely many coefficients $C(\mathcal{F}_M;\Delta,r)$ will be negative rather than positive. What does hold for any M and any r (mod $2M$) is that the values of $C(\mathcal{F}_M;\Delta,r)$ eventually all have the same sign, because the coefficient $\kappa(\mathcal{F}_M,r)$ in (9.38) can never vanish, since the primitive $(2M)^{\text{th}}$ roots of unity are linearly independent over $\mathbb{Q}$.

9.6 Higher weights

So far we have studied two families of meromorphic Jacobi forms $\varphi_{1,m}(\tau,z)$ and $\varphi_{2,m}(\tau,z)$ with particularly simple singularities, and the corresponding mock Jacobi forms. We now discuss in much less detail the analogous families for higher weights. We mention that other cases of the decomposition $\varphi=\varphi^F+\varphi^P$ for meromorphic Jacobi forms with higher order poles[27] [17, 98], and the asymptotics of their Fourier coefficients [20], have been studied in the literature.

The starting point is a meromorphic Jacobi form $\varphi(\tau,z)=\varphi_{k,m}(\tau,z)$ of weight k and arbitrary index $m\in\mathbb{N}$ having as its unique singularity (modulo the period lattice $\mathbb{Z}\tau+\mathbb{Z}$) a pole of order k at $z=0$, which we normalized by requiring the leading term of φ to be $(k-1)!/(2\pi iz)^k$. By subtracting a linear combination of functions $\varphi_{k',m}$ with $k'<k$ we can then fix the entire principal part of φ at $z=0$ to be

$$\varphi(\tau,z)\;=\;\frac{(k-1)!}{(2\pi iz)^k}\sum_{0\le 2j<k}\Bigl(\frac{m\,E_2(\tau)}{12}\Bigr)^j\,\frac{(2\pi iz)^{2j}}{j!}\;+\;\mathrm{O}(1)\qquad\text{as } z\to 0.$$

We can make a standard choice, generalizing the previously defined forms (9.2) and (9.1), by taking φ to be the unique polynomial in A^{-1} and B (resp. C times such a polynomial if k is odd) with modular coefficients of the appropriate weight having this principal part, the next three of these being

$$\varphi^{\text{stand}}_{3,m}\;=\;\frac{B^m\,C}{12^m A^2}\,,\qquad\varphi^{\text{stand}}_{4,m}\;=\;\frac{6\,B^{m+2}}{12^{m+2}A^2}\,,\qquad\varphi^{\text{stand}}_{5,m}\;=\;\frac{(B^2-mE_4A^2/2)\,B^{m-1}\,C}{12^m\,A^3}\,.$$

Any other allowed choice of $\varphi_{k,m}$ will differ from this standard one by a weak Jacobi form of weight k and index m, and any two choices will have the same polar part. To write it down, we introduce Euler's functions

$$\mathcal{E}_k(y)\;=\;\mathrm{Av}_{\mathbb{Z}}\Bigl[\frac{(k-1)!}{(2\pi iz)^k}\Bigr]\;=\;\Bigl(-y\,\frac{d}{dy}\Bigr)^{k-1}\mathrm{Av}_{\mathbb{Z}}\Bigl[\frac{1}{2\pi iz}\Bigr]\;=\;\bigl(-y\,\frac{d}{dy}\bigr)^{k-1}\Bigl(\frac{1}{2}\,\frac{y+1}{y-1}\Bigr)\;\in\;\mathbb{Q}\Bigl[\frac{1}{y-1}\Bigr]$$

(which for $k=1$ and $k=2$ coincide with the functions $\mathcal{R}_0$ and $\mathcal{R}_0^{(2)}$ from §8) and their index m averages

$$\mathcal{A}_{k,m}(\tau,z)\;=\;\mathrm{Av}^{(m)}_{\mathbb{Z}\tau+\mathbb{Z}}\Bigl[\frac{(k-1)!}{(2\pi iz)^k}\Bigr]\;=\;\mathrm{Av}^{(m)}\bigl[\mathcal{E}_k(y)\bigr]\;=\;\sum_{s\in\mathbb{Z}}q^{ms^2}y^{2ms}\mathcal{E}_k(q^sy)$$

---

[27] These were considered in [17] while answering a question due to Kac concerning the modularity of certain characters of affine Lie superalgebras.

generalizing (9.3). These functions all have wall-crossing, with Fourier expansions given by

$$\mathcal{E}_k(y) \;=\; \begin{cases} \frac{1}{2}\,\delta_{k,1} \,+\, \sum_{t>0} t^{k-1}y^{-t} & \text{if } |y|>1 \\ -\frac{1}{2}\,\delta_{k,1} \,-\, \sum_{t<0} t^{k-1}y^{-t} & \text{if } |y|<1 \end{cases} \;=\; \sum_{t\in\mathbb{Z}} \frac{\operatorname{sgn}(t)-\operatorname{sgn}(z_2)}{2}\, t^{k-1}y^{-t}$$

and

$$\mathcal{A}_{k,m}(\tau,z) \;=\; \sum_{s,\,t\in\mathbb{Z}} \frac{\operatorname{sgn}(t) \,-\, \operatorname{sgn}(s+z_2/\tau_2)}{2}\, t^{k-1}q^{ms^2-st}y^{2ms-t}\,. \tag{9.55}$$

(Note that in the latter expression the coefficient of y^r is a Laurent polynomial in q for every r and that the discriminant $4nm-r^2$ is the negative of a perfect square for each monomial q^ny^r occurring.) Then the polar part of $\varphi_{k,m}$ is given by

$$\varphi^P_{k,m}(\tau,z) \;=\; \sum_{0\le 2j<k} \frac{(k-1)!}{(k-1-2j)!\,j!}\Bigl(\frac{m\,E_2(\tau)}{12}\Bigr)^j\,\mathcal{A}_{k-2j,m}(\tau,z)\,.$$

(To see this, observe that by (9.55) each of the functions $\mathcal{A}_{k,m}$, and hence any linear combination of them with coefficients depending only on τ, is in the kernel of the operator $\varphi\mapsto h_\ell$ defined by (8.2) for all $\ell\in\mathbb{Z}$.) Its finite part $\Phi_{k,m} = \varphi^F_{k,m} = \varphi_{k,m}-\varphi^P_{k,m}$ is a weakly holomoprhic elliptic form that depends on the particular choice of $\varphi_{k,m}$. From the results of §10 (specifically, Theorem 10.1) it follows that for $k\ge 3$ the function $\varphi_{k,m}$ can always be chosen so that $\Phi_{k,m}$ is strongly holomorphic, this choice then obviously being unique up to the addition of a strongly holomorphic Jacobi form.

As an example, consider $k=3$ and $m=2$. (This is the smallest possibility since index 1 cannot occur in odd weight.) The finite part of our standard choice is

$$\Phi^{\text{stand}}_{3,2} \;=\; \frac{B^2C}{144A^2} \,-\, \mathcal{A}_{3,2} \,-\, \frac{E_2}{3}\,\mathcal{A}_{3,1} \;=\; h^{\text{stand}}_{3,2}\,\bigl(\vartheta_{2,1} \,-\, \vartheta_{2,3}\bigr)$$

with

$$h^{\text{stand}}_{3,2} \;=\; \frac{1}{144}\,q^{-1/8}\,\bigl(1+51q+2121q^2+14422q^3+60339q^4+201996q^5+588989q^6+\cdots\bigr)\,.$$

This is weakly holomorphic and has large Fourier coefficients, but by subtracting a multiple of the unique weak Jacobi form E_4C of this weight and index we get a new choice

$$\Phi^{\text{opt}}_{3,2} \;=\; \Phi^{\text{stand}}_{3,2} \,-\, \frac{E_4}{144}\,C \;=\; h^{\text{opt}}_{3,2}\,\bigl(\vartheta_{2,1} \,-\, \vartheta_{2,3}\bigr)$$

that is strongly holomorphic and has much smaller coefficients

$$h^{\text{opt}}_{3,2} \;=\; h^{\text{stand}}_{3,2} \,-\, \frac{E_4}{144\,\eta^3} \;=\; -\frac{4}{3}\,q^{-1/8}\,\bigl(q+4q^2+5q^3+11q^4+6q^5+21q^6+\cdots\bigr)\,,$$

in accordance with the theorem just cited.

However, this choice, although optimal from the point of view of the order of growth of its Fourier coefficients, is not the most enlightening one. By subtracting a different multiple of E_4C from $\Phi_{3,2}^{\text{stand}}$, we get a third function

$$\Phi_{3,2} \;=\; \Phi_{3,2}^{\text{stand}} + \frac{7E_4}{144}\,C \;=\; \Phi_{3,2}^{\text{opt}} + \frac{E_4}{18}\,C \;=\; h_{3,2}\bigl(\vartheta_{2,1} \,-\, \vartheta_{2,3}\bigr)$$

with

$$h_{3,2} \;=\; h_{3,2}^{\text{stand}} + \frac{7E_4}{144\,\eta^3} \;=\; h_{3,2}^{\text{opt}} + \frac{E_4}{18\,\eta^3} \;=\; \frac{1}{18}\,q^{-1/8}\,(1 + 219q + 2793q^2 + 15262q^3 + \cdots)\,.$$

This function can be identified: it is given by

$$h_{3,2} \;=\; \frac{1}{3}\,\partial_{1/2}^{\text{RS}}(h_2)\,,$$

where $h_2(\tau) = q^{-1/8}(-1 + 45q + 231q^2 + \cdots)$ is the mock theta function defined in (7.16) (the one occurring in the Mathieu moonshine story) and $\partial_{1/2}^{\text{RS}}$ is the Ramanujan-Serre derivative as defined in (3.7). We can also write this at the level of mock Jacobi forms as

$$\Phi_{3,2} \;=\; \frac{1}{24}\,\mathcal{L}_{1,2}(\mathcal{F}_2)\,,$$

where $\mathcal{F}_2$ is the mock Jacobi form defined in (7.32) and $\mathcal{L}_{1,2}$ the modified heat operator defined in (4.12).

An analogous statement holds in general, e.g., for weight 3 we have

$$\Phi_{3,m} \;=\; -\,\mathcal{L}_{1,m}\bigl(\Phi_{1,m}\bigr) \qquad \pmod{\widetilde{J}_{3,m}}$$

for any index m and any choice of the functions $\Phi_{3,m}$ and $\Phi_{1,m}$ in their defining classes, and similarly for higher weight, the specific formulas for $k \in \{3,4\}$ and the standard choices being

$$\begin{aligned}
\Phi_{3,m}^{\text{stand}} + \mathcal{L}_{1,m}\bigl(\Phi_{1,m}^{\text{stand}}\bigr) \;&=\; -\,\frac{m-1}{12^m}\Bigl(4(m-2)E_6A \,+\, (2m+3)E_4B\Bigr)\,B^{m-3}C\,,\\
\Phi_{4,m}^{\text{stand}} + \mathcal{L}_{2,m}\bigl(\Phi_{2,m}^{\text{stand}}\bigr) \;&=\; -\,\frac{m+1}{72\cdot 12^m}\Bigl(4mE_6A \,+\, (2m-3)E_4B\Bigr)\,B^{m-1}\,.
\end{aligned}$$

Thus in one sense, the higher-weight families are better than the weight 1 and weight 2 families (because they can be made strongly holomorphic by subtracting an appropriate weak Jacobi form), but in another, they are much less interesting (because they are always combinations of derivatives of lower-weight examples and ordinary Jacobi forms, so that they do not produce any essentially new functions).

10. Structure theorems for Jacobi and mock Jacobi forms

In the last section we introduced two special families of meromorphic Jacobi forms and the associated mock Jacobi forms and described various observations concerning them. In this section we try to give theoretical explanations for some of these. We begin by studying in §10.1 how the holomorphic Jacobi forms of weight k and index m lie in the space of weak Jacobi forms of the same weight and index, or equivalently, what the relations are among the polar Fourier coefficients (i.e., the coefficients of $q^n y^r$ with $4nm < r^2$) of weak Jacobi forms. The results described here are relatively easy consequence of results in the literature but are, as far as we know, new. The remaining two subsections describe the application of these results to mock Jacobi forms in general and to our two special families in particular, providing fairly complete explanations of the experimentally found properties of the weight two family and partial explanations in the weight one case.

10.1 Relations among the polar coefficients of weak Jacobi forms

The definitions and main properties of holomorphic and weak Jacobi forms were reviewed in §4, following the more detailed treatment in [57]. Here we investigate the relationship of these two spaces in more detail.

By definition, a weak Jacobi form has coefficients $c(n,r)$ which are non-zero only for $n \geq 0$, whereas a holomorphic one has coefficients that vanish unless $4nm \geq r^2$. By virtue of the periodicity property (4.4), this stronger condition need only be checked for r running over a set of representatives for $\mathbb{Z}/2m\mathbb{Z}$, say $-m < r \leq r$, and since condition (4.1) with $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) = \left(\begin{smallmatrix} -1 & 0 \\ 0 & -1 \end{smallmatrix}\right)$ also implies that $c(n,-r) = (-1)^k c(n,r)$ and consequently $C(\Delta,-r) = (-1)^k C(\Delta,r)$, it in fact suffices to consider the coefficients with $0 \leq r \leq m$ if k is even and those with $0 < r < m$ if k is odd. In other words, for all positive integers k and m we have an exact sequence

$$0 \longrightarrow J_{k,m} \longrightarrow \widetilde{J}_{k,m} \xrightarrow{P} \mathbb{C}^{\mathcal{N}_{\pm,m}} \qquad (\,(-1)^k = \pm 1\,)\,, \tag{10.1}$$

where

$$\begin{aligned} \mathcal{N}_{+,m} &= \left\{(r,n) \in \mathbb{Z}^2 \;\middle|\; 0 \leq r \leq m,\ 0 \leq n < r^2/4m\right\}\,, \\ \mathcal{N}_{-,m} &= \left\{(r,n) \in \mathbb{Z}^2 \;\middle|\; 0 < r < m,\ 0 \leq n < r^2/4m\right\}\,, \end{aligned}$$

and where the map P ("polar coefficients") associates to $\varphi \in \widetilde{J}_{k,m}$ the collection of its Fourier coefficients $c_\varphi(n,r)$ for $(n,r) \in \mathcal{N}_{\pm,m}$. In particular we have

$$\dim J_{k,m} \;\geq\; j(k,m) \;:=\; \dim \widetilde{J}_{k,m} \;-\; \left|\mathcal{N}_{\pm,m}\right| \qquad (\,(-1)^k \;=\; \pm 1\,)\,, \tag{10.2}$$

with equality if and only if the map P in (10.1) is surjective. (Cf. [57], p. 105.)

Using the description of $\widetilde{J}_{*,*}$ given in §4 (eqs. (4.25) and (4.35)) and the definition of $\mathcal{N}_{\pm,m}$, we can write this lower bound on the dimension explicitly as

$$j(k,m) \;=\; \begin{cases} \sum_{0\le j\le m}\big(\dim M_{k+2j} - \lceil j^2/4m\rceil\big) & \text{if } k \text{ is even,} \\ \sum_{0< j< m}\big(\dim M_{k+2j-1} - \lceil j^2/4m\rceil\big) & \text{if } k \text{ is odd,} \end{cases} \tag{10.3}$$

where $\lceil x\rceil$ denotes the "ceiling" of a real number x ($=$ smallest integer $\ge x$). This formula is computable and elementary since $\dim M_k = k/12 + \mathrm{O}(1)$ with the $\mathrm{O}(1)$ term depending only on $k \pmod{12}$, but is nevertheless not a good formula because the two terms $\sum \dim M_{k+2j}$ and $\sum \lceil j^2/4m\rceil$ are each equal to $m^2/12 + \mathrm{O}(m)$, and $j(k,m)$ is only of the order of m. In [57], pp. 122–125 it was shown that, somewhat surprisingly, the numbers $j(k,m)$ can be given by a completely different-looking formula involving class numbers of imaginary quadratic fields. This formula has the form

$$j(k,m) \;=\; \frac{2k-3}{24}\,(m+1) \,+\, \frac{b}{4} \,-\, \frac{1}{4}\sum_{d|4m} h(-d) \,+\, \mathrm{O}(1)\,, \tag{10.4}$$

where $m = ab^2$ with a square-free and where the $\mathrm{O}(1)$ term depends only on m and k modulo 12. In particular, $j(k,m) = \frac{2k-3}{24}\,m \,+\, \mathrm{O}(m^{1/2+\varepsilon})$ as $m\to\infty$ with k fixed. The formula (10.4) has an interesting interpretation as the dimension of a certain space of classical modular forms of level m and weight $2k-2$, discussed in detail on pp. 125–131 of [57].

In [57], it was shown that the inequality (10.2) is an equality for $k \ge m$ and it was conjectured that this holds for all $k \ge 3$. This was later proved in [115] as a consequence of a difficult trace formula calculation. In fact, a slightly stronger statement was proved there: It is clear that the exact sequence (10.1) remains valid if one replaces $J_{k,m}$ by $J^0_{k,m}$ and the map $P : \widetilde{J}_{k,m} \to \mathbb{C}^{\mathcal{N}_{\pm,m}}$ by the analogously defined map $P^0 : \widetilde{J}_{k,m} \to \mathbb{C}^{\mathcal{N}^0_{\pm,m}}$, where $\mathcal{N}^0_{\pm,m}$ is defined exactly like $\mathcal{N}_{\pm,m}$ but with the strict inequality $n < r^2/4m$ replaced by $n \le r^2/4m$. Then the dimension formula proved in [115] says that $\dim J^0_{k,m} = \dim \widetilde{J}_{k,m} - |\mathcal{N}^0_{\pm,m}|$ and hence that the map P^0 is surjective, which is a stronger statement than the surjectivity of P since the set $\mathcal{N}^0_{\pm,m}$ is larger than $\mathcal{N}_{\pm,m}$. In summary, the results of [57] and [115] together give the following complete description of the "polar coefficients" maps for both holomorphic and cuspidal Jacobi forms when $k \ge 3$:

Theorem 10.1. *For $k > 2$ and all $m \ge 1$ the map $P^0 : \widetilde{J}_{k,m} \to \mathbb{C}^{\mathcal{N}^0_{\pm,m}}$ is surjective and we have a commutative diagram of short exact sequences*

$$\begin{tikzcd}
0 \arrow[r] & J^0_{k,m} \arrow[r] \arrow[d, phantom, "\cap"] & \widetilde{J}_{k,m} \arrow[r, "P^0"] \arrow[d, equal] & \mathbb{C}^{\mathcal{N}^0_{\pm,m}} \arrow[r] \arrow[d, twoheadrightarrow] & 0 \\
0 \arrow[r] & J_{k,m} \arrow[r] & \widetilde{J}_{k,m} \arrow[r, "P"] & \mathbb{C}^{\mathcal{N}_{\pm,m}} \arrow[r] & 0
\end{tikzcd} \tag{10.5}$$

We now turn to the case $k=2$, the one of main interest for us. Here formula (10.4) takes the explicit form

$$j(2,m) \;=\; \frac{1}{2}\Bigl(\Bigl\lfloor\frac{m+1}{3}\Bigr\rfloor \,+\, \Bigl\lfloor\frac{m+1}{3}\Bigr\rfloor\Bigr) \,-\, \frac{m-b-1}{4} \,-\, \frac{1}{4}\sum_{d|4m} h(-d)\,, \tag{10.6}$$

but for this value of k it was observed in [57] (p. 131) that equality could not always hold in (10.2) (indeed, the right-hand side is often negative) and that, for reasons explained in detail there, one should replace the number $j(k,m)$ by the modified number

$$j^*(2,m) \;:=\; j(2,m) \,+\, \delta(m)\,, \qquad \text{where} \qquad \delta(m) \;:=\; \sum_{\substack{d\le\sqrt{m}\\ d|m,\; d^2\nmid m}} 1\;. \tag{10.7}$$

We note that $\delta(m)$ is a linear combination of three multiplicative functions of m, namely

$$\delta(m) \;=\; \frac{1}{2}\sigma_0(m) \,+\, \frac{1}{2}\,\delta_{a,1} \,-\, \sigma_0(b) \tag{10.8}$$

(with $m=ab^2$, a square-free as before), or equivalently in terms of a generating Dirichlet series

$$\sum_{m=1}^{\infty}\frac{\delta(m)}{m^s} \;=\; \frac{1}{2}\,\zeta(s)^2 \,+\, \frac{1}{2}\,\zeta(2s) \,-\, \zeta(s)\zeta(2s)\;. \tag{10.9}$$

We also note that $\delta(m)$ depends only on the "shape" of m (= the collection of exponents ν_i if m is written as $\prod p_i^{\nu_i}$), the first three cases being

$$\delta(p^\nu) \;=\; 0\,, \tag{10.10}$$

$$\delta(p_1^{\nu_1}p_2^{\nu_2}) \;=\; n_1n_2\,, \tag{10.11}$$

$$\delta(p_1^{\nu_1}p_2^{\nu_2}p_3^{\nu_3}) \;=\; 3n_1n_2n_3+\varepsilon_1n_2n_3+\varepsilon_2n_1n_3+\varepsilon_3n_1n_2\,, \tag{10.12}$$

in which we have written each ν_i as $2n_i+\varepsilon_i-1$ with $n_i\ge1$ and $\varepsilon_i\in\{0,1\}$.

The conjecture made in [57] that $\dim J_{k,m}=j^*(2,m)$ for all $m\ge1$ was proved in [115], but here we want to give a sharper statement describing the cokernel of the map P explicitly. To do this, we follow [57], pp. 132, where an elementary argument (containing a small error which will be corrected below) was given to show that $\dim J_{2,m}\ge j^*(2,m)$ for square-free m. Actually, it is more convenient to work with cusp forms, since the corresponding statement here is

$$\dim J^0_{2,m} \;=\; \dim \widetilde{J}_{2,m} \,-\, |\mathcal{N}^0_{+,m}| \,+\, \delta^0(m) \tag{10.13}$$

with

$$\delta^0(m) \;=\; \sum_{d|m,\; d\le\sqrt{m}} 1 \;=\; \sum_{\substack{m=m_1\cdot m_2\\ \text{up to order}}} 1\,, \tag{10.14}$$

and $\delta^0(m)$ is a slightly simpler function than $\delta(m)$. (The third term in (10.8) is missing.) We want to explain formula (10.13) by finding an explicit map

$$\beta\,:\,\mathbb{C}^{\mathcal{N}^0_{+,m}}\;=\;\bigoplus_{\substack{0\le r\le m\\ 0\le n\le r^2/4m}}\mathbb{C}\;\longrightarrow\;\Delta^0(m):=\bigoplus_{\substack{m=m_1\cdot m_2\\ \text{up to order}}}\mathbb{C} \tag{10.15}$$

such that the sequence

$$0\longrightarrow J^0_{2,m}\longrightarrow \widetilde{J}_{2,m}\xrightarrow{P^0}\mathbb{C}^{\mathcal{N}^0_{+,m}}\xrightarrow{\beta}\Delta^0(m)\longrightarrow 0\;. \tag{10.16}$$

is exact.

To give a natural definition of the map β, we work, not with $\widetilde{J}_{2,m}$ or even with $J^!_{2,m}$, but with the larger vector spaces $\widetilde{\mathcal{E}}_{+,m}$ and $\mathcal{E}^!_{+,m}$ of even weak or weakly holomorphic elliptic forms of index m, as defined at the end of §4.4. We define a "residue map" $\mathcal{R}:\mathcal{E}^!_{+,m}\to\mathbb{C}$ by

$$\varphi\;=\;\sum_{n\ge0,\,r\in\mathbb{Z}}c(n,r)\,q^n\,y^r\quad\mapsto\quad\mathcal{R}[\varphi]\;=\;\mathrm{Res}_{\tau=\infty}\big(\varphi(\tau,0)\,d\tau\big)\;=\;\sum_{r\in\mathbb{Z}}c(0,r)\;. \tag{10.17}$$

Then $\mathcal{R}[\varphi]=0$ if $\varphi\in J^!_{2,m}$ because in that case $\varphi(\,\cdot\,,0)$ belongs to $M^!_2$ and the q^0 term of any weakly holomorphic modular form f of weight two is zero by the residue theorem applied to the $SL(2,\mathbb{Z})$-invariant 1-form $f(\tau)d\tau$. (The map $\mathcal{R}$ was already used in [57], but it was erroneously stated there that for $\varphi\in\widetilde{J}_{2,m}$ the function $\varphi(\tau,0)$ itself, rather than just its residue at infinity, vanishes.) Now for each decomposition $m=m_1\cdot m_2$ (up to order, i.e., without distinguishing the splittings $m_1\cdot m_2$ and $m_2\cdot m_1$) we define $R_{m_1,m_2}:\mathcal{E}^!_{+,m}\to\mathbb{C}$ by setting $R_{m_1,m_2}(\varphi)=\mathcal{R}\big[\varphi\big|W_{m_1}\big]$ if $(m_1,m_2)=1$, where W_{m_1} is the involution defined in §4.4, while if $(m_1,m_2)=t>1$ then we define $R_{m_1,m_2}(\varphi)$ as $R_{m_1/t,m_2/t}(\varphi|u_t)$, where u_t is the map from $\mathcal{E}^!_{+,m}$ to $\mathcal{E}^!_{+,m/t^2}$ defined in §4.4. (It was pointed out there that both W_{m_1} for $(m_1,m/m_1)=1$ and u_t for $t^2|m$ make sense on all of $\mathcal{E}^!_{+,m}$, and not just on the subspace of holomorphic Jacobi forms, but that this is *not* true for weak elliptic or weak Jacobi forms, which is why we are now working with weakly holomorphic forms.) We put all of these maps together to a single map $R:\,\mathcal{E}^!_{+,m}\to\Delta^0(m)$ and then define the desired map β by the commutative diagram

$$\begin{tikzcd}
\widetilde{\mathcal{E}}_{+,m} \arrow[rr, "P^0"] \arrow[d, phantom, "\cap"] & & \mathbb{C}^{\mathcal{N}^0_{+,m}} \arrow[d, phantom, "\cap"] \\
\mathcal{E}^!_{+,m} \arrow[rr] \arrow[dr, "R"'] & & \mathbb{C}^{\mathcal{N}^{!,0}_{+,m}} \arrow[dl, "\beta"] \\
& \Delta^0(m) &
\end{tikzcd} \tag{10.18}$$

with $\mathbb{C}^{\mathcal{N}^{!,0}_{+,m}}$ defined as in (10.23) below. (To see that such a map β exists, observe that the coefficients $c(0,r)$ occurring in (10.17) all have discriminant $\Delta=-r^2\le0$, that the operators

W_{m_1} and u_t can be defined purely in terms of the coefficients $C_\varphi(\Delta,r)$ and preserve the condition $\Delta\le 0$, and finally that the coefficients $C_\varphi(\Delta,r)$ for $\varphi\in\widetilde{\mathcal{E}}_{+,m}$ can all be expressed in terms of the coefficients $c_\varphi(n,r)$ with $(n,r)\in\mathcal{N}_{+,m}$ by virtue of the periodicity and evenness conditions defining $\widetilde{\mathcal{E}}_{+,m}$.) The discussion above shows that the composition $\beta\circ P^0$ in (10.16) vanishes, since $\mathcal{R}$ vanishes on weakly holomorphic and hence in particular on weak Jacobi forms, and combining this statement with the dimension formula (10.13) proved in [115] we obtain the main result describing strong and weak Jacobi forms of weight 2 and arbitrary index:

Theorem 10.2. *The sequence* (10.16) *with* β *defined by* (10.18) *is exact for all integers* $m\ge 1$.

The two theorems above give a complete description of the space of Jacobi forms of all weights $k\ge 2$. We end this subsection by discussing the case of weight one. Here the description of Jacobi forms is very simple to state (though its proof is quite deep), since we have the following theorem of Skoruppa ([111], quoted as Theorem 5.7 of [57]):

Theorem 10.3. *We have* $J_{1,m}=\{0\}$ *for all* $m\ge 1$.

Combining this with the discussion above, we find that in this case we have an exact sequence

$$0\longrightarrow \widetilde{J}_{1,m}\longrightarrow \bigoplus_{\substack{0<r<m\\ 0\le n<r^2/4m}}\mathbb{C}\longrightarrow \mathbb{C}^{|j(1,m)|}\longrightarrow 0\,. \tag{10.19}$$

with

$$|j(1,m)| \;=\; -j(1,m)\;=\;\frac{m}{24}\;+\;\mathrm{O}\big(m^{1/2+\varepsilon}\big)\,.$$

We have not been able to find a natural description of the last space, or explicit description of the last map, in (10.19), analogous to the results given for $k=2$.

10.2 Choosing optimal versions of weak elliptic forms

In this subsection, we will apply the theorem just explained to show how to make "optimal versions" of elliptic forms by counting actual Jacobi forms to get poles of small order.

Let $\widetilde{\mathcal{E}}_{+,m}$ be as in the previous subsection and $\widetilde{\mathcal{E}}_{-,m}$ be the similarly defined space with $c(n,-r)=-c(n,r)$, and let $\mathcal{E}_{\pm,m}$ and $\mathcal{E}^0_{\pm,m}$ be the corresponding spaces with the condition (4.7) replaced by (4.5) and (4.6), respectively. The discussion of §10.1 can be summarized as saying that we have a commutative diagram of short exact sequences,

$$\begin{tikzcd}
0 \arrow[r] & \mathcal{E}_{\pm,m} \arrow[r] & \widetilde{\mathcal{E}}_{\pm,m} \arrow[r, "P"] & \mathbb{C}^{\mathcal{N}_{\pm,m}} \arrow[r] & 0 \\
0 \arrow[r] & J_{k,m} \arrow[r] \arrow[u, phantom, "\cup"] & \widetilde{J}_{k,m} \arrow[r] \arrow[u, phantom, "\cup"] & \mathbb{C}^{\mathcal{N}_{\pm,m}} \arrow[r] \arrow[u, phantom, "||"] & 0
\end{tikzcd} \tag{10.20}$$

for $k > 2$, $(-1)^k = \pm 1$, and similarly with $J_{k,m}$ and $\mathcal{E}_{\pm,m}$ replaced by $J^0_{k,m}$ and $\mathcal{E}^0_{\pm,m}$, $\mathcal{N}_{\pm,m}$ by $\mathcal{N}^0_{\pm,m}$ and P by P^0. For $k = 2$, we have instead:

$$\begin{tikzcd}
0 \arrow[r] & \mathcal{E}^0_{+,m} \arrow[r] \arrow[d, phantom, "\cup"] & \widetilde{\mathcal{E}}_{+,m} \arrow[r, "P^0"] \arrow[d, phantom, "\cup"] & \mathbb{C}^{\mathcal{N}^0_{+,m}} \arrow[r] \arrow[d, equal] & 0 & \\
0 \arrow[r] & J^0_{2,m} \arrow[r] & \widetilde{J}_{2,m} \arrow[r] & \mathbb{C}^{\mathcal{N}^0_{+,m}} \arrow[r, "\beta"] & \Delta^0(m) \arrow[r] & 0
\end{tikzcd} \tag{10.21}$$

in the cuspidal case, where $\Delta^0(m)$ was defined in (10.15) and β is defined by $\beta \circ P^0 = R$. As a consequence of these diagrams and of the vanishing of $\delta(p^\nu)$ (*cf.* equation (10.10)), which implies that the diagram (10.20) also holds for $k = 2$ when m is a prime power, we obtain:

Theorem 10.4. *Let $k \geq 2$, and $\varphi \in \widetilde{\mathcal{E}}_{\pm,m}$, where $(-1)^k = \pm 1$. Then φ is the sum of an element of $\widetilde{J}_{k,m}$ and an element of $\mathcal{E}^0_{\pm,m}$ if and only if either*

(i) $\quad k > 2\,,$ *or*

(ii) $\quad k = 2$ *and* $R(\varphi)\ (= \beta(P^0(\varphi)))\ = 0\,;$

If $k = 2$ and m is a prime power, then φ is the sum of an element of $\widetilde{J}_{k,m}$ and an element of $\mathcal{E}_{\pm,m}$.

Theorem 10.4 for $k = 2$ makes a negative statement: if $\varphi \in \widetilde{\mathcal{E}}_{+,m}$ has $\mathcal{R}[\varphi] \neq 0$, and m is not a prime power, then φ *cannot* in general be decomposed as the sum of a weak Jacobi form of weight 2 and a holomorphic elliptic form. However, it turns out that we can come very close to this, writing φ as a sum of images under Hecke-like operators of forms that "have optimal growth" in the sense of §9.3. We now explain this in two steps. We first use the decomposition (4.44), and its variants for weakly holomorphic Jacobi or elliptic forms, to reduce to the case of primitive forms. We then show that any primitive even elliptic form can be corrected by the addition of a weakly holomorphic weight 2 Jacobi form to give a new elliptic form whose non-zero Fourier coefficients $c(n, r)$ all have discriminant $4mn - r^2 \geq -1$.

Since the decomposition (4.44), as was already observed in §4.3 fails for weak Jacobi forms but holds for weakly holomorphic ones, we must first extend the above results to weakly holomorphic forms.

Proposition 10.1. *All statements in Theorem 10.4 remain true* mutatis mutandis *if all $\widetilde{\mathcal{E}}$, $\widetilde{J}$ are replaced by $\mathcal{E}^!$, $J^!$.*

The proposition is equivalent to saying that the analog of (10.21) still holds with weakly holomorphic rather than weak forms, i.e. we have a diagram

$$\begin{tikzcd}
0 \arrow[r] & \mathcal{E}^0_{+,m} \arrow[r] \arrow[d, phantom, "\cup"] & \mathcal{E}^!_{+,m} \arrow[r, "P^0"] \arrow[d, phantom, "\cup"] & \mathbb{C}^{\mathcal{N}^{0,!}_{+,m}} \arrow[r] \arrow[d, equal] & 0 & \\
0 \arrow[r] & J^0_{2,m} \arrow[r] & J^!_{2,m} \arrow[r] & \mathbb{C}^{\mathcal{N}^{0,!}_{+,m}} \arrow[r, "\beta"] & \Delta^0(m) \arrow[r] & 0
\end{tikzcd} \tag{10.22}$$

where

$$\mathcal{N}^{0,!}_{+,m} \;=\; \bigl\{(r,n)\in\mathbb{Z}^2 \;\mid\; 0\le r\le m,\; -\infty<n\le r^2/4m\bigr\}\,. \tag{10.23}$$

We again prove this by comparing dimensions, even though the middle spaces in each row in the diagram (10.22) are infinite-dimensional. Since any elliptic form φ has a minimal value of n with $c_\varphi(n,r)\neq 0$ for some r, it suffices to prove the exactness of the rows in (10.22) with $\mathcal{E}^!_{+,m}$, $J^!_{2,m}$, and $\mathbb{C}^{\mathcal{N}^{0,!}_{+,m}}$ replaced by the spaces $\mathcal{E}^{\ge N}_{+,m}$, $J^{\ge N}_{2,m}$, and $\mathbb{C}^{\mathcal{N}^{0,\ge N}_{+,m}}$, of forms with non-zero coefficients only for $n\ge -N$ for some $N\ge 0$. The only non-trivial part is the exactness at $\mathbb{C}^{\mathcal{N}^{0,\ge -N}_{+,m}}$, and since the composition of the maps P^0 and β vanishes, we only need to check that the alternating sum of dimensions is zero. For this, we observe that the dimensions of $J^{\ge -N}_{2,m}$ and $\mathbb{C}^{\mathcal{N}^{0,\ge -N}_{+,m}}$ are both larger by $(m+1)N$ than their values at $N=0$: for $\mathbb{C}^{\mathcal{N}^{0,\ge -N}_{+,m}}$, this is obvious since $\mathcal{N}^{0,\ge -N}_{+,m}$ differs from $\mathcal{N}^0_{+,m}$ by the addition of N rows of length $m+1$, and for $J^{\ge -N}_{2,m}$ it follows from the computation

$$\begin{aligned}\dim J^{\ge -N}_{2,m} \;&=\; \dim \widetilde{J}_{12N+2,m} \qquad \bigl(\text{because } J^{\ge -N}_{2,m} = \Delta(\tau)^{-N}\widetilde{J}_{12N+2,m}\bigr)\\ &=\; \sum_{j=0}^{m}\dim M_{k+12N+2j} \;=\; \dim \widetilde{J}_{2,m} \;+\; (m+1)N\,. \end{aligned} \tag{10.24}$$

This completes the proof of the proposition. □

Now we can apply the decomposition (4.44) to the whole diagram (10.22) to find that everything can be reduced to primitive forms (and their images under the U_t operators). The key point is that although U_t and u_t change the discriminant $\Delta = 4mn - r^2$ by multiplying or dividing it by t^2, respectively, they do not change its sign, and therefore all of the spaces in our diagram can be decomposed as direct sums of primitive parts of lower index and their images under U_t. This reduces everything to case of primitive forms.

For primitive forms our diagram becomes

$$\begin{tikzcd} 0 \arrow[r] & \mathcal{E}^{0,\mathrm{prim}}_{+,m} \arrow[r] & \mathcal{E}^{!,\mathrm{prim}}_{+,m} \arrow[r, "P^0"] & \mathbb{C}^{\mathcal{N}^{0,!,\mathrm{prim}}_{+,m}} \arrow[r] & 0 & \\ & \cup & \cup & \| & & \\ 0 \arrow[r] & J^{0,\mathrm{prim}}_{2,m} \arrow[r] & J^{!,\mathrm{prim}}_{2,m} \arrow[r] & \mathbb{C}^{\mathcal{N}^{0,!,\mathrm{prim}}_{+,m}} \arrow[r, "\beta"] & \Delta^{0,\mathrm{prim}}(m) \arrow[r] & 0 \end{tikzcd} \tag{10.25}$$

where

$$\Delta^{0,\mathrm{prim}}(m) = \bigoplus_{\substack{m=m_1\cdot m_2\\ (m_1,m_2)=1\\ \text{up to order}}} \mathbb{C}\,. \tag{10.26}$$

The map β in (10.25) is again defined by the requirement that $\beta\circ P^0 = R$ on $\mathcal{E}^{!,\mathrm{prim}}_{+,m}$, and lands in $\Delta^{0,\mathrm{prim}}(m)$ because $\varphi|u_t = 0$ for φ primitive and $t>1$. The space $\Delta^{0,\mathrm{prim}}(m)$ has dimension $\delta^{0,\mathrm{prim}}(m) = 2^{s-1}$ if $m>1$, where s is the number of primes dividing m. (The failure of this formula for $m=1$ corresponds to the second term in (10.8).)

We also have the non-cusp-form analogs of the diagrams (10.22) and (10.25), where all superscripts "0" have been dropped and where $\mathcal{N}^!_{+,m}$ is defined as in (10.23) but with the condition $4mn - r^2 \leq 0$ replaced by the strict inequality $4mn - r^2 < 0$, while $\Delta^{\rm prim}(m)$ is a space of dimension $\delta^{\rm prim}(m) = \delta^{0,{\rm prim}}(m) - 1 = 2^{s-1} - 1$ (compare equation (10.8)). This space is the quotient of the space in (10.26) by the one-dimensional subspace of vectors with all components equal. This is essentially the idea of the proof of Theorem 9.4 given below.

Having completed these preparations, we now proceed to the proofs of our main results. We consider the case of square-free index first and then give a brief description of the modifications needed to extend them to primitive forms of arbitrary index.

For $m > 1$ square-free, we will show that any $\varphi \in \widetilde{\mathcal{E}}_{+,m}$ can be corrected by a weak Jacobi form of weight 2 to get a another elliptic form whose non-zero Fourier coefficients $c(n, r)$ all have discriminant $4mn - r^2 \geq -1$, i.e., that we have a decomposition

$$\widetilde{\mathcal{E}}_{+,m} \;=\; \widetilde{J}_{2,m} + \mathcal{E}^{\rm OG}_{+,m} \qquad (m \text{ square-free}), \tag{10.27}$$

with $\mathcal{E}^{\rm OG}_{+,m}$ defined as in §9.3. Actually, this is still not quite the statement we want, since it is slightly wasteful: the codimension of $\mathcal{E}^0_{+,m}$ in $\mathcal{E}^{\rm OG}_{+,m}$ is $2^{s-1}+1$, where s as before is the number of prime factors of m (there are 2^{s-1} pairs $(r, n) \in \mathcal{N}^0_{+,m}$ with $\Delta := 4nm - r^2$ equal to -1, and one pair (0,0) with $\Delta = 0$), and there are only $\dim \Delta^0(m) = 2^{s-1}$ constraints $R_{m_1,m_2}(\varphi) = 0$ coming from diagram (10.21). Correspondingly, the intersection of the two spaces on the right-hand side of (10.27) contains $J_{2,m}$ ($= J^0_{2,m}$ in this case) as a subspace of codimension 1. To get a sharp statement, we should therefore replace $\mathcal{E}^{\rm OG}_{+,m}$ by a suitable codimension one subspace. There are three natural ways to do this, each of which leads to a sharpening of (10.27), corresponding exactly (in the square-free case) to the various choices of $\Phi^0_{2,m}$ introduced in the discussion preceding Theorem 9.5. What's more, all statements remain true verbatim for arbitrary $m > 1$ if we restrict to primitive forms. We state all three variants in a single theorem.

Theorem 10.5. *Suppose that $m > 1$ is square-free and let $\mathcal{E}^{{\rm OG},\star}_m$ ($\star$ = I, II, III) denote the codimension one subspace of $\mathcal{E}^{\rm OG}_{+,m}$ defined by one of the three conditions*

(I) $\sum_{0<r<m,\; r^2\equiv 1 \pmod{4m}} C_\varphi(-1; r) = 0$,

(II) $c_\varphi(0, 1) = 0$,

(III) $c_\varphi(0, 0) = 0$,

respectively. Then we have an exact sequence

$$0 \longrightarrow J_{2,m} \xrightarrow{\rm diag} \widetilde{J}_{2,m} \oplus \mathcal{E}^{{\rm OG},\star}_m \xrightarrow{-} \widetilde{\mathcal{E}}_{+,m} \longrightarrow 0\;, \tag{10.28}$$

i.e., any even weak elliptic form of index m can be decomposed as the sum of a weak Jacobi form of weight 2 and index m and an element of $\mathcal{E}^{{\rm OG},\star}_m$, and this decomposition is unique up to a holomorphic Jacobi form (which can be added to one term and subtracted from the other).

For $m > 1$ the same statement remains true if we replace $\widetilde{\mathcal{E}}_{+,m}$ by its subspace $\widetilde{\mathcal{E}}^{\mathrm{res-prim}}_{+,m}$ of forms φ satisfying $R(\varphi|u_t) = 0$ for all $t > 1$ and $\mathcal{E}^{\mathrm{OG},\star}_{m}$ by its intersection with $\widetilde{\mathcal{E}}^{\mathrm{res-prim}}_{+,m}$.

Proof. By the exactness of the top line of diagram (10.21), we can find functions $\psi_{m;(r,n)} \in \widetilde{\mathcal{E}}_{+,m}$, unique up to the addition of cusp forms, mapping to the canonical basis $\delta_{(r,n)}$ of $\mathbb{C}^{\mathcal{N}^0_{+,m}}$. Clearly, the space $\mathcal{E}^{\mathrm{OG,III}}_{+,m}/\mathcal{E}^0_{+,m}$ is spanned by $\psi_{m;(r,n)}$ with $0 < r < m$ and $4mn - r^2 = -1$, and has dimension 2^{s-1}. (There are exactly two square roots of 1 modulo $2P$ for each exact prime power divisor P of m and these can be combined arbitrarily by the Chinese remainder theorem. This gives 2^s residue classes $r \pmod{2m}$ with $r^2 \equiv 1 \pmod{4m}$, and if we choose the representatives of smallest absolute values then half of them are positive.) Moreover, the basis elements can be chosen to be a single orbit of the group $\{W_{m_1}\}_{m_1|m}$ introduced in §4.4, whose cardinality is the same number 2^{s-1}. Namely, if A_m is any choice of $\psi_{m;(1,0)}$, i.e. any function in $\widetilde{\mathcal{E}}_{+,m}$ whose unique non-zero coefficient in $\mathcal{N}^0_{+.m}$ is $c(0,1) = 1$, then the other functions $\psi_{m;(r,n)}$ with $(r,n) \in \mathcal{N}^0_{+,m}$ and $4mn - r^2 = -1$, can be chosen to be the images of A_m under the Atkin-Lehner involutions W_{m_1}, $m = m_1 m_2$. More explicitly, with this choice $\psi_{m;(r,n)}$ equals $A_m|W_{m_1}$ with $m_1 = \gcd\left(\frac{r+1}{2}, m\right)$, $m_2 = \gcd\left(\frac{r-1}{2}, m\right)$, and conversely $A_m|W_{m_1}$ for any decomposition $m = m_1 m_2$ equals $\psi_{m;(|r_0|,(r_0^2-1)/4m)}$ where r_0 ($= 1^*$ in the notation of §4.4) is the unique r_0 satisfying

$$r_0 \equiv -1 \pmod{2m_1}\ , \qquad r_0 \equiv 1 \pmod{2m_2}\ , \qquad |r_0| < m\ . \tag{10.29}$$

On the other hand, for any $\varphi \in \mathcal{E}^{\mathrm{OG,III}}_{+,m}$, we have

$$R_{1,m}(\varphi) \;=\; \mathcal{R}[\varphi] \;=\; 2c_\varphi(0,1) \tag{10.30}$$

(because $c_\varphi(0,-1) = c_\varphi(0,1)$ and $c_\varphi(0,r) = 0$ for all $r \neq \pm 1$ by the defining property of $\mathcal{E}^{\mathrm{OG,III}}_{+,m}$), and more generally,

$$R_{m_1,m_2}(\varphi) \;=\; 2\,c_\varphi(r_0,(r_0^2-1)/4m) \tag{10.31}$$

for each decomposition $m = m_1 m_2$, and with r_0 as in (10.29). It follows that, for any two decompositions $m = m_1 m_2$ and $m = m_1' m_2'$, we have

$$R_{m_1,m_2}\big(A_m\,|\,W_{m_1'}\big) \;=\; \begin{cases} 2 & \text{if } m_1' = m_1 \text{ or } m_1' = m_2\ , \\ 0 & \text{otherwise}\ . \end{cases} \tag{10.32}$$

This shows that the map

$$\mathcal{E}^{\mathrm{OG,III}}_{+,m}/\mathcal{E}^0_{+,m} \xrightarrow{R} \bigoplus_{\substack{m=m_1\cdot m_2 \\ \text{up to order}}} \mathbb{C} \tag{10.33}$$

is an isomorphism, and in combination with Theorem 10.4, completes the proof of the theorem in the case of square-free m and $\star = \mathrm{III}$: any $\varphi \in \widetilde{\mathcal{E}}_{+,m}$ can be decomposed, uniquely up to Jacobi cusp forms, as the sum of $\frac{1}{2}\sum_{m=m_1m_2} R_{m_1,m_2}(\varphi)A_m|W_{m_1} \in \mathcal{E}^{\mathrm{OG,III}}_{+,m}$ and an element of $\widetilde{J}_{2,m}$.

The proofs for $\star = \mathrm{I}$ and $\star = \mathrm{II}$ are almost identical, changing the basis $\{\psi_{m;(r,n)} = A_m|W_{m_1}\}$ of $\mathcal{E}^{\mathrm{OG,III}}_{+,m}/\mathcal{E}^{0}_{+,m}$ in both cases in such a way as to satisfy the new defining condition without changing the residues, i.e., in the case $\star = \mathrm{II}$ by replacing the first basis element $\psi_{m;(1,0)}$ by $2\psi_{m;(0,0)}$, and in the case $\star = \mathrm{I}$ by adding $2\psi_{m;(0,0)} - 2^{-s+1}\sum_{r'}\psi_{m;(r',n)}$ to each basis element.

The proof of the statement for forms of arbitrary index m is very similar, since there are still 2^{s-1} polar coefficients of a form in $\mathcal{E}^{\mathrm{OG}}_{+,m}$, in one-to-one correspondence with the decompositions of m into two coprime factors. The details are left to the reader. ☐

Theorem 10.5 says that the first line in the diagram

$$\begin{tikzcd}
0 \arrow[r] & J^{\mathrm{prim}}_{2,m} \arrow[r, "\mathrm{diag}"] \arrow[d, phantom, "\cap"] & \widetilde{J}^{\mathrm{prim}}_{2,m} \oplus \mathcal{E}^{\mathrm{OG,prim},\star}_{m} \arrow[r, "-"] \arrow[d, phantom, "\cap"] & \widetilde{\mathcal{E}}^{\mathrm{prim}}_{+,m} \arrow[r] \arrow[d, equal] & 0 \\
0 \arrow[r] & J^{\mathrm{OG,prim}}_{2,m} \arrow[r, "\mathrm{diag}"] & \widetilde{J}^{\mathrm{prim}}_{2,m} \oplus \mathcal{E}^{\mathrm{OG,prim}}_{m} \arrow[r, "-"] & \widetilde{\mathcal{E}}^{\mathrm{prim}}_{+,m} \arrow[r] & 0
\end{tikzcd} \tag{10.34}$$

is exact. The exactness of the second line is a trivial consequence, and the fact that $\mathcal{E}^{\mathrm{OG,prim},\star}_{+,m}$ has codimension exactly one in $\mathcal{E}^{\mathrm{OG,prim}}_{+,m}$ implies that $J^{\mathrm{prim}}_{2,m}$ has codimension one in $J^{\mathrm{OG,prim}}_{2,m}$. Moreover, the proof of the theorem also shows that $J^{\mathrm{OG},\star}_{2,m} = J_{2,m}$. (If $\varphi \in J^{\mathrm{OG}}_{2,m}$, then the vanishing of the residues $R_{m_1m_2}(\varphi)$ for all decompositions with $(m_1, m_2) = 1$ implies that the polar coefficients $C_\varphi(-1, r)$ are all equal to one another and to $-\frac{1}{2}c_\varphi(0,0)$, so that imposing any of the conditions (I), (II), (III) forces φ to be holomorphic. Conversely, if $\varphi \in J_{2,m}$, then the conditions OG, (I), (II) are trivial, and (III) holds because $\mathcal{R}[\varphi] = 0$.) It follows that the codimension of $J_{2,m}$ in $J^{\mathrm{OG}}_{2,m}$ is also one.

10.3 The residues of mock Jacobi forms

We can apply the general theorems of the previous subsection to mock Jacobi forms. In particular, if we have any weak mock Jacobi form of weight $k \geq 3$ and index m, it will be in $\widetilde{\mathcal{E}}_{\pm,m}$, and can be corrected by a weak Jacobi form to get a holomorphic mock Jacobi form. In the case $k = 2$, there is an obstruction $R(\varphi)$ to this being true, but, by the way we defined it, this obstruction can only depend on the shadow of φ. In this subsection, we show how to compute $R(\varphi)$ explicitly in terms of the shadow. Since $R(\varphi)$ is the vector with components $\mathcal{R}\big[\varphi|u_{(m_1,m_2)}|W_{m_1/(m_1,m_2)}\big]$, it suffices to compute $R[\varphi]$ for a weak mock Jacobi form of weight 2 in terms of the shadow of φ.

Let $\varphi(\tau, z)$ be a (strong or weak) mock Jacobi form of weight 2 and index m. Then, by definition, φ has a theta expansion (4.10) where each h_ℓ is a (in general weakly holomorphic) mock modular form of weight 3/2 and has a completion $\widehat{h}_\ell = h_\ell + g^*_\ell$ for some modular form g_ℓ of weight 1/2 such that the completion $\widehat{\varphi} = \sum_\ell \widehat{h}_\ell\,\vartheta_{m,\ell} = \varphi + \sum_\ell g^*_\ell\,\vartheta_{m,\ell}$ transforms like a Jacobi form of weight 2 and index m.

As usual, we denote by $\vartheta^0_{m,\ell}(\tau)$ the Thetanullwert $\vartheta_{m,\ell}(\tau,0)$.

Theorem 10.6. *Let φ be as above. Then*

$$\mathcal{R}[\varphi] \;=\; \frac{\sqrt{\pi}}{6}\sum_{\ell \;(\mathrm{mod}\; 2m)} \bigl(\vartheta^0_{m,\,\ell}, g_\ell\bigr)\,, \tag{10.35}$$

where $(\,\cdot\,,\,\cdot\,)$ denotes the Petersson scalar product in weight 1/2.

Proof. With the normalization of the Petersson scalar product as given in (3.14), we have

$$\sum_{\ell \;(\mathrm{mod}\; 2m)} \bigl(\vartheta^0_{m,\ell}, g_\ell\bigr) \;=\; \frac{3}{\pi}\int_{\mathcal{F}} F(\tau)\, d\mu(\tau)\;, \tag{10.36}$$

where

$$F(\tau) \;=\; \tau_2^{1/2}\sum_{\ell \;(\mathrm{mod}\; 2m)} \overline{g_\ell(\tau)}\,\vartheta^0_{m,\ell}(\tau)\;, \tag{10.37}$$

and $\mathcal{F}$ denotes a fundamental domain for $\Gamma \equiv SL_2(\mathbb{Z})$. This makes sense since the function $F(\tau)$ is Γ-invariant (the individual terms in (10.37) are not, which is why we had to be a little careful in the normalization of the scalar product) and is convergent because the weight of the modular forms g_ℓ and $\vartheta^0_{m,\ell}$ is less than 1. From eq. (7.1) it follows that the $\overline{\tau}$-derivative of the completion

$$\widehat{\varphi}(\tau,0) \;=\; \varphi(\tau,0) \,+\, \sum_{\ell \;(\mathrm{mod}\; 2m)} g^*_\ell(\tau)\,\vartheta^0_{m,\ell}(\tau)\,, \tag{10.38}$$

of $\varphi(\tau,0)$ satisfies

$$\frac{\partial}{\partial\overline{\tau}}\,\widehat{\varphi}(\tau,0) \;=\; \frac{1}{4i\sqrt{\pi}}\,\frac{F(\tau)}{\tau_2^2}\,. \tag{10.39}$$

The fact that $\widehat{\varphi}(\tau,0)$ transforms like a modular form of weight 2 on Γ implies that the differential one-form $\omega = \widehat{\varphi}(\tau,0)\,d\tau$ is Γ invariant, and equation (10.39) implies

$$d\omega \;=\; d\bigl(\widehat{\varphi}(\tau,0)\,d\tau\bigr) \;=\; -\frac{\partial\,\widehat{\varphi}(\tau,0)}{\partial\overline{\tau}}\,d\tau\,d\overline{\tau} \;=\; \frac{1}{2\sqrt{\pi}}\,F(\tau)\,d\mu(\tau)\;. \tag{10.40}$$

Therefore, by Stokes's theorem, we have

$$\frac{\sqrt{\pi}}{6}\sum_{\ell \;(\mathrm{mod}\; 2m)} \bigl(\vartheta^0_{m,\ell}, g_\ell\bigr) \;=\; \int_{\mathcal{F}} d\omega \;=\; \int_{\partial\mathcal{F}} \omega \;=\; \lim_{T\to\infty}\int_{\partial\mathcal{F}(T)} \omega \tag{10.41}$$

where $\mathcal{F}(T)$ is the truncated fundamental domain

$$\{\tau \in \mathcal{H} \mid |\tau| > 1\,,\; |\tau_1| < \frac{1}{2}\,,\; \tau_2 < T\}\;. \tag{10.42}$$

On the other hand, we have

$$\int_{\partial\mathcal{F}(T)}\omega \;=\; \int_{-\frac12+iT}^{\frac12+iT}\omega \;=\; \int_{-\frac12+iT}^{\frac12+iT}\varphi(\tau,0)\,d\tau \;+\; O\Bigl(\frac{1}{\sqrt{T}}\Bigr)\,. \qquad (10.43)$$

The first equality holds because ω is Γ-invariant, and all the edges of $\mathcal{F}(T)$ except the top edge $\tau_2 = T$ come in pairs which are Γ-equivalent, but of opposite orientation. The second equality follows from (10.38), and because $\vartheta^0_{m,\ell}$ is $O(1)$ and $g^*_\ell(\tau)$ is $O(T^{-1/2})$ by (7.2) with $k = 3/2$. The theorem then follows. ☐

The theorem immediately implies a more general formula for the residue $R_{m_1,m_2}(\varphi) = \mathcal{R}\bigl[\varphi\big|W_{m_1}\bigr]$ when $m = m_1m_2$ with $(m_1, m_2) = 1$ in terms of Petersson scalar products, namely,

$$R_{m_1,m_2}(\varphi) \;=\; \frac{\sqrt{\pi}}{6}\sum_{\ell\;(\mathrm{mod}\;2m)}\bigl(\vartheta^0_{m,\,\ell},\, g_{\ell^*}\bigr)\,, \qquad (10.44)$$

where $\ell \mapsto \ell^*$ is the involution on $(\mathbb{Z}/2m\mathbb{Z})^*$ appearing in the definition of W_{m_1}.

10.4 Remaining proofs of theorems from §9

In this subsection, we apply the results proved so far to the special family studied in §9, namely, the meromorphic Jacobi forms $\varphi_{2,m}$ having a pole $1/(2\pi iz)^2$ at the origin and their associated mock Jacobi forms $\Phi_{2,m}$. Specifically, we shall prove Theorems 9.1, 9.2, 9.4, 9.5, and 9.7.

We begin with a preliminary remark. Two of the results we need to prove are Theorem 9.1 and the statement that the functions $\Phi^0_{2,m}$ defined implicitly by (9.37) are primitive modulo weak Jacobi forms. Both of these have the form that a certain elliptic form is in fact a (weak) Jacobi form, i.e., that its shadow vanishes. Since the forms in question are defined using the Hecke-like operators defined in §4.4, we first have to explain how the action of these operators extends to non-holomorphic elliptic forms, since then we can apply them to the completions of our mock Jacobi forms and verify the necessary identities between shadows. The definitions of the Hecke-like operators were given in terms of the Fourier coefficients $c(n, r)$ or $C(\Delta, \ell)$ defined by (4.3) and (4.4). In the case of the completions of mock modular forms Φ, when we apply equation (4.36) or (4.37) for the action of U_t or V_t with the φ there replaced by $\Phi^C := \widehat{\Phi} - \Phi$ (the "correction term" discussed at the end of §8.3), we must interpret $c(n, r)$ as the coefficient of $\beta(|n|\tau_2)\,q^n\,y^r$ rather than simply q^ny^r as in the holomorphic case, where $\beta(t) = \sqrt{\pi/4m}\;\mathrm{erfc}(2\sqrt{\pi t})$ in the weight 2 case, and similarly for equation (4.43) and $C(\Delta,\, r\;(\mathrm{mod}\;2m))$. In view of (9.5) and (7.2), these coefficients in the case of $\Phi_{2,m}$ are given by

$$C(\Phi^C_{2,m};\Delta,\,\ell\;(\mathrm{mod}\;2m)) \;=\; \sum_{\substack{\lambda^2=-\Delta\\ \lambda\equiv\ell\;(\mathrm{mod}\;2m)}}|\lambda|\,. \qquad (10.45)$$

Proof of Theorem 9.1: We have to show that for $m = P_1 \cdots P_r$ ($P_i = p_i^{\nu_i}$, p_i distinct primes) we have

$$\Phi_{2,m} \,|\, \prod_{i=1}^{r}(1+\varepsilon_i W_{P_i}) \;\equiv\; \Bigl(\Phi_{2,M} \,|\, \prod_{p|M}(1-W_p)\Bigr) \,|\, \mathcal{V}^{(M)}_{2,m/M}\,, \tag{10.46}$$

where M is the product of the primes p_i for which $\varepsilon_i = -1$ and "$\equiv$" means that the two sides of the equation differ by a weak Jacobi form. Because of the multiplicativity of the Hecke-like operators U_d, V_t and W_{m_1}, this formula can be rewritten as

$$\Phi_{2,m} \,|\, \prod_{i=1}^{r}(1+\varepsilon_i W_{P_i}) \;\equiv\; \Phi_{2,M} \,|\, \prod_{\varepsilon_i=-1}(1-W_{p_i})\mathcal{V}^{(p_i)}_{P_i/p_i} \,|\, \prod_{\varepsilon_i=+1} \mathcal{V}^{(1)}_{P_i}\,, \tag{10.47}$$

so by induction on r, it suffices to show that if $P = p^\nu || m$ then

$$\Phi_{2,m} \,|\, (1\,+\,W_P) \;\equiv\; \Phi_{2,m/P} \,|\, \mathcal{V}^{(1)}_{2,P}\,, \qquad \Phi_{2,m} \,|\, (1\,-\,W_P) \;\equiv\; \Phi_{2,mp/P} \,|\, (1-W_p)\,\mathcal{V}^{(p)}_{2,P/p}\,. \tag{10.48}$$

For this, it is enough to show that in each the difference of the left-hand side and the right-hand side has shadow zero.

For the first equation in (10.48), eq. (10.45) implies that the "correction term" for the left-hand side is given by

$$\begin{aligned} &C(\Phi^C_{2,m}|(1+W_P)\,;\Delta,\ell \text{ (mod } 2m)) = C(\Phi^C_{2,m}\,;\Delta,\ell \text{ (mod } 2m)) + C(\Phi^C_{2,m}\,;\Delta,\ell^* \text{ (mod } 2m)) \\ &= \begin{cases} D(\delta^{(2m)}_{D,\ell} + \delta^{(2m)}_{D,-\ell} + \delta^{(2m)}_{D,\ell^*} + \delta^{(2m)}_{D,-\ell^*}) & \text{if } \Delta = -D^2, \text{ for some } D \in \mathbb{N} \\ 0 & \text{if } -\Delta \text{ is not a perfect square} \end{cases} \end{aligned} \tag{10.49}$$

where ℓ^* (mod $2m$) is defined by $\ell^* \equiv -\ell$ (mod $2P$), $\ell^* \equiv +\ell$ (mod $2m/P$), and the notation $\delta^{(n)}_{a,b}$ means $\delta_{a,b \text{ (mod } n)}$. The correction term for the right-hand side, on the other hand, is given (since $\mathcal{V}^{(1)}_{2,P} = V_{2,P} - pV_{2,P/p^2}U_p$, where the second term is omitted if $p^2 \nmid P$) by

$$\begin{aligned} &\sum_{d|(\frac{\Delta+\ell^2}{4m},\ell,P)} d\,C\Bigl(\Phi^C_{2,\frac{m}{P}}\,;\frac{\Delta}{d^2},\frac{\ell}{d}\text{ (mod } 2\frac{m}{P})\Bigr) \quad - p \sum_{d|(\frac{\Delta+\ell^2}{4m},\ell,\frac{P}{p^2})} d\,C\Bigl(\Phi^C_{2,\frac{m}{P}}\,;\frac{\Delta}{p^2d^2},\frac{\ell}{pd}\text{ (mod } 2\frac{m}{P})\Bigr) \\ &\quad = \sum_{d|(\frac{\Delta+\ell^2}{4m},\ell,P)} \;\sum_{\substack{\lambda^2=-\Delta \\ \lambda\equiv\ell \text{ (mod } \frac{2md}{P})}} |\lambda| \quad - \sum_{d|(\frac{\Delta+\ell^2}{4m},\ell,\frac{P}{p^2})} \;\sum_{\substack{\lambda^2=-\Delta \\ \lambda\equiv\ell \text{ (mod } \frac{2md}{P})}} |\lambda|\,, \\ &\quad = \sum_{\substack{d\in\{P,P/p\} \\ d|(\frac{\Delta+\ell^2}{4m},\ell,P)}} \;\sum_{\substack{\lambda^2=-\Delta \\ \lambda\equiv\ell \text{ (mod } \frac{2md}{P})}} |\lambda|\,, \end{aligned} \tag{10.50}$$

where the last line holds because the terms in the first sum in the second line with $d|Pp^{-2}$ cancel with the terms in the second sum. The terms with $d = P$ in the third line give the first two terms $\sqrt{-D} = \pm\ell^*$ of the right hand side of (10.49), while the terms with $d = P$ in the third line give the second two terms $\sqrt{-D} = \pm\ell^*$.

The correction term for the left-hand side of the second equation in (10.48) is given by the the right-hand side of (10.49) with the signs of the last two terms changed. This is now equal to zero unless $(\ell, m) = 1$, in which case it is equal to $\sqrt{-\Delta}$ (resp. $-\sqrt{-\Delta}$) if $D \equiv \pm\ell \pmod{2m}$ (resp. $D \equiv \pm\ell^* \pmod{2m}$). The correction term for the right-hand side, on the other hand, is given by

$$\begin{aligned}\sum_{d|(\ell,\frac{P}{p},\frac{\Delta+\ell^2}{4m})} d\,\biggl(C\Bigl(\Phi^C_{2,mp/P}\,;\frac{\Delta}{d^2}\,,\frac{\ell}{d}\ \bigl(\mathrm{mod}\ \frac{2mp}{P}\bigr)\Bigr)\;-\;C\Bigl(\Phi^C_{2,mp/P}\,;\frac{\Delta}{d^2}\,,\frac{\ell^*}{d}\ \bigl(\mathrm{mod}\ \frac{2mp}{P}\bigr)\Bigr)\biggr) \\ =\ \sum_{d|(\ell,\frac{P}{p},\frac{\Delta+\ell^2}{4m})}\Biggl(\ \sum_{\substack{\lambda^2=-\Delta\\ \frac{\lambda}{d}\equiv\frac{\ell}{d}\ (\mathrm{mod}\ \frac{2mp}{P})}}\ -\ \sum_{\substack{\lambda^2=-\Delta\\ \frac{\lambda}{d}\equiv\frac{\ell^*}{d}\ (\mathrm{mod}\ \frac{2mp}{P})}}\ \Biggr)|\lambda|\,,\end{aligned}\tag{10.51}$$

where $\ell^* \pmod{2mp/P}$ is now defined by $\ell^* \equiv -\ell \pmod{2p}$, $\ell^* \equiv +\ell \pmod{2m/P}$. If $p|\ell$, then $\ell^* = \ell$ and the expression vanishes, so that only $d = 1$ contributes in the first summation. The condition $4m|(\Delta + \ell^2)$ combined with $\lambda \equiv \ell \pmod{2mp/P}$ implies $\lambda \equiv \ell \pmod{2m}$ (and similarly for ℓ^* since $\ell^2 \equiv \ell^{*2} \pmod{2mp/P}$), thus proving the second equation in (10.48). $\square$

Proof of Theorem 9.2: By Möbius inversion, the mock Jacobi forms $\Phi_{2,m}$ associated to any choice of minimal meromorphic Jacobi forms $\varphi_{2,m}$ can be represented in the form (9.37), where $\Phi^0_{2,m}$ is defined by

$$\Phi^0_{2,m} \;=\; \sum_{d^2|m} \mu(d)\ \Phi_{2,m/d^2}\,|\,U_d\,. \tag{10.52}$$

We have to show that $\Phi^0_{2,m}$ can be chosen to be primitive and to have optimal growth.

To prove the second of these statements, it is enough to show that $\Phi^0_{2,m}|u_p$ has no shadow for all primes p with $p^2|m$. Then, by Theorem 10.5, the weak elliptic form $\Phi^0_{2,m}$ can be chosen (by adding a weak Jacobi form) to have optimal growth. Writing the square divisors of m as d^2p^{2i} with $p \nmid d$ and noting that $\mu(dp^i) = 0$ for $i > 1$ and that $U_{dp} = U_dU_p$, $U_du_p = u_pU_d$, and $U_pu_p = p$, we find from (10.52) that

$$\begin{aligned}\Phi^0_{2,m}\,|\,u_p \;&=\; \sum_{d^2|m,\,p\nmid d} \mu(d)\bigl[\Phi_{2,m/d^2}\,|\,U_d \;-\; \Phi_{2,m/d^2p^2}\,|\,U_d\,|\,U_p\bigr]\;|\;u_p \\ &=\; \sum_{d^2|m,\,p\nmid d} \mu(d)\bigl[\Phi_{2,m/d^2}\,|\,u_p \;-\; p\,\Phi_{2,m/d^2p^2}\bigr]\;|\;U_d\,,\end{aligned}$$

so it suffices to show that $\Phi_{2,m}|u_p$ and $p\,\Phi_{2,m/p^2}$ have the same shadow for any m with $p^2|m$. But the shadow of $\Phi_{2,m} = \varphi^{\mathrm{F}}_{2,m}$ is determined by $\varphi^C_{2,m} = \widehat{\Phi}_{2,m} - \Phi_{2,m}$ (cf. comments at the end of §8.3), and by (10.45), we have:

$$C(\varphi^C_{2,m}\,;\Delta p^2,\,rp\ (\mathrm{mod}\ 2m))\ =\ \begin{cases} p|\lambda| & \text{if } \Delta=-\lambda^2,\quad \lambda\equiv r\ (\mathrm{mod}\ 2m/p)\,,\\ 0 & \text{otherwise}\,.\end{cases} \tag{10.53}$$

Then, from (4.43), we have:

$$\begin{aligned} C(\varphi^C_{2,m}|u_p\,;\Delta,\,\ell\ (\mathrm{mod}\ 2m/p^2)) \ &=\ \sum_{\substack{r\ (\mathrm{mod}\ 2m/p)\\ r\equiv\ell\ (\mathrm{mod}\ 2m/p^2)}} C(\varphi^C_{2,m}\,;\Delta p^2,\,rp\ (\mathrm{mod}\ 2m))\,,\\ &=\ \begin{cases} p|\lambda| & \text{if } \Delta=-\lambda^2,\quad \lambda\equiv\ell\ (\mathrm{mod}\ 2m/p^2)\,,\\ 0 & \text{otherwise}\,.\end{cases}\\ &=\ p\,C(\varphi^C_{2,m/p^2}\,;\Delta,\ell)\,. \end{aligned} \tag{10.54}$$

This completes the proof of the fact that $\Phi^0_{2,m}$ can be chosen to have optimal growth. Now, by formula (4.43), we have that $\Phi^0_{2,m}|u_t$, and hence also $\Phi^0_{2,m}|u_t|U_t$, is holomorphic for $t>1$, so by replacing $\Phi^0_{2,m}$ by $\pi^{\mathrm{prim}}(\Phi^0_{2,m})$ as defined in (4.46) we can also assume that $\Phi^0_{2,m}$ is primitive. ☐

Proof of Theorem 9.4: The proof of Theorem 10.5 given in §10.2 the following discussion already showed that $J^{\mathrm{OG}}_{2,m}/J_{2,m}$ is one-dimensional and that any representative $\mathcal{K}_m$ of this quotient space, if we normalize it to have $c(\mathcal{K}_m\,;0,0)=2$, has polar coefficients as given in the statement of Theorem 9.4. Since all the polar coefficients $C(\mathcal{K}_m\,;-1,r)$ are equal, we have that $\mathcal{K}_m|W_{m_1}-\mathcal{K}_m\in J_{2,m}$ for all $m_1||m$, so (by averaging) we can choose $\mathcal{K}_m$ to be invariant under all Atkin-Lehner operators. Finally, we can make $\mathcal{K}_m$ primitive by the argument used at the end of the proof of Theorem 9.2. ☐

Remark. For square-free m, since all holomorphic Jacobi forms are in fact cusp forms, $\mathcal{K}_m$ is unique up to Jacobi cusp forms, and its coefficients with $\Delta=0$ are unique. In this case the only such coefficient, up to translation, is $c(0,0)$. If m is not square-free, there is more than one coefficient $c(n,r)$ such that $\Delta=0$. Notice that $r^2\equiv 0\ (\mathrm{mod}\ 4m)\Leftrightarrow(r,2m)=2m/t$ with $t^2|m$. For each t with $t^2|m$, we have

$$\sum_{j\ (\mathrm{mod}\ t)} C(\mathcal{K}_m\,;0,\frac{2mj}{t}\ (\mathrm{mod}\ 2m))\ =\ \begin{cases} -2 & \text{if } t=1\,,\\ 0 & \text{if } t>1\,.\end{cases} \tag{10.55}$$

(For $t=1$, the sum on the left reduces to the single term $c(\mathcal{K}_m\,;0,0)=-2$, and for $t>1$, it equals $C(\mathcal{K}_m|u_t;0,0)$, which vanishes because $\mathcal{K}_m|u_t\in J_{2,m/t^2}$.) We can choose the $\Delta=0$ coefficients arbitrarily subject to this one constraint, and once we have made a choice, then $\mathcal{K}_m$ is unique up to cusp forms even in the non-square-free case. For instance, at the expense of introducing denominators, we could fix $\mathcal{K}_m$ uniquely up to cusp forms by requiring that $C(\mathcal{K}_m;0,r)$

depends only on the gcd of r and $2m$. (This would correspond to choosing $a = \frac{1}{2}$ in the first and third tables at the end of §9.3.) Another choice, more similar to our "$\star = \mathrm{II}$" condition, would be to choose $C(\mathcal{K}_m; 0, r) = 0$ for all r with $4m|r^2$ and $r \nmid 2m$, in which case the remaining coefficients $C(\mathcal{K}_m; 0, 2m/t)$ $(t^2|m)$ are uniquely determined by (10.55). (This would correspond to choosing $a = 1$ in the first of the tables at the end of §9.3.) The reader can easily work out the complete formula for all of the coefficients $C(\mathcal{K}_m; 0, r)$ for either of these two special choices.

Our next task is to prove Theorem 9.5. For this we need to calculate the residues of $\Phi_{2,m}$, using the results of the previous subsection. We therefore have to apply the formula (10.44) to the mock modular form $\Phi_{2,m} = \varphi^{\mathrm{F}}_{2,m}$. (Note that the residue of this form will be independent of the specific choice of $\varphi_{2,m}$, since any two choices differ by a Jacobi form and the residues of Jacobi forms vanish.) Since the completion of $\Phi_{2,m}$ involves the weight $1/2$ unary theta series $\vartheta^0_{m,\ell}$, the first step is to compute the scalar products of these theta series.

Proposition 10.2. *For $m \in \mathbb{N}$, and $\ell_1, \ell_2 \in \mathbb{Z}/2m\mathbb{Z}$, we have*

$$(\vartheta^0_{m,\ell_1}\,,\,\vartheta^0_{m,\ell_2}) \;=\; \frac{1}{2\sqrt{m}}\big(\delta_{\ell_1,\ell_2\,(\mathrm{mod}\ 2m)} + \delta_{\ell_1,-\ell_2\,(\mathrm{mod}\ 2m)}\big) \tag{10.56}$$

Proof. Formula (3.15) gives

$$(\vartheta^0_{m,\ell_1}\,,\,\vartheta^0_{m,\ell_2}) \;=\; \frac{1}{2}\,\mathrm{Res}_{s=\frac{1}{2}}\left(\sum_{r>0}\frac{(\delta_{r,\ell_1\,(2m)} + \delta_{r,-\ell_1\,(2m)})(\delta_{r,\ell_2\,(2m)} + \delta_{r,-\ell_2\,(2m)})}{(r^2/4m)^s}\right).$$

The propostition follows. ☐

Proposition 10.3. *Let $\varphi_{2,m}$ be any meromorphic Jacobi form of weight 2 and index m with pole $1/(2\pi iz)^2$ and its translates, and let $\Phi_{2,m}$ be its finite part $\varphi^{\mathrm{F}}_{2,m}$. Then*

$$R_{m_1,m_2}(\Phi_{2,m}) \;=\; \frac{m_1+m_2}{12}\,. \tag{10.57}$$

Proof. By equation (9.5), the ℓ^{th} component g_ℓ of the shadow for $\Phi_{2,m}$ is $-\sqrt{\frac{m}{4\pi}}\vartheta^0_{m,\ell}$. When $(m_1,m_2) = 1$, $R_{m_1,m_2}(\Phi_{2,m}) = \mathcal{R}[\Phi_{2,m}\,|\,W_{m_1}]$. Theorem 10.6 then gives:

$$\begin{aligned}\mathcal{R}[\Phi_{2,m}\,|\,W_{m_1}] \;&=\; \frac{\sqrt{m}}{\sqrt{4\pi}}\frac{\sqrt{\pi}}{6}\sum_{\ell\,(\mathrm{mod}\ 2m)}\big(\vartheta^0_{m,\ell},\vartheta^0_{m,\ell^*}\big)\\ &=\; \frac{1}{24}\sum_{\ell\,(\mathrm{mod}\ 2m)}\big(\delta_{\ell,\ell^*\,(\mathrm{mod}\ 2m)} + \delta_{\ell,-\ell^*\,(\mathrm{mod}\ 2m)}\big)\\ &=\; \frac{1}{12}\,(m_1+m_2)\,.\end{aligned}$$

In this calculation, we used Proposition 10.2 to get the second line. For the third line, recall that ℓ^* is defined by $(\ell^* \equiv -\ell \pmod{2m_1}, \ell^* \equiv \ell \pmod{2m_2})$, so that $\ell^* \equiv \ell \pmod{2m} \Leftrightarrow m_1\,|\,\ell$ (which is true for $2m_2$ values of ℓ in $\mathbb{Z}/2m\mathbb{Z}$), and similarly, $\ell^* \equiv -\ell \pmod{2m} \Leftrightarrow m_2\,|\,\ell$ (which is true for $2m_1$ values of ℓ). When $(m_1, m_2) = t > 1$, we have $R_{m_1,m_2}(\Phi_{2,m}) = R_{m_1/t,m_2/t}(\Phi_{2,m}\,|\,u_t)$. As we have shown in the proof of Theorem 9.2, the shadow of $\Phi_{2,m}\,|\,u_t$ is the same as the shadow of $t\Phi_{2,m/t^2}$, so $R_{m_1/t,m_2/t}(\Phi_{2,m}\,|\,u_t) = tR_{m_1/t,m_2/t}(\Phi_{2,m/t^2}) = t(\frac{m_1}{t} + \frac{m_2}{t})/12 = (m_1+m_2)/12$ by the special case already proved. ☐

The reader might find it helpful to compare the statement of this proposition with the table in §9.2 presenting the data for the case $m = 6$, in which the function $\Phi = \Phi_{2,6}$ (in any of its three versions I, II, or III) has

$$\begin{aligned} R_{1,6}(\Phi) \;&=\; 2C(\Phi; -1, \pm 1 \,(\mathrm{mod}\ 12)) + C(\Phi; 0, 0\,(\mathrm{mod}\ 12)) \;=\; 7/12\,, \\ R_{2,3}(\Phi) \;&=\; 2C(\Phi; -1, \pm 5 \,(\mathrm{mod}\ 12)) + C(\Phi; 0, 0\,(\mathrm{mod}\ 12)) \;=\; 5/12\,. \end{aligned}$$

Proof of Theorem 9.5: We can now complete the proof of Theorem 9.5 and its corollary. For m square-free, any choice of $\Phi = \Phi^0_{2,m}$ in $\mathcal{E}^{\mathrm{OG}}_m$, and any r with $r^2 \equiv 1 \pmod{4m}$, we have

$$2C(\Phi;\,-1,\ell) + C(\Phi;\,0,0) \;=\; \mathcal{R}[\Phi\,|\,W_{m_1}] \;=\; \frac{m_1+m_2}{12} \tag{10.58}$$

by Proposition 10.3, where $m = m_1 m_2$ is the decomposition of m for which $r^* = 1$. Since $C(\Phi^{\mathrm{III}}; 0, 0) = 0$, this proves Theorem 9.5 and also gives the corresponding formulas

$$C(\Phi^{\mathrm{I}}; -1, r) \;=\; -\frac{(m_1-1)(m_2-1)}{12}\,, \qquad C(\Phi^{\mathrm{II}}; -1, r) \;=\; -\frac{1}{12}\left(\frac{m_1+m_2}{2} - \prod_{p|m}\frac{p+1}{2}\right)$$

for Φ^{I} and Φ^{II}, as well as formula (9.43) for the polar coefficients of $\mathcal{Q}_M$ when $\mu(M) = 1$. If m is not square-free, then the solutions $r \pmod{2m}$ of $r^2 \equiv 1 \pmod{4m}$ are still in 1:1 correspondence with the decompositions of m into coprime factors m_1 and m_2. To compute the corresponding Fourier coefficient of $\Phi^0_{2,m}$, we look at each term in (10.52) separately, writing each d as $d_1 d_2$ with $d_i^2 | m_i$ and noting that $\frac{m_1}{d_1^2} = (\frac{r-1}{2}, \frac{m}{d^2})$, $\frac{m_2}{d_2^2} = (\frac{r+1}{2}, \frac{m}{d^2})$, after which (9.41) follows from (10.57) and the fact that $\mathcal{R}[\varphi\,|\,U_d] \;=\; \mathcal{R}[\varphi]$. ☐

Proof of Theorem 9.7: It is enough to show that any weak Jacobi form of optimal growth is actually holomorphic since, as we have seen in Theorem 10.3, there are no holomorphic Jacobi forms of weight 1. To show this, we use the "residue operator on weight 1 forms" defined by

$$\mathcal{R}^{(1)}[\varphi] \;=\; \mathrm{Res}_{\tau=\infty}\big(\varphi'(\tau,0)\,d\tau\big) \;=\; \sum_{r\in\mathbb{Z}} r\,c_\varphi(0,r) \tag{10.59}$$

instead of (10.17), where, as usual, $\varphi'(t,z) = \frac{1}{2\pi i}\frac{d}{dz}\,\varphi(t,z)$. This residue vanishes if $\varphi \in \widetilde{J}_{1,m}$, since then $\varphi'(\cdot,0) \in M^!_2$. If, further, φ has optimal growth, then $2c_\varphi(0,1) = \mathcal{R}^{(1)}[\varphi] = 0$, so $C_\varphi(-1,1)$ vanishes. By the same argument with φ replaced by φ acted upon by each of the Atkin-Lehner operators, one has that $C_\varphi(-1,r) = 0$ for all r with $r^2 \equiv -1 \pmod{4m}$, and thus $\varphi \in J_{1,m}$. $\square$

11. Quantum black holes and mock modular forms

We now have all the ingredients required to address the questions posed in the introduction. These answers follow from applying our results of §8, in particular theorem 8.3, to the quarter-BPS partition function of the the $\mathcal{N} = 4$ theory. It turns out that in this case, many of the mathematical objects in the theorem simplify. A reader who has not gone through the details of §8 could still fruitfully read this section to obtain the relevant results for this example.

In particular, we show in §11.1 that the immortal black hole degeneracies extracted from the asymptotic partition function (6.14) are Fourier coefficients of a (mixed) mock Jacobi form. The completion transforms as a true Jacobi form and obeys a first order partial differential equation (11.23) which can be understood as a holomorphic anomaly equation. In §11.2 we discuss the physical origin of the meromorphy of the asymptotic counting function in this example and how it is related to the noncompactness of the microscopic brane dynamics. In §11.3 we analyze the contour corresponding to the M-theory limit to embed our analysis in the context of AdS_3/CFT_2 holography near the horizon of a black string. We conclude in §11.4 with comments and open problems.

11.1 Mock Jacobi forms, immortal black holes, and AdS_2 holography

We first discuss the consequences of the S-duality symmetry and its relation to the spectral flow symmetry for the moduli-independent immortal degeneracies $d^*(n,\ell,m)$ defined by (6.14). Recall that under the S-duality transformations

$$\begin{pmatrix} 1 & b \\ 0 & 1 \end{pmatrix} \tag{11.1}$$

with integer b, the S-modulus (2.21) transforms as:

$$S \to S + b\,. \tag{11.2}$$

which means that the axion transforms as $a \to a + b$. Since the axion arises from a dimensional reduction of the 3-form field in the M-theory frame (discussed in §11.3), this subgroup (11.1) of S-duality has its origins in large gauge transformations of the 3-form field. When the axion transforms as above, the effective theta angle changes and as a result the charge vector of the dyon transforms as $(Q,P) \to (Q + Pb, P)$ due to the Witten effect [122]. Consequently, the charge-invariants transform as

$$n \to n + mb^2 + b\ell\,, \qquad \ell \to \ell + 2mb\,, \qquad m \to m. \tag{11.3}$$

which are nothing but the spectral flow transformations. Note that m is left fixed by this subgroup of S-duality whereas other elements of the S-duality group would change m. Thus, only this subgroup is expected to act on the sector with a fixed m. The covariance of the spectrum under these S-duality transformations implies

$$d(n,\ell,m)|_{S,\mu} \;=\; d(n+mb^2+b,\ell+2mb,m)|_{S+b,\mu}\,. \tag{11.4}$$

Since the degeneracies of immortal black holes are independent of the moduli by definition, they are actually invariant under S-duality:

$$d^*(n+mb^2+b,\ell+2mb,m) \;=\; d^*(n,\ell,m)\,. \tag{11.5}$$

From the mathematical point of view, this is precisely the action of the elliptic part of the Jacobi transformations (4.2) on the Fourier coefficients of a Jacobi (or mock Jacobi) form.

The immortal degeneracies $d^*(n,\ell,m)$ are computed using the attractor contour (6.13), for which the imaginary parts of the potentials are proportional to the charges and scale as

$$\mathrm{Im}(\sigma) \;=\; 2n/\varepsilon\,, \qquad \mathrm{Im}(\tau) \;=\; 2m/\varepsilon\,, \qquad \mathrm{Im}(z) \;=\; -\ell/\varepsilon\,, \tag{11.6}$$

with ε very small and positive. In other words,

$$|p| = \lambda^{2n}\,, \quad |q| = \lambda^{2m}\,, \quad |y| = \lambda^{-\ell}\,, \qquad \text{with } \lambda = \exp(-2\pi/\epsilon) \to 0 \tag{11.7}$$

on the attractor contour. We assume that $n > m$ without loss of generality, otherwise one can simply exchange σ and τ. Moreover, using the spectral flow symmetry (11.5) we can always bring ℓ to the window $0 \le \ell < 2m$ for the immortal degeneracies.

To extract the Fourier coefficient from the product representation (5.13) of the counting function (5.14) using (11.7), we need to expand a typical term in the product of the form

$$\frac{1}{(1-p^r q^s y^t)^{2C_0(4rs-t^2)}}\,. \tag{11.8}$$

where $2C_0$ is the Fourier coefficient of the elliptic genus of a single copy of $K3$. Depending on whether $|p^r q^s y^t|$ is less than one or greater than one, we expand the denominator using

$$\frac{1}{1-x} \;=\; \begin{cases} 1+x+x^2+\ldots & \text{for } |x|<1\,, \\ -(x^{-1}+x^{-2}+x^{-3}+\ldots) & \text{for } |x|>1\,. \end{cases} \tag{11.9}$$

We see that it is not *a priori* obvious that expanding first in p is the same as using the attractor contour because if the powers of t are sufficiently large and positive, the attractor contour may correspond to expanding some terms effectively in p^{-1} instead of in p.

To address this question we now show that for the terms that appear in the product representation, $|p^r q^s y^t|$ is always less than one using the fact that

$$C_0(\Delta) = 0 \qquad \text{for } \Delta < -1\,. \tag{11.10}$$

To begin with, the p-dependent terms with $\Delta = 0, -1$ arise only for $s = 0$ and are of the form

$$\frac{1}{(1-py)^2(1-py^{-1})^2(1-p^r)^{20}} \tag{11.11}$$

These involve only single powers y or y^{-1} and positive powers of p. The absolute value of py or py^{-1} for the attractor contour goes as $\lambda^{2m\pm l}$ which is always much less than one for $0 \leq |l| < 2m$. The remaining p-dependent terms with $s > 0$ have $\Delta = 4rs - t^2 > 0$ and $r > 0$. The absolute value of $p^r q^s y^t$ goes as

$$\lambda^{2nr+2ms-\ell t}\,. \tag{11.12}$$

The exponent is most negative when ℓ takes its maximum positive value $\ell_{max} = \sqrt{2mn}$ and t takes its maximum positive value $t_{max} = \sqrt{2rs}$. For black hole configurations with a smooth horizon, $4mn - \ell^2 > 0$ because the classical area of the horizon is the square-root of this quantity. Hence the most negative value of the exponent would be

$$2nr + 2ms - 2\sqrt{mnrs} \;=\; 2(\sqrt{nr} - \sqrt{ms})^2 > 0\,, \tag{11.13}$$

and the absolute value of $p^r q^s y^t$ is always less than or equal to

$$\lambda^{2(\sqrt{nr}-\sqrt{ms})^2} \tag{11.14}$$

which is always much less than one. This implies that to extract the attractor Fourier coefficients, we expand all terms in the product in the small p expansion using (11.9) thus giving us the Jacobi form ψ_m of (1.1) as a partition function in the remaining two chemical potentials.

The degeneracies extracted from $\psi_m(\tau, z)$ still experience many wall-crossings, and we should now use the rest of the attractor contour to analyze the immortal part of the degeneracies of ψ_m. We do this in two steps by first performing the inverse Fourier transform in z, and then in τ. For the first step, we need to specify a contour for the imaginary part of z relative to that of τ. The conditions (11.6) on the imaginary parts of (τ, z) implies that $\mathrm{Im}(z) = -\frac{\ell}{2m}\mathrm{Im}(\tau)$. Since by moving the contour in a purely horizontal direction we do not cross any poles, we can add an arbitrary real part to z, which we can choose so that $z = -\ell\tau/2m$. This gives the result of the first integral to be:

$$f^*_{m,\ell}(\tau) \;=\; e^{-\pi i l^2\tau/2m} \int_P^{P+1} \psi_m(\tau, z)\, e^{-2\pi i \ell z}\, dz\,, \qquad P = -\ell\tau/2m\,. \tag{11.15}$$

We then have to perform a τ integral with the contour specified by the attractor values (11.6), but since the integrand $f^*_{m,\ell}(\tau)$ is holomorphic in τ, the answer is independent of the contour. We thus get the degeneracies $d^*(n,\ell,m)$ to be:

$$d^*(n,\ell,m) \;=\; \int e^{\pi i\ell^2\tau/2m}\, f^*_{m,\ell}(\tau)\, d\tau\,, \tag{11.16}$$

where the integral is over an interval of length 1 for the fixed imaginary value (11.6) of τ.

To extend to other values of ℓ, we use the spectral flow invariance (11.5) and sum over all values of ℓ to get a canonical partition function in the two variables (τ, z). Because of the factor $e^{\pi i\ell^2\tau/2m}$ in (11.16), the sum over spectral-flow images yields the function $\vartheta_{m,l}(\tau, z)$. Putting all this together, and comparing the above equations (11.15), (11.16) with our definition (8.3) of the finite part of a meromorphic Jacobi form, we see that the single centered black hole degeneracies are Fourier coefficients of precisely the *finite* part of ψ_m as defined in §8:

$$\sum_{\ell \bmod (2m)} f^*_{m,\ell}(\tau)\, \vartheta_{m,\ell}(\tau,z) \;=\; \psi^{\mathrm{F}}_m(\tau,z)\,. \tag{11.17}$$

We see that the seemingly unconventional charge-dependent choice for the contour in §8 for defining the finite part is completely natural from the point of view of the attractor mechanism (indeed, it was motivated there by these physical considerations). According to our analysis in §8, this finite part ψ^{F}_m is a *mock* Jacobi form. This is one of the main conclusions of our analysis, so we summarize the entire discussion by the following concise statement:

> *The degeneracies of single centered (immortal) black holes with magnetic charge invariant $M^2/2 = m$ are Fourier coefficients of a mock Jacobi form of index m.*

We stress here that the converse is not true. The single centered black hole solution exists only when the discriminant $4mn - \ell^2$ is positive, and its degeneracy grows exponentially for large values of the discriminant. On the other hand, as we saw in §4, any Jacobi form with exponential growth necessarily has negative discriminant states. This means that the partition function for single centered black holes alone with fixed magnetic charge and varying electric charge cannot have good modular properties. Indeed the partition function ψ^{F}_m does contain negative discriminant states for example for $n < m$. These low-lying states do not correspond to single centered black holes [31, 108].

We now turn to the physical interpretation of the polar part $\psi^{\mathrm{P}}_m(\tau, z)$ of the meromorphic Jacobi form defined in (8.44). As mentioned in the introduction, the only multi-centered gravitational configurations that contribute to the supersymmetric index of quarter-BPS dyons in our $\mathcal{N} = 4$ string theory have exactly two centers [38] each of which is a half-BPS state. At a wall, one of these two-centered configurations decays. A basic decay at a wall-crossing is when one center is purely electric and the other is purely magnetic. Other decays are related to this basic decay by duality [105]. For this two-centered configuration, with one electric and one magnetic center, the indexed partition function after summing over the electric charges is:

$$p_{24}(m+1) \cdot \frac{1}{\eta^{24}(\tau)} \cdot \sum_{\ell>0} \ell\, y^{\ell}\,, \tag{11.18}$$

where the first factor is the degeneracy of the half-BPS magnetic center, the second factor is the partition function of the electric center [39], and the third factor is the partition function counting the dimensions of the $SU(2)$ multiplets with angular momentum $(\ell-1)/2$ contained in the electromagnetic field generated by the two centers [46] for which $N \cdot M = \ell$. The third factor is an expansion of the function

$$\frac{y}{(1-y)^2} \tag{11.19}$$

in the range $|q| < |y| < 1$ (see equation (9.7)). Here we already see the basic wall-crossing of the theory because different ways of expanding this meromorphic function for $|y| < 1$ and $|y| > 1$ will give different degeneracies. Other wall-crossings are related to this basic wall-crossing by S-duality which as we have explained is nothing but spectral flow for a given fixed m. Thus the full partition function that captures all wall-crossings is obtained by 'averaging' over the spectral-flow images of (11.19). This averaging is nothing but the averaging operation defined in (9.3) and (9.4)

$$\mathrm{Av}^{(m)}\Big[\frac{y}{(y-1)^2}\Big] \;=\; \frac{q^{ms^2+s}y^{2ms+1}}{(1-q^s y)^2} \tag{11.20}$$

It is now easy to see that this averaging over spectral-flow images gives exactly the polar part ψ_m^{P} of the meromorphic Jacobi form ψ_m:

$$\frac{p_{24}(m+1)}{\eta^{24}(\tau)} \sum_{s\in\mathbb{Z}} \frac{q^{ms^2+s}y^{2ms+1}}{(1-q^s y)^2} \;=\; \psi_m^{\mathrm{P}}(\tau,z)\,. \tag{11.21}$$

This follows from the fact that the poles of $\psi_m(\tau,z)$ are exactly at $z \in \mathbb{Z}\tau + \mathbb{Z}$ and the residue at $z = 0$ is

$$\frac{p_{24}(m+1)}{\eta^{24}(\tau)}\,.$$

as mentioned in (1.5).

We thus see that the decomposition theorem (8.3) as applied to our dyon partition function $\psi_m(\tau,z)$ has a natural physical interpretation. It is simply the statement that the full partition function is a sum of its immortal and decaying constituents:

$$\psi_m(\tau,z) \;=\; \psi_m^{\mathrm{F}}(\tau,z) \,+\, \psi_m^{\mathrm{P}}(\tau,z)\,. \tag{11.22}$$

The nontrivial part is of course the implication of such a decomposition for modularity. By separating part of the function ψ_m, we have evidently broken modularity, and $\psi_m^{\mathrm{F}}(\tau,z)$ is not a

Jacobi form any more. However, the decomposition theorem (8.3) guarantees that ψ^{F}_m still has a very special modular behavior in that it is a mock Jacobi form. The mock behavior can be summarized by the following partial differential equation obeyed by its completion:

$$\tau_2^{3/2}\,\frac{\partial}{\partial\overline{\tau}}\,\widehat{\psi}^{\mathrm{F}}_m(\tau,z)\;=\;\sqrt{\frac{m}{8\pi i}}\;\frac{p_{24}(m+1)}{\Delta(\tau)}\sum_{\ell\,\mathrm{mod}\,(2m)}\overline{\vartheta_{m,\ell}(\tau,0)}\,\vartheta_{m,\ell}(\tau,z)\,. \tag{11.23}$$

Note that ψ^{P}_m also admits a completion $\widehat{\psi^{\mathrm{P}}_m}$ which is modular. However, the function $\widehat{\psi^{\mathrm{P}}_m}$, unlike $\widehat{\psi^{\mathrm{F}}_m}$, is meromorphic, and therefore has wall-crossings. We refer the reader to the summary at the end of §8.3 for a detailed discussion of the relationship between meromorphy (in z), holomorphy (in τ) and modularity.

Let us now discuss the implications of these results for AdS_2/CFT_1 holography. The near horizon geometry of a supersymmetric black hole is a two-dimensional anti de Sitter space AdS_2 and the dual theory is a one-dimensional conformal field theory CFT_1. The partition function of this CFT_1 is nothing but the integer $d^*(n,\ell,m)$ which gives the number of microstates of the black hole [106, 107]. Our results show that that these integers are the Fourier coefficients of a mock modular form and as a result there is a hidden modular symmetry. Such a modular symmetry would make it possible to use powerful techniques such as the Hardy-Ramanujan-Rademacher expansion to process the integers $d^*(n,\ell,m)$ into a form that can be more readily identified with a bulk partition function of string theory in AdS_2. There has been recent progress in evaluating the bulk partition function using localization techniques which makes it possible to study the subleading nonperturbative corrections in the Rademacher expansion in a systematic way [34, 35, 70, 96]. It would be interesting to see if the additional terms in the Rademacher expansion arising from the 'mock' modular nature can be given a physical bulk interpretation.

11.2 Meromorphy, mock modularity, and noncompactness

From the mathematical point of view, we have seen how the mock modularity of ψ^F_m is a consequence of meromorphy of the Jacobi form ψ_m. In the $\mathcal{N}=4$ example above, we can understand the physical origin of this meromorphy as coming from the non-compactness of the underlying brane dynamics. To see this more clearly, we write the meromorphic Jacobi form $\psi_m(\tau,z)$ as

$$\psi_m(\tau,z)=\frac{1}{\varphi_{-2,1}(\tau,z)}\,\frac{1}{\Delta(\tau)}\;\chi(\tau,z;\mathrm{Sym}^{m+1}(K3))\,. \tag{11.24}$$

The three factors in the above equations have the following physical interpretation [42]. The function $\psi_m(\tau,z)$ can be viewed as an indexed partition function of the following $(0,4)$ SCFT

$$\sigma(\mathrm{TN})\times\sigma_L(\widetilde{K}\text{-}n)\times\sigma(\mathrm{Sym}^{m+1}(K3))\,. \tag{11.25}$$

Each CFT factor has a natural interpretation from the microscopic derivation of the dyon counting formula [42] using the 4d-5d lift [60]. The $\sigma_L(\widetilde{K}\text{-}n)$ factor is the purely left-moving bosonic CFT associated with $\widetilde{K}$-n bound states of the Kaluza-Klein monopole with momentum. The $\sigma(\mathrm{TN})$ factor is a $(4,4)$ SCFT associated with the motion of the center of mass of motion in the Kaluza-Klein background in going from five dimensions to four dimensions in the 4d-5d lift. The $\sigma(\mathrm{Sym}^{m+1}(K3))$ is the $(4,4)$ SCFT that is associated with the five-dimensional Strominger-Vafa $Q1$-$Q5$-n system. Note that the SCFT $\sigma(\mathrm{TN})$ has a *noncompact* target space and the double pole of $1/\varphi_{-2,1}(\tau, z)$ can be traced back to this noncompactness.

Going over from the partition function to the Fourier coefficients corresponds to going over from the canonical ensemble with fixed z to the micro-canonical ensemble with fixed ℓ. The Fourier coefficient is supposed to count the number of right-moving ground-states in this fixed charge sector. Right-moving states with nonzero energy cancel in pairs in this index. Now, counting ground states for a compact theory is a well-defined operation. However, when the target-space is noncompact, the wavefunctions are not properly normalized without putting an infrared regulator in the target space. In the present context, the essential physics of the noncompactness is captured by the point particle motion of the center of mass in the Taub-NUT geometry. A simple regulator can be introduced by turning on the axion field which according to (2.22) corresponds in the Type-IIB frame to taking the modulus $U_B = U_{1B} + iU_{2B}$ to have a small nonzero real part U_{1B} [42]. This introduces a nonzero potential on the Taub-NUT geometry proportional to $U_{1B}^2 U_{2B}$ that regulates the infrared behavior to give a well defined counting problem [62, 100]. However, the index thus computed depends on the sign of U_{1B} and jumps as U_{1B} goes from being slightly negative to slightly positive. Indeed the partition function for these modes is precisely the function

$$\frac{y}{(1-y)^2} \tag{11.26}$$

which can be expanded either in power of y or in powers of y^{-1} depending on whether U_{1B} is positive or negative. For ℓ positive, there are ℓ normalizable states when $U_{1B} < 0$ and none when $U_{1B} > 0$. This is the essential source of the wall-crossing behavior in this context. We should emphasize that even though turning on U_{1B} appears to make the problem effectively compact, this is true only up to some maximal ℓ_{max} which scales as $U_{1B}^2 U_{2B}$ [62, 100]. For a given ℓ positive, one can always make the problem well-defined with a compact target space by choosing the moduli so that ℓ_{max} is larger than the ℓ of interest. The partition function in that case is well-defined without any poles and goes as

$$y + 2y^2 + \ldots + \ldots + \ell_{max} y^{\ell_{max}}\,. \tag{11.27}$$

However, if one wishes to compute the canonical partition function that sums over all ℓ, one has to essentially take $U_{1B}^2 U_{2B}$ to go to infinity which is what leads to the pole at $y = 1$ in

(11.26). This in essence is the origin of the meromorphy of the canonical counting function of the asymptotic states, and therefore indirectly also of the mock modularity of the immortal near-horizon counting function.

As we have seen, this meromorphy of the asymptotic counting function ψ_m implies that the counting function of the near-horizon immortal states cannot be both modular and holomorphic at the same time. One can either have the holomorphic function ψ_m^{F} which is not quite modular, or a modular function $\widehat{\psi}_m^{\mathrm{F}}$ which is not quite holomorphic. From this point of view, the shadow can be regarded as a 'modular anomaly' in ψ_m^{F} or as a 'holomorphic anomaly' in the completion $\widehat{\psi}_m^{\mathrm{F}}$.

A natural question that arises from this discussion is if the mock Jacobi form and the holomorphic anomaly can be given a direct physical interpretation rather than arrive at it via a meromorphic Jacobi form as we have done. To address this question, it is useful to view the problem from the perspective of AdS_3 holography in M-theory as we now discuss.

11.3 The M-Theory limit and AdS_3 holography

From the perspective of AdS_2/CFT_1 holography discussed above, there is no *a priori* reason why the black hole degeneracy should have anything to do with modularity. It is only when we can view the black hole as an excitation of a black string that we can have an *a priori* physical expectation of modularity. This is because the near horizon geometry of a black string is a three-dimensional anti de Sitter space AdS_3. The Euclidean thermal AdS_3 has a conformal torus as a boundary whose complex structure parameter is τ. The partition function of the dual boundary conformal field theory CFT_2 depends on on τ. In this framework the modular symmetry is identified with the $SL(2,\mathbb{Z})$ mapping class group of the boundary torus [86], whereas the elliptic symmetry is identified with large gauge transformations of the 3-form field [44] as we have already discussed in §11.1.

We now describe how the quarter-BPS black holes considered thus far can be regarded as excitations of a black string in an appropriate M-theory frame. This will enable us to make contact with AdS_3/CFT_2 holography. The M-theory framework is natural also from the point of view of generalizing these considerations to BPS black holes in $\mathcal{N}=2$ compactifications on a general Calabi-Yau manifold X_6.

To go to the M-theory frame, we consider the T^2 to be a product of two circles $S^1 \times \tilde{S}^1$ and consider the charge configuration (2.15) in the Type-IIB frame. We first T-dualize the $\tilde{S}$ circle to the $\hat{S}^1$ circle to go to the Type-IIA frame and then use mirror symmetry of $K3$ to map the Type-IIB configuration (2.15) to a Type-IIA configuration of D4-F1-n-NS5 charges. We then lift it to M-theory to obtain a charge configuration consisting of M5-M2 bound states carrying momentum along S^1. This configuration now has M5-branes wrapping $D \times S^1$ where D is a divisor in $K3 \times \hat{T}^2$, an M2-brane wrapping the $\hat{T}^2 = \hat{S}^1 \times S^1_m$, with some momentum along S^1. This is a precisely a configuration of the kind considered by Maldacena, Strominger, and Witten [87]. Since all M5-branes wrap S^1 and the momentum is along S^1, it is natural flip S^1_m and S^1 and regard the S^1 as the new M-circle. In the limit when the radius R of the new M-circle S^1 is very large, the low-lying excitations of this M5-brane are described by the MSW string wrapping the M-circle. To write the final configuration in the M-theory frame, let C^1 to be the homology 2-cycle of the $\hat{T}^2$, and let C^2 and C^3 be two 2-cycles in $K3$ with intersection matrix

$$\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} . \tag{11.28}$$

The intersection number of these three 2-cycles is

$$\int_{K3\times\hat{T}^2} C^1 \wedge C^2 \wedge C^3 = 1\,. \tag{11.29}$$

Let $\{D_a\}$ be the 4-cycles dual to $\{C^a\}$, $D_a \cap C^b = \delta^b_a$. In this basis, the M5-brane is wrapping the 4-cycle

$$D = \sum_{a=1}^{3} p^a D_a$$

with $p^1 = \tilde{K}$, $p^2 = Q_1$ and $p^3 = Q_5$. The M2-brane charges are $q_2 = q_3 = 0$ and $q_1 = \tilde{n}$, and M-momentum or equivalently the D0-brane charge from the Type-IIA perspective is $q_0 = n$. Using this notation we see that

- The electric charges in (2.15) map to n units of momentum along the M-circle S^1, and $\tilde{K}$ M5-branes wrapping $D_1 \times S^1$.
- The magnetic charges in (2.15) map to Q_1 M5-branes wrapping $D_2 \times S^1$, Q_5 M5-branes wrapping $D_3 \times S^1$, and $\tilde{n}$ M2-branes wrapping $\hat{T}^2$.

In summary, the charge configuration of our interest is

$$\Gamma = \begin{bmatrix} N \\ M \end{bmatrix} = \begin{bmatrix} 0, & n; & 0, & \tilde{K} \\ Q_1, & \tilde{n}; & Q_5, & 0 \end{bmatrix}_B = \begin{bmatrix} 0, & q_0; & 0, & p^1 \\ p^2, & q_1; & p^3, & 0 \end{bmatrix}_M \tag{11.30}$$

Reduction of this charge configurations along S^1 gives a configuration in Type-IIA frame consisting of only D4-D2-D0-branes.

Since the effective MSW string wraps the M-circle, we have to take the radius R of this circle to be large keeping other scales fixed to obtain an AdS_3 near-horizon geometry of a long black string. This implies that in the original heterotic frame in which we have labeled the charges (2.3), the radius R goes to infinity keeping other scales and moduli fixed. Since the 2-torus in the heterotic frame is also a simple product of two circles $S^1 \times \tilde{S}^1$, the moduli in (2.20) take the form

$$G_{ij} = \begin{pmatrix} \tilde{R}^2 & 0 \\ 0 & R^2 \end{pmatrix} , \quad B_{ij} = 0 \tag{11.31}$$

which implies that for the three moduli S, T, U we have

$$S \; = \; a + i\frac{R\tilde{R}}{g_6^2}\,, \qquad T \; = \; iR\tilde{R}\,, \qquad U = i\,\frac{R}{\tilde{R}}\,, \tag{11.32}$$

where g_6 is the six-dimensional string coupling constant of heterotic compactified on T^4 and we have allowed a nonzero axion field a. This means in particular that

$$S_2 \sim R, \quad T_2 \sim R, \quad U_2 \sim R \tag{11.33}$$

and for the charge configuration (11.30), the central charge matrix scales as

$$\mathcal{Z} \sim \begin{pmatrix} R & 0 \\ 0 & 0 \end{pmatrix} + \frac{1}{R}\begin{pmatrix} 2n & \ell + ag_6^2/\tilde{R} \\ \ell + ag_6^2/\tilde{R} & 2m + (Q_1^2/\tilde{R}^2 + Q_5^2\tilde{R}^2) \end{pmatrix} . \tag{11.34}$$

From the contour prescription (6.10), we conclude that the imaginary parts for the Fourier integral scale as

$$\mathrm{Im}(\sigma) \sim R \tag{11.35}$$

$$\mathrm{Im}(\tau) \sim 1/R \tag{11.36}$$

$$\mathrm{Im}(z) \sim 1/R\,. \tag{11.37}$$

Therefore, in the region of the moduli space corresponding to the M-theory limit, $p := \exp(2\pi i\sigma)$ is becoming much smaller compared to $q := \exp(2\pi i\tau)$ and $y := \exp(2\pi i z)$. Hence one must first expand around $p = 0$:

$$\frac{1}{\Phi_{10}(\Omega)} \; = \; \sum_{m=-1}^{\infty} p^m \psi_m(\tau, z) \; . \tag{11.38}$$

Since the function $\Phi_{10}(\Omega)$ has double zeros at $z = 0$, the function $\psi_m(\tau, z)$ is meromorphic with double poles at $z = 0$ and its translates.

We conclude that the function $\psi_m(\tau, z)$ can be interpreted as the asymptotic partition function for counting the BPS excitation of this MSW M5-brane for fixed value of the magnetic charge $M^2/2 = m$ and is a *meromorphic* Jacobi form of weight -10 and index m. This is the essential new ingredient compared to other situations encountered earlier such as the partition function of the D1-D5 string [118] which is a *holomorphic* weak Jacobi form[28].

Note that $\psi_m(\tau, z)$ is the asymptotic counting function in the canonical ensemble for a fixed chemical potential z where one sums over all M2-brane charges ℓ for a fixed chemical potential z. To obtain the micro-canonical partition function for a fixed M2-brane charge, one has to perform the Fourier integral in z. There is an infinity of double poles in the z plane at $z = \alpha\tau$ for $\alpha \in \mathbb{Z}$. The z contour can be made to lie between the poles at $(\alpha - 1)\tau$ and $\alpha\tau$ depending on how $\mathrm{Im}(z)$ compares with $\mathrm{Im}(\tau)$ given the $O(1/R)$ terms in the central charge matrix (11.34). It is easy to see that by varying the moduli, the contour can be made to cross all poles. Thus, there are an infinity of walls still accessible in the regime when the radius of the M-circle becomes large.

---

[28] Here we mean holomorphic or meromorphic in the z variable that is conjugate to ℓ. This should not be confused with the nomenclature used in §4 while discussing growth conditions (4.5).

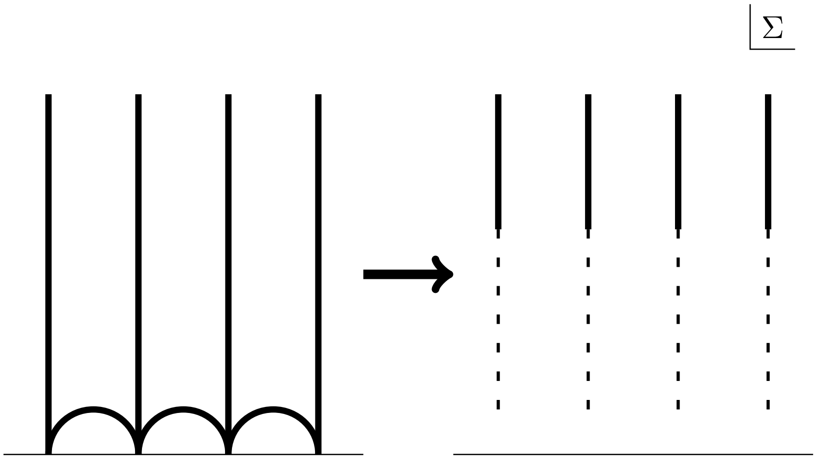

Figure 1: The diagram on the left shows the moduli space projected onto the Σ upper-half plane divided into chambers separated by walls where a quarter-BPS state decays into two half-BPS states. The M-theory limit, shown on the right, corresponds to taking $\mathrm{Im}(\Sigma)$ to be very large. In this limit several walls are no longer visible. There are still an infinite number of walls which can be crossed by varying $\mathrm{Re}(\Sigma)$. Spectral flow transformation maps one chamber to another chamber.

To display this graphically it is useful to define a complex scalar field $\Sigma = \Sigma_1 + i\Sigma_2$ by

$$\mathcal{Z} \sim \frac{1}{\Sigma_2}\begin{pmatrix} |\Sigma|^2 & \Sigma_1 \\ \Sigma_1 & 1 \end{pmatrix} . \tag{11.39}$$

For fixed charges, the MSW region which corresponds to taking Σ_2 large with Σ_1 fixed corresponding to vanishing axion. Varying Σ_1 allows one to access the infinite number of chambers separated by walls as shown in Fig. 1. Degeneracies in these different chambers can be obtained simply by choosing the Fourier contour in z for an appropriate value of α. Note that the field Σ_1 depends both on the moduli and on the charges and thus varies as moduli are varied for fixed charges or as the charges are varied for fixed moduli. In particular, even for fixed values of moduli, one can cross all walls by varying ℓ appropriately.

With this embedding into M-theory, we now outline what we regard as a consistent physical picture to interpret $\widehat{\psi}^F_m$ even though we do not yet fully understand the details. In the limit of large radius R, we effectively have a five-dimensional theory obtained from compactifying M-theory on $K3 \times \hat{T}^2$. For a given a set of M5-brane charges $\{p^i\}$ at asymptotic infinity, the five-dimensional supergravity admits a single-centered black string solution carrying magnetic charges $\{p^i\}$. The near horizon geometry of this solution is an AdS_3 geometry where all vector multiplet moduli of the five-dimensional supergravity are fixed to their attractor values. Following the usual reasoning of holography, we expect that the superconformal field theory describing the low energy excitations of the M5-brane will be dual to this near horizon AdS_3. The indexed partition function of this SCFT is expected to describe the BPS gravitational configurations inside the AdS_3.

What is the indexed partition function of this SCFT? It cannot possibly be the meromorphic Jacobi form ψ_m that exhibits many wall-crossings, because all vector-multiplet moduli are fixed in the attractor AdS_3 geometry and no wall-crossings are possible. It cannot possibly be ψ^F_m, because it is not modular as would be expected from the symmetry under the $SL(2,\mathbb{Z})$ mapping class group of the boundary torus. We propose that the most natural object to identify with the indexed partition function of the $SCFT_2$ dual to the AdS_3 is the modular completion $\widehat{\psi}^F_m(\tau, z)$. It satisfies (in a rather nontrivial way) both requirements of being properly modular and not having any wall-crossings. The non-holomorphy is not something that we would naively expect for the indexed partition function but this can be a reflection of noncompactness as we comment upon later. The quarter-BPS black holes discussed in this paper are excitations inside this single AdS_3 represented as BTZ black holes and their degeneracies should then be captured by the Fourier coefficients of $\psi^F_m(\tau, z)$ which is indeed the case for $n > m$.

This *microscopic* picture is consistent with the *macroscopic* analysis of multi-centered black string solutions [45] of five dimensional supergravity. These solutions can be obtained by lifting multi-centered black hole solutions of four-dimensional supergravity. According to this supergravity analysis, given a set of asymptotic magnetic charges $\{p^i\}$ of a wrapped M5-brane, the single-centered AdS_3 throat described above is not the only allowed solution [45]. There exist multi-centered solutions with multiple AdS_3 throats with the same total asymptotic charge. Now, as we have seen from the microscopic analysis, there are still infinite chambers separated by walls visible in the M-theory limit as shown in Fig 1. These chambers can thus correspond to chambers in which different multi-string configurations exist as stable solutions. The wall-crossings can result not from decays of multi-centered black holes inside a single AdS_3 throat but from the decays of these multi-string solutions. Thus, it is reasonable to identify $\widehat{\psi}^F_m$, which has no wall-crossings, with the (indexed) partition function of the CFT dual to the single AdS_3 throat.

11.4 Open problems and comments

The interpretation of $\widehat{\psi}^F_m(\tau, z)$ proposed above raises a number of interesting questions. The essentially new feature of our proposal is the fact that the modular partition function $\widehat{\psi}^F_m(\tau, z)$ is nonholomorphic and correspondingly the holomorphic counting function ψ_m^F is mock modular. It would clearly be important to understand the physical origin of this nonholomorphy and mock modularity from the boundary and bulk perspectives.

- *Mock modularity from the boundary perspective*:

  We have seen in §11.2 that the mock modularity of ψ_m^F is tied to the noncompactness of the asymptotic SCFT. A more interesting question is to understand this mock modularity directly from the point of view of the near horizon SCFT. It is natural to assume that the near horizon SCFT is also noncompact and this noncompactness is what is responsible for the mock modularity. The connection between mock modularity/nonholomorphy and noncompactness has been noted earlier in physics. For example, the partition function of topological $SO(3)$ $\mathcal{N} = 4$ Yang-Mills theory on $\mathbb{CP}^2$ is a mock modular form and it was suggested in [120] that it is related to the noncompactness of flat directions in field space. The nonholomorphy of the elliptic genus has also been noted in the context of superconformal field theories [54, 119] with the noncompact $SL(2,\mathbb{R})/U(1)$ target space.

  In this context, the nonholomorphy can be understood in complete detail [119, 4] as a consequence of the continuum of spectrum of the noncompact SCFT. It would be interesting to see if the holomorphic anomaly (11.23) of the completion of $\widehat{\psi}_m^F$ can be understood from such a path integral perspective of the conformal field theory.

  In the framework of AdS_2 holography, the quantity of interest is the integer $d^*(n, m, \ell)$ which is identified with the partition function of the boundary CFT. Using the fact that the completion $\widehat{\psi}_m^F(\tau, z)$ is modular, it should be possible to develop a Rademacher-like expansion for the $d^*(n, m, \ell)$ along the lines of [13, 14, 15]. This method has been used to prove that the black hole degeneracies are positive integers [19].

- *Mock modularity from the bulk perspective*:

  If mock modularity is indeed a consequence of the noncompactness of the boundary CFT, what are the implications of this noncompactness in the bulk AdS_3? In particular, if the spectrum of conformal dimensions is continuous, then the bulk theory must have a continuum of masses. Perhaps these are to be identified with some extended long-string like excitations. It would be interesting to see if the mock modularity of the elliptic genus can be understood in terms of such bulk excitations. Indeed, recent investigations seem to indicate that the bulk string partition function in string theories [71] based on the non-compact $SL(2,\mathbb{R})/U(1)$ CFT [64, 94] show a mock modular behavior.

  The M-theory limit corresponds to the attractor contour for $n > m$ and $0 \leq \ell < 2m$ but the converse is not necessarily true, as explained in §11.1. For $n \leq m$, we have the possibility that there will be multi-centered configurations. In particular, if $n \leq m$, then even if $\ell < 2m$, it is possible to have states with non-positive discriminant ($\Delta = 4mn - \ell^2 \leq 0$). Since, the discriminant must be positive for a black hole horizon, such states cannot possibly correspond to single-centered black holes and must be realized in supergravity as multi-centered configurations if there are smooth solutions corresponding to them at all. Hence, if $\widehat{\psi}^F_m$ is indeed the elliptic genus of a single-centered AdS_3, then there must be supergravity configurations corresponding to these states for $n \leq m$ that fit inside a single AdS_3.

This microscopic prediction is plausible from the supergravity perspective. According to [45], all two-centered black hole solutions where each center is a D4-D2 bound state, are scaled out of a single AdS_3 throat. However, the two-centered solutions that have one center carrying D6-brane charge and the other carrying anti-D6-brane charge can continue to exist as stable solutions inside a single AdS_3. Such configurations can give the supergravity realization of the negative discriminant states. Further analysis is required to verify these consequences of our proposed interpretation of $\widehat{\psi}^F_m$.

- *Generalization to $\mathcal{N} = 2$ compactifications*:

One motivation for the present investigation is to abstract some general lessons which could be applicable to the more challenging case of dyons in $\mathcal{N} = 2$ compactifications on a general Calabi-Yau three-fold. In the $\mathcal{N} = 4$ case, the mock modularity of ψ^F_m was a consequence of meromorphy of ψ_m. As we have seen in §11.2, this meromorphy is in turn a consequence of noncompactness of Taub-NUT factor $\sigma(\mathrm{TN})$ in the asymptotic SCFT (11.25)[29]. This suggests that the SCFT dual to the near horizon AdS_3 is also noncompact. In the $\mathcal{N} = 2$ context also, there is no a priori reason to expect that the MSW SCFT will be compact in general everywhere in the moduli space. If this SCFT is noncompact, then our results suggest that mock Jacobi forms would provide the right framework for making the holographic $SL(2,\mathbb{Z})$ symmetry manifest for the indexed partition function considered, for example, in [49, 44, 89]. In the $\mathcal{N} = 4$ case, the mock modularity is closely correlated with the wall-crossing phenomenon. The wall-crossing phenomenon in $\mathcal{N} = 2$ case corresponds to jumps in the Donaldson-Thomas invariants and is known to be much more complicated [48, 78, 76, 88]. It would be interesting though to define the analog of the counting function for the immortal degeneracies in this case. Since these degeneracies do not change under wall-crossing, such a counting function is likely to have an interesting mathematical interpretation. Moreover, it is expected to have nice (mock) modular properties from the considerations of holography discussed above.

---

[29] Note that this is not to be confused with $\mathbb{R}^3$ factor corresponding to the center of mass motion. It corresponds to the relative motion of the KK-monopole and the D1D5 system [42] and thus would belong to what is called the "entropic" factor [92] for the MSW string in the M-theory frame.

- *Mock modularity and indefinite theta series*:

  Mock modular forms appear in Zwegers's work as members of three quite different families of functions:

  1. Fourier coefficients of meromorphic Jacobi forms,
  2. Appell-Lerch sums,
  3. Indefinite theta series.

  We have seen that the first two families appear naturally in the context of black hole physics with natural physical interpretations. This suggests that the indefinite theta series could also play a role in this physical context. It would be interesting to develop this connection further. For some earlier work in this direction, see [90, 1].

A. Appendix: Tables of special mock Jacobi forms

This appendix contains three collections of tables. The first gives the first Fourier coefficients of the weight 2 mock Jacobi forms $\mathcal{Q}_M$ for all products of two primes less than 50, the second gives coefficients of the primitive mock Jacobi forms $\Phi^0_{1,m}$ for all known cases having optimal growth, and the third gives coefficients of the weight 1 mock Jacobi forms $\mathcal{Q}_M$ for all products of three primes less than 150.

A.1 Table of $\mathcal{Q}_M$ (weight 2 case)

For each M with $\mu(M) = 1$ with $1 < M < 50$ we tabulate the value of c_M and the Fourier coefficients $c(\mathcal{F}_M; n, r_{\min})$ for n ranging from 0 to some limit and all values of $r_{\min}$, (defined as the minimal positive representatives prime to M of their squares modulo $4M$). Here c_M is the smallest positive rational number such that $\mathcal{F}_M = -c_M\mathcal{Q}_M$ has integral coefficients, as defined in (9.52). The asterisk before a value of $r_{\min}$ means that the corresponding row contains at least one negative non-polar coefficient.

A.2 Table of $\Phi^0_{1,m}$ of optimal growth

We give the Fourier coefficients of the primitive weight 1 mock Jacobi form $\Phi^0_{1,m}$ for the fourteen known values of m for which it has optimal growth, in the same format as was used in the $k = 2$ case above. The number c is the factor relating the true value of $\Phi^0_{1,m}$ to the form whose coefficients have been tabulated, and which has been normalized to have integral Fourier coefficients with no common factor except for the values $C(\Delta = 0, r)$, which are allowed to have a denominator of 2. (This happens for the indices 9, 16, 18, and 25.)

A.3 Table of $\mathcal{Q}_M$ (weight 1 case)

We give the coefficients of $\mathcal{Q}_M$ for all products of three primes less than 150 for which $\mathcal{Q}_M$. We also show the factor c_M relating $\mathcal{Q}_M$ to $\mathcal{F}_M$ and the minimal discriminant of $\mathcal{F}_M$, since it is no longer assumed to be -1. This time an asterisk means simply that the corresponding row contains (non-polar) coefficients of opposite signs, since here there are many examples of values of $r \pmod{2m}$ for which the scalar factor κ_r that determines the sign of the coefficients $C(\Delta, r)$ for large Δ is negative rather than positive for $r = r_{\min}$.

Monstrous moonshine and monstrous Lie superalgebras.

Invent. Math. 109, 405-444 (1992).

Richard E. Borcherds,

Department of pure mathematics and mathematical statistics, 16 Mill Lane, Cambridge CB2 1SB, England.

We prove Conway and Norton's moonshine conjectures for the infinite dimensional representation of the monster simple group constructed by Frenkel, Lepowsky and Meurman. To do this we use the no-ghost theorem from string theory to construct a family of generalized Kac-Moody superalgebras of rank 2, which are closely related to the monster and several of the other sporadic simple groups. The denominator formulas of these superalgebras imply relations between the Thompson functions of elements of the monster (i.e. the traces of elements of the monster on Frenkel, Lepowsky, and Meurman's representation), which are the replication formulas conjectured by Conway and Norton. These replication formulas are strong enough to verify that the Thompson functions have most of the "moonshine" properties conjectured by Conway and Norton, and in particular they are modular functions of genus 0. We also construct a second family of Kac-Moody superalgebras related to elements of Conway's sporadic simple group Co_1. These superalgebras have even rank between 2 and 26; for example two of the Lie algebras we get have ranks 26 and 18, and one of the superalgebras has rank 10. The denominator formulas of these algebras give some new infinite product identities, in the same way that the denominator formulas of the affine Kac-Moody algebras give the Macdonald identities.

1 Introduction.

The main result of the first half of this paper is the following.

Theorem 1.1. *Suppose that $V=\oplus_{n\in\mathbf{Z}}V_n$ is the infinite dimensional graded representation of the monster simple group constructed by Frenkel, Lepowsky, and Meurman [16,17]. Then for any element g of the monster the Thompson series $T_g(q)=\sum_{n\in\mathbf{Z}}\mathrm{Tr}(g|V_n)q^n$ is* *a Hauptmodul for a genus 0 subgroup of $SL_2(\mathbf{R})$, i.e., V satisfies the main conjecture in Conway and Norton's paper [13].*

We prove this by constructing a $\mathbf{Z}^2$-graded Lie algebra acted on by the monster, called the monster Lie algebra. This is a generalized Kac-Moody algebra, and by calculating the "twisted denominator formulas" of this Lie algebra explicitly we get enough information about the Thompson series $T_g(q)$ to determine them.

In this introduction we explain this result in more detail and briefly describe the proof, which is contained in sections 6 to 9. The rest of this paper is organized as follows. Section 2 is an introduction to the second half of the paper (sections 10 to 14) which uses some of the techniques of the proof to find some new infinite product formulas and infinite dimensional Lie algebras. Sections 3, 4, and 5 summarize some known results about vertex algebras, Kac-Moody algebras, and the no-ghost theorem that we use in the proof of theorem 1.1. Section 15 contains a list of some open questions. There is a list of notation we use at the end of section 1.

The Fischer-Griess monster sporadic simple group, of order $2^{46}3^{20}5^97^611^213^317.19.23.29.31.41.47.59.71$, acts naturally and explicitly on a graded real vector space $V = \oplus_{n\in\mathbf{Z}} V_n$ constructed by Frenkel, Lepowsky and Meurman [16,17] (The vector spaces V and V_n are denoted by $V^\natural$ and $V^\natural_{-n}$ in [16].) The dimension of V_n is equal to the coefficient $c(n)$ of the elliptic modular function $j(\tau) - 744 = \sum_n c(n)q^n = q^{-1} + 196884q + 21493760q^2 + \dots$ (where we write q for $e^{2\pi i\tau}$, and $\mathrm{Im}(\tau) > 0$). One of the main remaining problems from [16], which theorem 1.1 solves, is to calculate the character of V as a graded representation of the monster, or in other words to calculate the trace $\mathrm{Tr}(g|V_n)$ of each element g of the monster on each space V_n. The best way to describe this information is to define the Thompson series

$$T_g(q) = \sum_{n\in\mathbf{Z}} \mathrm{Tr}(g|V_n)q^n$$

for each element g of the monster, so we want to calculate these Thompson series. For example, if 1 is the identity element of the monster then $\mathrm{Tr}(1|V_n) = \dim(V_n) = c(n)$, so that the Thompson series $T_1(q) = j(\tau) - 744$ is the elliptic modular function. McKay, Thompson, Conway and Norton conjectured [13] that the Thompson series $T_g(q)$ are all Hauptmoduls for certain explicitly given modular groups of genus 0. (More precisely, they only conjectured that there should be some graded module for the monster whose Thompson series are Hauptmoduls, since their conjectures came before the construction of V.) This conjecture follows from theorem 1.1. The corresponding Hauptmoduls are the ones listed in [13] (with their constant terms removed), so this completely describes V as a representation of the monster.

We recall the definition of a Hauptmodul. The group $SL_2(\mathbf{Z})$ acts on the upper half plane $H = \{\tau \in \mathbf{C}|\mathrm{Im}(\tau) > 0\}$ by $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)(\tau) = \frac{a\tau+b}{c\tau+d}$. A meromorphic function on H invariant under $SL_2(\mathbf{Z})$ and satisfying a certain regularity condition at $i\infty$ is called a modular function of level 1. The phrase "level 1" refers to the group $SL_2(\mathbf{Z})$; if this is replaced by some commensurable group we get modular functions of higher levels. The elliptic modular function $j(\tau)$ is, up to normalizations, the simplest nonconstant modular function of level 1; more precisely, the modular functions of level 1 are the rational functions of j. The element $\left(\begin{smallmatrix}1&1\\0&1\end{smallmatrix}\right)$ of $SL_2(\mathbf{Z})$ takes τ to $\tau+1$, so in particular $j(\tau)$ is periodic and can be written as a Laurent series in $q=e^{2\pi i\tau}$. An exact expression for j is

$$j(\tau)=\frac{(1+240\sum_{n>0}\sigma_3(n)q^n)^3}{q\prod_{n>0}(1-q^n)^{24}}$$

where $\sigma_3(n)=\sum_{d|n}d^3$ is the sum of the cubes of the divisors of n; see any book on modular forms or elliptic functions, for example [30]. Another way of thinking about j is that it is an isomorphism from the quotient space $H/SL_2(\mathbf{Z})$ to the complex plane, which can be thought of as the Riemann sphere minus the point at infinity.

We can also consider functions invariant under some group G commensurable with $SL_2(\mathbf{Z})$ acting on H. The quotient H/G is again a compact Riemann surface $\overline{H/G}$ with a finite number of points removed. If this compact Riemann surface is a sphere, rather than something of higher genus, then we say that G is a genus 0 group. In this case a function giving an isomorphism from the compact Riemann surface $\overline{H/G}$ to the sphere $\mathbf{C}\cup\infty$ taking $i\infty$ to ∞ is called a Hauptmodul for the genus 0 group G; it is unique up to addition of a constant and multiplication by a nonzero constant. If a Hauptmodul can be written as $e^{-2\pi i a\tau}+$ a function vanishing at $i\infty$ for some positive a then we say that it is normalized. Every genus 0 group has a unique normalized Hauptmodul. For example, $j(\tau)-744=e^{-2\pi i\tau}+0+196884e^{2\pi i\tau}+\dots$ is the normalized Hauptmodul for the genus 0 group $SL_2(\mathbf{Z})$.

Another example is $G=\Gamma_0(2)$, where $\Gamma_0(N)=\{\left(\begin{smallmatrix}a&b\\c&d\end{smallmatrix}\right)\in SL_2(\mathbf{Z})|c\equiv 0 \bmod N\}$. The quotient H/G is then a sphere with 2 points removed, so that G is a genus 0 group. Its normalized Hauptmodul is $T_{2-}(q)=24+q^{-1}\prod_{n>0}(1-q^{2n+1})^{24}=q^{-1}+276q-2048q^2+\dots$, and is equal to the Thompson series of a certain element of the monster of order 2 (of type 2B in atlas [14] notation). Similarly $\Gamma_0(N)$ is a genus 0 subgroup for several other values of N which correspond to elements of the monster. (However the genus of $\Gamma_0(N)$ tends to infinity as N increases, so there are only a finite number of integers N for which it has genus 0; more generally Thompson [31] has shown that there are only a finite number of conjugacy classes of genus 0 subgroups of $SL_2(\mathbf{R})$ which are commensurable with $SL_2(\mathbf{Z})$.)

So we want to calculate the Thompson series $T_g(\tau)$ and show that they are Hauptmoduls of genus 0 subgroups of $SL_2(\mathbf{R})$. The difficulty with doing this is as follows. Frenkel, Lepowsky, and Meurman constructed V as the sum of two subspaces V^+ and V^-, which are the $+1$ and -1 eigenspaces of a certain element of order 2 in the monster. If an element g of the monster commutes with this element of order 2, then it is not difficult to to work out its Thompson series $T_g(q)=\sum_n \mathrm{Tr}(g|V_n)q^n$ as the sum of two series given by its traces on V^+ and V^- (this is done in [16,17]), and it would probably be tedious but straightforward to check directly that these are all Hauptmoduls. Unfortunately, if an element of the monster is not conjugate to something that commutes with this element of order 2 then there is no obvious direct way of working out its Thompson series, because it muddles up V^+ and V^- in a very complicated way.

We calculate these Thompson series indirectly using the monster Lie algebra M. This is a $\mathbf{Z}^2=\mathbf{Z}\oplus\mathbf{Z}$ graded Lie algebra, whose piece of degree $(m,n)\in\mathbf{Z}^2$ is isomorphic as a module over the monster to V_{mn} if $(m,n)\neq(0,0)$ and to $\mathbf{R}^2$ if $(m,n)=(0,0)$, so for small degrees it looks like

$$\begin{array}{ccccccccc}
 & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \\
\cdots & 0 & 0 & 0 & 0 & V_3 & V_6 & V_9 & \cdots \\
\cdots & 0 & 0 & 0 & 0 & V_2 & V_4 & V_6 & \cdots \\
\cdots & 0 & 0 & V_{-1} & 0 & V_1 & V_2 & V_3 & \cdots \\
\cdots & 0 & 0 & 0 & \mathbf{R}^2 & 0 & 0 & 0 & \cdots. \\
\cdots & V_3 & V_2 & V_1 & 0 & V_{-1} & 0 & 0 & \cdots \\
\cdots & V_6 & V_4 & V_2 & 0 & 0 & 0 & 0 & \cdots \\
\cdots & V_9 & V_6 & V_3 & 0 & 0 & 0 & 0 & \cdots \\
 & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots &
\end{array}$$

Very briefly, this Lie algebra is constructed as the space of physical states of a bosonic string moving in a Z_2-orbifold of a 26-dimensional torus (or strictly speaking, about half the physical states). See section 6 for more details. The space of physical states is a subquotient of a vertex algebra constructed from the vertex algebra V; vertex algebras are described in more detail in [3,16,18], and the properties we use are summarized in section 3. This subquotient can be identified using the no-ghost theorem from string theory ([21] or section 5), and is as described above.

We need to know what the structure of the monster Lie algebra is. It turns out to be something called a generalized Kac-Moody algebra, so we explain what these are.

Section 4 describes the results about generalized Kac-Moody algebras that we use. This paragraph gives a brief summary of them. Kac-Moody algebras can be thought of as Lie algebras generated by a copy of sl_2 for each point in their Dynkin diagram. Generalized Kac-Moody algebras are rather like Kac-Moody algebras except that we are allowed to glue together the sl_2's in more complicated ways, and are also allowed to use Heisenberg Lie algebras as well as sl_2's to generate the algebra. The main difference between Kac-Moody algebras and generalized Kac-Moody algebras is that the roots α of a Kac-Moody algebra may be either real ($(\alpha,\alpha)>0$) or imaginary ($(\alpha,\alpha)\leq 0$) but all the simple roots must be real, while generalized Kac-Moody algebras may also have imaginary simple roots. Kac-Moody algebras have a "denominator formula", which says that a product over positive roots is equal to a sum over the Weyl group; for example, the denominator formula for the affine Kac-Moody algebra $sl_2(\mathbf{R}[z,z^{-1}])$ is the Jacobi triple product identity. Generalized Kac-Moody algebras have a denominator formula which is similar to the one for Kac-Moody algebras, except that it has some extra correction terms for the imaginary simple roots. (The simple roots of a generalized Kac-Moody algebra correspond to a minimal set of generators for the subalgebra corresponding to the positive roots. For Kac-Moody algebras the simple roots also correspond to the points of the Dynkin diagram and to the generators of the Weyl group.)

We return to the monster Lie algebra. This is a generalized Kac-Moody algebra, and we will now write down its denominator formula, which says that a product over the positive roots is a sum over the Weyl group. The positive roots are the vectors (m,n) with $m>0$, $n>0$, and the vector $(1,-1)$, and the root (m,n) has multiplicity $c(mn)$. The Weyl group has order 2 and its nontrivial element maps (m,n) to (n,m), so it exchanges

$p = e^{(1,0)}$ and $q = e^{(0,1)}$. The denominator formula for the monster Lie algebra is the product formula for the j function

$$p^{-1} \prod_{m>0, n\in Z} (1 - p^m q^n)^{c(mn)} = j(p) - j(q).$$

(The left side is antisymmetric in p and q because of the factor of $p^{-1}(1 - p^1 q^{-1})$ in the product.) The reason why we get $j(p)$ and $j(q)$ rather than monomials in p and q on the right hand side (as we would for ordinary Kac-Moody algebras) is because of the correction due to the imaginary simple roots of M. The simple roots of M correspond to a set of generators of the subalgebra E of the elements of M whose degree is to the right of the y axis (so the roots of E are the positive roots of M), and turn out to be the vectors $(1, n)$ each with multiplicity $c(n)$. In the picture of the monster Lie algebra given earlier, the simple roots are given by the column just to the right of the one containing $\mathbf{R}^2$. The sum of the simple root spaces is isomorphic to the space V. The simple root $(1, -1)$ is real of norm 2, and the simple roots $(1, n)$ for $n > 0$ are imaginary of norm $-2n$ and have multiplicity $c(n) = \dim(V_n)$. As these multiplicities are exactly the coefficients of the j function, it is not surprising that j appears in the correction caused by the imaginary simple roots. This discussion is slightly misleading because we have implied that we obtain the product formula of the j function as the denominator formula of the monster Lie algebra by using our knowledge of the simple roots; in fact we really have to use this argument in reverse, using the product formula for the j function in order to work out what the simple roots of the monster Lie algebra are. We do this in section 7.

We can now extract information about the coefficients of the Thompson series $T_g(\tau)$ from a twisted denominator formula for the monster Lie algebra as follows: for an arbitrary generalized Kac-Moody algebra there is a more general version of the Weyl denominator formula which states that

$$\Lambda(E) = H(E),$$

where E is the subalgebra corresponding to the positive roots. Here $\Lambda(E) = \Lambda^0(E) \ominus \Lambda^1(E) \oplus \Lambda^2(E) \ldots$ is a virtual vector space which is the alternating sum of the exterior powers of E, and similarly $H(E)$ is the alternating sum of the homology groups $H_i(E)$ of the Lie algebra E (see [10]). This identity is true for any finite dimensional Lie algebra E because the $H_i(E)$'s are the homology groups of a complex whose terms are the $\Lambda^i(E)$'s. The left hand side corresponds to a product over the positive roots because $\Lambda(A \oplus B) = \Lambda(A) \otimes \Lambda(B)$, $\Lambda(A) = 1 - A$ if A is one dimensional, and E is the sum of $\mathrm{mult}(\alpha)$ one dimensional spaces for each positive root α. For infinite dimensional Lie algebras E we need to be careful that the infinite dimensional virtual vector spaces $H(E)$ and $\Lambda(E)$ are well defined; in this paper they are always differences of graded vector spaces with finite dimensional homogeneous pieces and so are well defined. It is more difficult to identify $H(E)$ with a sum over the Weyl group, and we do this roughly as follows. For Kac-Moody algebras $H_i(E)$ turns out to have dimension equal to the number of elements in the Weyl group of length i; for finite dimensional Lie algebras this was first observed by Bott, and was used by Kostant [26] to give a homological proof of the Weyl character formula. The sum over the homology groups can therefore be identified with a sum over the Weyl group.

For Kac-Moody algebras the same is true and was proved by Garland and Lepowsky [20]. For generalized Kac-Moody algebras things are a bit more complicated. The sum over the homology groups can still be identified with a sum over the Weyl group, but the things we sum are more complicated and contain terms corresponding to the imaginary simple roots.

We can work out the homology groups of E explicitly provided we know the simple roots of our Lie algebra M; for example, the first homology group $H_1(E)$ is the sum of the simple root spaces. For the monster Lie algebra we have worked out the simple roots using its denominator formula, which is the product formula for the j function. In section 8 we use this to work out the homology groups of E, and they turn out to be $H_0(E) = \mathbf{R}$, $H_1(E) = \sum_{n\in\mathbf{Z}} V_n pq^n$, $H_2(E) = \sum_{m>0} V_m p^{m+1}$, and all the higher homology groups are 0. Each homology group is a $\mathbf{Z}^2$-graded representation of the monster, and we use the p's and q's to keep track of the grading. If we substitute these values into the formula $\Lambda(E) = H(E)$ we find that

$$\Lambda(\sum_{n\in\mathbf{Z},m>0} V_{mn}p^m q^n) = \sum_m V_m p^{m+1} - \sum_n V_n pq^n.$$

Both sides of this are virtual graded representations of the monster. If we replace everything by its dimension we recover the product formula for the j function. More generally, we can take the trace of some element of the monster on both sides, which after some calculation gives the identity

$$p^{-1}\exp\Big(-\sum_{i>0}\sum_{m>0,n\in\mathbf{Z}} \mathrm{Tr}(g^i|V_{mn})p^{mi}q^{ni}/i\Big) = \sum_{m\in\mathbf{Z}} \mathrm{Tr}(g|V_m)p^m - \sum_{n\in\mathbf{Z}} \mathrm{Tr}(g|V_n)q^n$$

where $\mathrm{Tr}(g|V_n)$ is the trace of g on the vector space V_n.

These relations between the coefficients $\mathrm{Tr}(g|V_n)$ of the Thompson series are strong enough to determine them from their first few coefficients. Norton and Koike checked that certain modular functions of genus 0 also satisfy the same recursion relations, so we can prove that the Thompson series $T_g(q)$ are these modular functions of genus 0 by checking that the first few coefficients of both functions are the same. Unfortunately this final step of the proof (in section 9) is a case by case check that the first few coefficients are the same. Norton has conjectured [28] that Hauptmoduls with integer coefficients are essentially the same as functions satisfying relations similar to the ones above, and a conceptual proof or explanation of this would be a big improvement to the final step of the proof. (It should be possible to prove Norton's conjecture by a very long and tedious case by case check, because all functions which are either Hauptmoduls or which satisfy the relations above can be listed explicitly. In [1] the authors use a computer to find all "completely replicable" functions with integer coefficients, and they all appear to be Hauptmoduls. Roughly half of them correspond to conjugacy classes of the monster.)

I thank J. McKay, U. Tillman, J. Lepowsky, and the referee, each of whom sent me many useful remarks about a draft of this paper.

Notation. (In roughly alphabetical order.)

$\mathbf{C}$	The complex numbers.
$c(n)$	are the coefficients of the elliptic modular function $j(q)-744$ (defined below).
$c_g(n)$	$=\mathrm{Tr}(g\mid V_n)$ is the n'th coefficient of the Thompson series $T_g(q)$ of g.
$\Gamma_0(N)$	is the subgroup of matrices $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ in $SL_2(\mathbf{Z})$ with $N\mid c$, and $\Gamma_0(N)+$ is its normalizer in $SL_2(\mathbf{R})$; see [13].
δ_i^j	is the Kronecker delta function, which is 1 if $i=j$ and 0 otherwise.
$\Delta(q)$	is the Dedekind delta function $q\prod_{n>0}(1-q^n)^{24}=\eta(q)^{24}$
E	The subalgebra of a generalized Kac-Moody algebra $G=F\oplus H\oplus E$ spanned by the positive root spaces.
E_8	The unique 8-dimensional positive definite even unimodular lattice.
$\epsilon(\alpha)$	The coefficient associated with the root α in the denominator formula of s generalized Kac-Moody algebra. See section 4.
$\eta(q)$	is the Dedekind eta function $q^{1/24}\prod_{n>0}(1-q^n)$. For η_g see sections 9 or 13, and for η_+, η_- see section 11.
$\theta_\Lambda(q)$	$=\sum_{\lambda\in\Lambda}q^{\lambda^2/2}=1+196560q^2+\dots$ is the theta function of the Leech lattice Λ. For other theta functions see section 11.
G	A generalized Kac-Moody algebra; see section 4.
H	The Cartan subalgebra of a generalized Kac-Moody algebra $G=F\oplus H\oplus E$.
$H_i(E)$	is a homology group of the Lie algebra E; $H(E)$ is the alternating sum of the homology groups of E.
$II_{1,1}$	is the unique even 2-dimensional unimodular Lorentzian lattice, which has inner product matrix $\left(\begin{smallmatrix} 0 & -1 \\ -1 & 0 \end{smallmatrix}\right)$. Its elements are usually represented as pairs $(m,n)\in\mathbf{Z}^2=\mathbf{Z}\oplus\mathbf{Z}$, and this element has norm $-2mn$.
$II_{25,1}$	is the unique even 26-dimensional unimodular Lorentzian lattice, which is isomorphic to $\Lambda\oplus II_{1,1}$.
$j(q)$	is the elliptic modular function with $j(q)-744=q^{-1}+196884q+\dots=\theta_\Lambda(q)/\Delta(q)-24=\sum_n c(n)q^n$
Λ	is the Leech lattice, the unique 24 dimensional even unimodular positive definite lattice with no vectors of norm 2. Its elements will often be denoted by λ. For its double cover $\hat{\Lambda}$ see section 12.
$\Lambda(E)$	is the alternating sum of the exterior powers of the vector space E.
$\Lambda^i(E)$	is the i'th exterior power of the vector space E.
M	$=\oplus_{m,n\in\mathbf{Z}}M_{m,n}$ is the monster Lie algebra with root lattice $II_{1,1}$, constructed in section 6.
M_Λ	is the fake monster Lie algebra, whose root lattice is $II_{25,1}$.
$\mu(d)$	is the Moebius function, equal to $(-1)^{(\text{number of prime factors of } d)}$ if d is square free, and 0 otherwise.
$\mathrm{mult}(r)$	The multiplicity of the root r.
p	A formal variable. It can usually be considered as a complex number with $\lvert p\rvert<1$.
$p_{24}(n)$	is the number of partitions of n into parts of 24 colours, so that $\sum_n p_{24}(1+n)q^n=q^{-1}\prod_{n>0}(1-q^n)^{-24}=\Delta(q)^{-1}=q^{-1}+24+324q+3200q^2+25650q^3+176256q^4+1073720q^5+\dots$. These are the multiplicities of roots of the fake monster Lie algebra M_Λ. For p_g see section 14.

q	A formal variable. It can usually be thought of as a complex number with $\lvert q\rvert < 1$, equal to $e^{2\pi i\tau}$. (I.e., the formal series usually converge for $\lvert q\rvert < 1$.)
r^2	The norm (r, r) of the vector r of some lattice.
$\mathbf{R}$	The real numbers.
ρ	is the Weyl vector of a root lattice, which by definition has the property that $(\rho, r) = -(r, r)/2$ for any simple root r. (The Weyl vector is not necessarily in the root lattice, although it does for most of the Lie algebras in this paper.) This has the opposite sign to the usual convention for the Weyl vector, for reasons explained in section 4. For the root lattice $II_{25,1} = \Lambda \oplus II_{1,1} = \Lambda \oplus \mathbf{Z}^2$ of the fake monster Lie algebra M_Λ, ρ is the vector $(0, 0, 1)$.
$\sigma_i(n)$	$= \sum_{d\mid n} d^i$ is the sum of the i'th powers of the divisors of n.
$T_g(q)$	$= \sum c_g(n)q^n$ is the Thompson series of an element g of the monster, with $c_g(n) = \mathrm{Tr}(g\mid V_n)$ where $V = \oplus_{n\in\mathbf{Z}} V_n$ is the module constructed by Frenkel, Lepowsky and Meurman [16,17]. (The spaces V and V_n are denoted by $V^\natural$ and $V^\natural_{-n}$ in [16].)
$\mathrm{Tr}(g\mid U)$	is the trace of an endomorphism g of a vector space U.
τ	A complex number with $\mathrm{Im}(\tau) > 0$.
V	$= \oplus_{n\in\mathbf{Z}} V_n$ is the monster vertex algebra discussed in section 3.
$V_{II_{1,1}}$	is the vertex algebra of the two dimensional even Lorentzian lattice $II_{1,1}$ (or more precisely the vertex algebra of its double cover).
V_Λ	is the the fake monster vertex algebra, which is the vertex algebra of the Leech lattice Λ (or more precisely of its double cover $\hat\Lambda$). See section 12.
W	is a Weyl group. Typical elements are often denoted by w. See section 4.
$\mathbf{Z}$	The integers.
ψ^i	An Adams operation on virtual group representations, defined by $\mathrm{Tr}(g\mid\psi^i(V)) = \mathrm{Tr}(g^i\mid V)$ for V a virtual representation of a group containing g.
ω	A Cartan involution (section 4) or a conformal vector of a vertex algebra (section 3).

2 Introduction (continued).

We describe the results in the second half of the paper (sections 10 to 14). This section can be omitted by those who are only interested in the proof of theorem 1.1.

We construct several Lie superalgebras which are similar to the monster Lie algebra. One method of constructing these is to consider the "twisted" denominator formulas of the monster Lie algebra as untwisted denominator formulas of some other Lie algebras or superalgebras; these seem to be related to other sporadic simple groups. A second method of constructing some of them is to replace the monster vertex algebra V by the vertex algebra of the Leech lattice V_Λ. From this we get the fake monster Lie algebra [8] (where it is called the monster Lie algebra) and several variations of it.

The Lie superalgebras we construct form two families as follows:

(1) A Lie algebra or superalgebra of rank 2 for many conjugacy classes g of the monster simple group. The monster Lie algebra is the one corresponding to the identity element of the monster. The ones corresponding to other elements of the monster are often related to other sporadic simple groups.

(2) A Lie superalgebra for many of the conjugacy classes of the group $\mathrm{Aut}(\hat\Lambda) = 2^{24}.2.Co_1$, where $\hat\Lambda$ is the standard double cover of the Leech lattice Λ (defined in section 12),

$\mathrm{Aut}(\hat\Lambda)$ is the group of its automorphisms which preserve the inner product on Λ, and $Co_1 = \mathrm{Aut}(\Lambda)/\mathbf{Z}_2$ is one of Conway's sporadic simple groups. (The symbol $A.B$ where A and B are groups stands for some extension of B by A, i.e., a group with a normal subgroup A such that the quotient by A is B; the notation is ambiguous.) For example, we get Lie algebras of ranks 26, 18, and 14 corresponding to certain automorphisms of $\hat\Lambda$ of orders 1, 2, and 3, and a Lie superalgebra of rank 10 corresponding to an automorphism of order 2. The Lie algebra of rank 26 is what we now call the fake monster Lie algebra and is studied in [8] (where it is called the monster Lie algebra, because the genuine monster Lie algebra had not been discovered then).

All of these algebras are generalized Kac-Moody algebras or superalgebras. Their root multiplicities can be described explicitly in terms of the coefficients of a finite number of modular forms of weight at most 0. (These modular forms are holomorphic on the upper half plane, and are meromorphic but not necessarily holomorphic at the cusps.) More precisely, there is a sublattice L of finite index in the root lattice, and for each coset of L in the root lattice there is a modular form, which is holomorphic except at the cusps and of weight $1 - \dim(L)/2$, such that the root multiplicity of a vector r in a given coset is the coefficient of $q^{-(r,r)/2}$ of the corresponding modular form. All the algebras have Weyl vectors ρ with norm $\rho^2 = (\rho, \rho) = 0$, and the simple roots are the roots r with $(r, \rho) = -(r, r)/2$. In particular the simple roots and root multiplicities can be described explicitly, and we use this to obtain some infinite product identities from the denominator formulas of these algebras. These algebras are closely related to the sporadic simple groups.

We now discuss both of these families of Lie algebras in more detail. We recall from section 1 that the monster Lie algebra M, is a generalized Kac-Moody algebra whose denominator formula is

$$p^{-1} \prod_{\substack{m>0\\ n\in\mathbf{Z}}} (1 - p^m q^n)^{c(mn)} = j(p) - j(q). \tag{2.1}$$

In section 10 we construct a similar Lie superalgebra for many elements g of the monster. In this case the denominator formula is

$$p^{-1} \prod_{\substack{m>0\\ n\in\mathbf{Z}}} (1 - p^m q^n)^{\mathrm{mult}(m,n)} = T_g(p) - T_g(q) \tag{2.2}$$

where $T_g(q) = \sum \mathrm{Tr}(g|V_n) q^n$ is the Thompson series of the element g, and the multiplicity $\mathrm{mult}(m, n)$ of the root (m, n) is given by

$$\mathrm{mult}(m, n) = \sum_{ds|(m,n)} \mu(d) \mathrm{Tr}(g^s | V_{mn/d^2 s^2})/ds \tag{2.3}$$

where $\mu(d)$ is the Moebius function, equal to $(-1)^{(\text{number of prime factors of } d)}$ if d is square free, and 0 otherwise. (The symbol (m, n) under the summation sign means the greatest common divisor of m and n, rather than the ordered pair.) For example, if N

is a squarefree integer such that the full normalizer $\Gamma_0(N)+$ of $\Gamma_0(N)$ has genus 0 then a special case of (2.2) is

$$p^{-1}\prod_{\substack{m>0\\ n\in\mathbf{Z}}}\prod_{d|(m,n,N)}(1-p^mq^n)^{c_N(mn/d)}=T_N(p)-T_N(q) \tag{2.4}$$

where $T_N(q)=\sum_n c_N(n)q^n$ is the normalized generator of the function field of $\Gamma_0(N)+$ with leading terms $q^{-1}+0+c_N(1)q+\ldots$.

In section 11 to 14 we construct a second series of Lie superalgebras, which are similar to the algebras above except that they are related to the vertex algebra V_Λ of the Leech lattice Λ instead of the monster vertex algebra V. The largest of these, which plays the same role for this series as the monster Lie algebra plays for the previous series, is the algebra which used to be called the monster Lie algebra in [8] and is now called the fake monster Lie algebra. (The Kac-Moody algebra whose Dynkin diagram is that of the reflection group of $II_{25,1}$ has also been called the monster Lie algebra ([7]); it is a large subalgebra of the fake monster Lie algebra, and does not seem to be interesting, except as an approximation to the fake monster Lie algebra.) The root lattice of the fake monster Lie algebra is the 26 dimensional even unimodular Lorentzian lattice $II_{25,1}$, and its denominator formula is

$$e^\rho\prod_{r\in\Pi^+}(1-e^r)^{p_{24}(1-r^2/2)}=\sum_{w\in W}\det(w)w(e^\rho\prod_{n>0}(1-e^{n\rho})^{24}).$$

Here ρ is a norm 0 Weyl vector for the reflection group W of $II_{25,1}$, Π^+ is the set of positive roots, which is the set of vectors r of norm at most 2 which are either positive multiples of ρ or have negative inner product with ρ, $p_{24}(1-r^2/2)$ is the multiplicity of the root r and is equal to the number of partitions of the integer $1-(r,r)/2$ into parts of 24 colours, and the simple roots are the norm 2 vectors r with $(r,\rho)=-1$ together with 24 copies of each positive multiple of ρ. This Lie algebra was first constructed in [3], and the properties stated above were proved in [8]; this construction depended heavily on the ideas in Frenkel [15].

The fake monster Lie algebra is acted on by the group $2^{24}.2.Co_1$ in the same way that the monster Lie algebra is acted on by the monster group, and we construct a superalgebra for many elements of $2^{24}.2.Co_1$ from the fake monster Lie algebra in the same way that we construct a superalgebra for every element of the monster from the monster Lie algebra. Some of the more interesting algebras we get in this way are a fake baby monster algebra of rank 18, a fake Fi_{24} Lie algebra of rank 14 associated with Fischer's sporadic simple group Fi_{24}, a fake Co_1 superalgebra of rank 10 associated with Conway's sporadic simple group Co_1, and several Lie algebras of smaller rank corresponding to some of the other sporadic simple groups involved in the monster.

The superalgebra of rank 10 is particularly interesting, so we describe it explicitly. It is the superalgebra associated with an element g of $\mathrm{Aut}(\hat\Lambda)$ which has order 2 and fixes an 8-dimensional sublattice of Λ, isomorphic to the lattice E_8 with all norms doubled. Its root lattice L is the dual of the sublattice of even vectors of $I_{9,1}$, so that L is a nonintegral lattice of determinant 1/4 all of whose vectors have integral norm. We represent vectors of L as triples (v, m, n), where $v \in E_8$ and $m, n \in \mathbf{Z}$, and (v, m, n) has norm $v^2 - 2mn$. The lattice $I_{9,1}$ is then the set of vectors (v, m, n) with $m + n$ even. We let ρ be the norm 0 vector $(0, 0, 1)$. We let the Weyl group W be the subgroup of $\mathrm{Aut}(L)$ generated by the reflections of norm 1 vectors, so that the simple roots of W are the norm 1 vectors r with $(r, \rho) = -1/2$. (Note that W is not the full reflection group of L, as L also has roots of norm 2.)

The simple roots of our superalgebra are the simple roots of W, together with the positive multiples $n\rho$ $(n > 0)$ of ρ, each with multiplicity $8(-1)^n$. Here we use the convention that multiplicity $-k < 0$ means a superroot of multiplicity k, so that the odd multiples of ρ are superroots. In general the vector (v, m, n) is an ordinary root or a superroot depending on whether $m + n$ is even or odd, so the ordinary roots are those in the sublattice $I_{9,1}$ of L.

The multiplicity of the root $r = (v, m, n) \in L$ is equal to

$$\mathrm{mult}(r) = (-1)^{(m-1)(n-1)} p_g((1 - r^2)/2) = (-1)^{m+n} |p_g((1 - r^2)/2)|,$$

where $p_g(n)$ is defined by

$$\sum p_g(n) q^n = q^{-1/2} \prod_{n>0} (1 - q^{n/2})^{-(-1)^n 8}$$

and as before negative multiplicity means a superroot. The denominator formula for this Lie superalgebra is

$$e^\rho \prod_{r \in \Pi^+} (1 - e^r)^{\mathrm{mult}(r)} = \sum_{w \in W} \det(w) w(e^\rho \prod_{n>0} (1 - e^{n\rho})^{(-1)^n 8}).$$

Similarly the denominator formula for the fake baby monster Lie algebra of rank 18 is

$$e^\rho \prod_{r \in L^+} (1 - e^r)^{p_g(1 - r^2/2)} \prod_{r \in 2L'^+} (1 - e^r)^{p_g(1 - r^2/4)} = \sum_{w \in W} \det(w) w(e^\rho \prod_{i>0} (1 - e^{i\rho})^8 (1 - e^{2i\rho})^8)$$

where L is the Lorentzian lattice which is the sum of the 16-dimensional Barnes-Wall lattice Λ_2 [12] and the two dimensional even Lorentzian lattice $II_{1,1}$, W is its reflection group which has Weyl vector ρ, L' is the dual of L and p_g is defined by $\sum_n p_g(n) q^n = \prod_{n>0} (1 - q^n)^{-8} (1 - q^{2n})^{-8}$. This Lie algebra is associated with an element g of order 2 of $\mathrm{Aut}(\hat{\Lambda})$ which fixes a 16-dimensional lattice of Λ isomorphic to the Barnes-Wall lattice.

There are similar Lie superalgebras associated with many other elements of $\mathrm{Aut}(\hat{\Lambda})$, which have denominator formulas similar to those above.

3 Vertex algebras.

We give a brief summary of the facts about vertex algebras that we use and list the properties of the monster vertex algebra that we need. For more information about vertex algebras, see [3], [9], [16], or [18]; the last two references contain proofs of the results quoted here.

A vertex algebra over the real numbers (which is the only case we use in this paper) is a vector space V over the real numbers with an infinite number of bilinear products, written $u_n v$ for $u, v \in V, n \in \mathbf{Z}$, such that

(1) $u_n v = 0$ for n sufficiently large (depending on u and v).

(2)

$$\sum_{i\in\mathbf{Z}} \binom{m}{i} (u_{q+i}v)_{m+n-i}w = \sum_{i\in\mathbf{Z}} (-1)^i \binom{q}{i} (u_{m+q-i}(v_{n+i}w) - (-1)^q v_{n+q-i}(u_{m+i}w))$$

for all u, v, and w in V and all integers m, n and q.

(3) There is an element $1 \in V$ such that $v_n 1 = 0$ if $n \geq 0$ and $v_{-1}1 = v$.

We often think of u_n as a linear map from V to V, taking v to $u_n v$. In [16,18] these operators are combined into the "vertex operator" $V(u, z) = \sum_{n\in\mathbf{Z}} u_n z^{-n-1}$, which is an operator valued formal Laurent series in z.

For example, if V is a commutative algebra over $\mathbf{R}$ with derivation D then we can make it into a vertex algebra by defining $u_n v$ to be $D^{-n-1}(u)v/(-n-1)!$ for $n < 0$ and 0 for $n \geq 0$, and conversely any vertex algebra over $\mathbf{R}$ for which $u_n v = 0$ whenever $n \geq 0$ arises from a commutative algebra in this way. These are the only finite dimensional examples of vertex algebras, and seem to be the only examples which are easy to construct. The vertex algebras we use here do not have this property and are much harder to construct; for example the detailed construction of the monster vertex algebra in [16] takes up most of a rather long book. Fortunately the details of this construction are not important for this paper, so at the end of this section we list the properties of it that we need.

We define the operator D of a vertex algebra by $D(v) = v_{-2}1$. (In [16] and [18] D is denoted by L_{-1}.) The vector space V/DV is a Lie algebra, where the bracket is defined by $[u, v] = u_0 v$ and DV is the image of V under D.

There is a vertex algebra V_L associated with any even lattice L (or more precisely with a certain central extension $\hat{L}$ of L by a group of order 2), which is constructed in [3]. The underlying vector space of this vertex algebra is the tensor product of the twisted group ring $Q(\hat{L})$ of the double cover $\hat{L}$ of L (see section 12) and the ring of polynomials $S(\oplus_{i>0} L_i)$ over the sum of an infinite number of copies L_i of $L \otimes \mathbf{R}$. We often use the vertex algebra $V_{II_{1,1}}$ of the 2-dimensional even unimodular Lorentzian lattice $II_{1,1}$. There is also a monster vertex algebra V ([3], [16]) which is acted on naturally by the monster sporadic simple group. (The referee has asked me to explain why I have never published my (long and messy) proof of the assertion in [3] that the module V constructed in [17] has the structure of a vertex algebra. The reason is that my proof used many results from the announcement [17], and the only published proof of this announcement, given in the book [16], incorporates the fact that V is a vertex algebra.) The underlying vector space of the monster vertex algebra is a graded vector space $V = \oplus_{n\in\mathbf{Z}} V_n$, with homogeneous pieces of dimensions 1, 0, 196884, ... equal to the coefficients of the elliptic modular function $j(q) - 744$.

A conformal vector of dimension (or "central charge") $c \in \mathbf{R}$ of a vertex algebra V is defined to be an element ω of V such that $\omega_0 v = D(v)$ for any $v \in V$, $\omega_1 \omega = 2\omega$,

$\omega_3\omega = c/2$, $\omega_i\omega = 0$ if $i = 2$ or $i > 3$, and any element of V is a sum of eigenvectors of the operator $L_0 = \omega_1$ with integral eigenvalues. If v is an eigenvector of L_0, then its eigenvalue is called the (conformal) weight of v. If v is an element of the monster vertex algebra V of conformal weight n, we sometimes say that v has degree $n - 1$ $(= n - c/24)$.

The vertex algebra of any c-dimensional even lattice has a canonical conformal vector of dimension c, and the monster vertex algebra has a conformal vector of dimension 24. If ω is a conformal vector of a vertex algebra V then we define operators L_i on V for $i \in \mathbf{Z}$ by

$$L_i = \omega_{i+1}.$$

These operators satisfy the relations

$$[L_i, L_j] = (i-j)L_{i+j} + \binom{i+1}{3}\frac{c}{2}\delta^i_{-j}$$

and so make V into a module over the Virasoro algebra. The operator L_{-1} is equal to D. We define the space P^i to be the space of vectors $w \in V$ such that $L_0(w) = iw$, $L_i(w) = 0$ if $i > 0$. The space $P^1/(DV \cap P^1)$ is a subalgebra of the Lie algebra V/DV, which is equal to P^1/DP^0 for the vertex algebras we use in this paper.

The vertex algebra of any even lattice and the monster vertex algebra both have a real valued symmetric bilinear form (,) such that the adjoint of the operator u_n is $(-1)^i \sum_{j\geq 0} L_1^j(\omega(u))_{2i-j-n-2}/j!$ if u has degree i, where ω is the automorphism of the vertex algebra defined by $\omega(e^w) = (-1)^{(w,w)/2}(e^w)^{-1}$ for e^w an element of the twisted group ring of L corresponding to the vector $w \in L$, or is 1 in the case of the monster vertex algebra. (There is an unfortunate clash of notation here, because ω is the standard notation for both the conformal vector and the Cartan automorphism of a Lie algebra. If L is the root lattice of a finite dimensional Lie algebra of type A_n, D_n, E_6, E_7, or E_8 then the Lie algebra is a subalgebra of the vertex algebra of L and the involution ω defined above restricts to the Cartan automorphism of the Lie algebra.) If a vertex algebra has a bilinear form with the properties above we say that the bilinear form is compatible with the conformal vector.

Frenkel, Lepowsky, and Meurman [16] use "vertex operator algebras", rather than vertex algebras, so we explain what the difference is. A vertex operator algebra is a vertex algebra with a conformal vector such that the eigenspaces of L_0 are all finite dimensional with nonnegative integral eigenvalues. For example, the monster vertex algebra is a vertex operator algebra. (Its conformal vector spans the subspace of V_1 fixed by the monster.) The vertex algebras used in this paper all have conformal vectors but the eigenspaces of L_0 are not always finite dimensional. An example of a vertex algebra without these properties is the vertex algebra $V_{II_{1,1}}$ of the 2-dimensional even unimodular Lorentzian lattice $II_{1,1}$.

If V and W are vertex algebras, then their tensor product $V \otimes W$ as vector spaces is also a vertex algebra, if $(a \otimes b)_n(c \otimes d)$ is defined to be $\sum_{i\in\mathbf{Z}}(a_ic) \otimes (b_{n-1-i}d)$ and the identity 1 is defined to be $1 \otimes 1$. (See [18].) If V and W have conformal vectors ω_V and ω_W of dimensions m and n then $\omega_V \otimes 1 + 1 \otimes \omega_W$ is a conformal vector of $V \otimes W$ of dimension $m + n$. If V and W have bilinear forms compatible with the conformal vectors then so does $V \otimes W$; in fact the obvious bilinear form on the tensor product will do.

The monster vertex algebra V [3, 16] is a vertex algebra acted on by the monster. The construction given in [16] is rather long, but fortunately we do not need to know many details of its construction. We list the three properties of it we do use, in case anyone finds a simpler construction of it that they wish to prove also satisfies Conway and Norton's moonshine conjectures.

(1) V is a vertex algebra over $\mathbf{R}$ with a conformal vector ω of dimension 24 and a positive definite bilinear form such that the adjoint of u_n is given by the expression above (with the automorphism ω acting trivially).

(2) V is a sum of eigenspaces V_i of the operator L_0, where V_i is the eigenspace on which L_0 has eigenvalue $i+1$, and the dimension of V_i is given by $\sum \dim(V_i)q^i = j(q) - 744 = q^{-1} + 196884q + \ldots$.

These two conditions turn out to imply that if g is any automorphism of V preserving the vertex algebra structure, the conformal vector and the bilinear form then $\sum \mathrm{Tr}(g|V_i)q^i$ is a completely replicable function (which means that identity (8.3) holds).

(3) The monster simple group acts on V, preserving the vertex algebra structure, the conformal vector ω and the bilinear form. The first few representations V_i of the monster (after $V_{-1} = \chi_1$, $V_0 = 0$) decompose as $V_1 = \chi_1 + \chi_2$, $V_2 = \chi_1 + \chi_2 + \chi_3$, $V_3 = 2\chi_1 + 2\chi_2 + \chi_3 + \chi_4$, $V_5 = 4\chi_1 + 5\chi_2 + 3\chi_3 + 2\chi_4 + \chi_5 + \chi_6 + \chi_7$ where χ_i, $1 \leq i \leq 7$ are the first seven irreducible representations of the monster, indexed in order of increasing dimension.

The construction of the vector space V and the action of the monster on it, preserving a small part of the vertex algebra structure, were announced in [17], and the vertex algebra structure was announced in [3]. The results quoted above have all been proved in [16] and [18], apart from the explicit description of the representations in (3). We show in section 9 that condition (3) can be proved using the explicit description in [16] of the traces of certain elements of the monster acting on V. In the course of proving theorem 1.1 we show that these three conditions characterize V as a graded representation of the monster.

4 Generalized Kac-Moody algebras

We summarize the results about generalized Kac-Moody algebras that we use, which can be found in [4], [5], [20], and the third edition of Kac's book [23]. We modify the original definition of generalized Kac-Moody algebras in [4] slightly so that these algebras are closed under taking universal central extensions, as in [5]. (This is not necessary for the proof of theorem 1.1, but makes the converse to theorem 4.1 slightly neater.) All Lie algebras are Lie algebras over the reals.

A Lie algebra G is defined to be a (split) generalized Kac-Moody algebra if it has an almost positive definite contravariant bilinear form, which means that G has the following three properties.

1. G can be $\mathbf{Z}$-graded as $G = \oplus_{i\in\mathbf{Z}} G_i$ and G_i is finite dimensional if $i \neq 0$.
2. G has an involution ω which maps G_i into G_{-i} and acts as -1 on G_0, so in particular G_0 is abelian.
3. G has an invariant bilinear form (,) invariant under ω such that G_i and G_j are orthogonal if $i \neq -j$, and such that $-(g, \omega(g)) > 0$ if g is a nonzero homogeneous element of G of nonzero degree.

The bilinear form $(,)_0$ defined by $(a,b)_0 = -(a,\omega(b))$ is called the contravariant bilinear form of G, and is positive definite on G_i if $i \neq 0$. For example any finite dimensional split semisimple Lie algebra over the reals has these properties, with ω equal to a Cartan involution, (,) equal to the Killing form, and the grading determined by the eigenvalues of some suitably normalized regular element. (If the contravariant bilinear form on G is positive semidefinite, then G is essentially a sum of affine, Heisenberg, and finite dimensional simple split Lie algebras.) In general the contravariant form can be indefinite on G_0. For the algebras we use in this paper the subalgebra G_0 has a vector such that the contravariant form is positive semidefinite on its orthogonal complement.

Suppose that $a_{ij}, i,j \in I$ is a symmetric countable (possibly infinite) real matrix such that $a_{ij} \leq 0$ if $i \neq j$ and such that if $a_{ii} > 0$ then $2a_{ij}/a_{ii}$ is an integer for any j. Then the universal generalized Kac-Moody algebra G of this matrix is defined to be the Lie algebra generated by elements e_i, f_i, h_{ij} for $i,j \in I$ satisfying the following relations. (It is true but not obvious that any universal generalized Kac-Moody algebra is a generalized Kac-Moody algebra; this fact is not needed in this paper.)

1. $[e_i, f_j] = h_{ij}$
2. $[h_{ij}, e_k] = \delta_i^j a_{ik} e_k, [h_{ij}, f_k] = -\delta_i^j a_{ik} f_k$
3. If $a_{ii} > 0$ and $i \neq j$ then $\mathrm{ad}(e_i)^n e_j = \mathrm{ad}(f_i)^n f_j = 0$, where $n = 1 - 2a_{ij}/a_{ii}$.
4. If $a_{ii} \leq 0, a_{jj} \leq 0$ and $a_{ij} = 0$ then $[e_i, e_j] = [f_i, f_j] = 0$.

We often write h_i for h_{ii}. There is a unique invariant bilinear form on this algebra such that $(e_i, f_j) = \delta_i^j$; this implies that $(h_i, h_j) = a_{ij}$.

Remark. If $a_{ii} > 0$ for all $i \in I$ then this algebra is the same as the Kac-Moody algebra with symmetrized Cartan matrix a_{ij}. In general these algebras have almost all the properties that Kac-Moody algebras have, and the only major difference is that generalized Kac-Moody algebras are allowed to have imaginary simple roots.

The main theorem about generalized Kac-Moody algebras [4,5] says that they can all be obtained from universal generalized Kac-Moody algebras.

Theorem 4.1. *Suppose that G is a generalized Kac-Moody algebra with some given grading, involution ω and bilinear form (,). Then there is a unique universal generalized Kac-Moody algebra, graded by putting* $\deg(e_i) = -\deg(f_i) = n_i$ *for some positive integers n_i, with a homomorphism f (not necessarily unique) to G such that*

(1) f preserves the gradings, involutions and bilinear forms (where the universal generalized Kac-Moody algebra is given the grading, involution and bilinear form defined above).

(2) The kernel of f is in the centre of the universal generalized Kac-Moody algebra (which is contained in the abelian subalgebra spanned by the elements h_{ij}).

(3) The image of f is an ideal of G, and G is the semidirect product of this subalgebra and a subalgebra of the abelian subalgebra G_0. Moreover the images of all the generators e_i and f_i are eigenvectors of G_0.

Remark. The converse of this theorem is also true (but not needed here): any universal generalized Kac-Moody algebra with a countable number of simple roots is a generalized Kac-Moody algebra. (The proof of this converse in [4] contains a gap which was pointed out and corrected by Kac in [23].) Theorem 4.1 says that we can construct any generalized

Kac-Moody algebra from some universal generalized Kac-Moody algebra by factoring out some of the centre and adding a commuting algebra of outer derivations.

We list some of the properties of universal generalized Kac-Moody algebras G from [4] and [5], many of which are also proved in the third edition of [23].

(1) The element h_{ij} is 0 unless the i'th and j'th columns of a are equal. The elements h_{ij} for which the i'th and j'th columns of a are equal form a basis for an abelian subalgebra H of G, called its Cartan subalgebra. In the case of Kac-Moody algebras, the i'th and j'th columns of a cannot be equal unless $i = j$, so the only nonzero elements h_{ij} are those of the form h_{ii}, which are usually denoted by h_i. Every nonzero ideal of G has nonzero intersection with H. The centre of G is contained in H and contains all the elements h_{ij} for $i \neq j$.

(2) The root lattice is defined to be the free abelian group generated by elements r_i for $i \in I$, with the bilinear form given by $(r_i, r_j) = a_{ij}$. The elements r_i are called the simple roots. The universal generalized Kac-Moody algebra is graded by the root lattice if we let e_i have degree r_i and f_i have degree $-r_i$. There is a natural homomorphism of abelian groups from the root lattice to the Cartan subalgebra H taking r_i to h_i which preserves the bilinear forms. If r is in the root lattice then the vector space of elements of the Lie algebra of that degree is called the root space of r; if r is nonzero and has a nonzero root space then r is called a root of the generalized Kac-Moody algebra. A root r is called positive if it is a sum of simple roots, and negative otherwise. It is called real if it has positive norm (r, r) and imaginary otherwise.

(3) The Weyl vector ρ is the additive map from the root lattice to $\mathbf{R}$ taking r_i to $-(r_i, r_i)/2$ for all $i \in I$. (This is the opposite sign from the usual definition.) We write its value on a root r as (ρ, r). The fundamental Weyl chamber (which we call the Weyl chamber for short, because it is the only one we use) is the set of vectors v of the Cartan subalgebra H with $(v, r_i) \leq 0$ for all real simple roots r_i, where we identify real simple roots with their images in H. (There is a misprint in the definition of Weyl chamber in [4]; the word "real" in "real simple roots" was omitted.)

Remark. The reason why we use nonstandard sign conventions for the Weyl vector and Weyl chamber is that we are using the convention that "everything should be in the Weyl chamber if possible". We want the imaginary simple roots to be in the Weyl chamber which forces us to use the opposite Weyl chamber from usual; similarly we change the sign of the Weyl vector to get it (or rather its image in H, when this exists) in the Weyl chamber, and we use lowest weight modules (rather than highest weight modules) because their lowest weights are in the Weyl chamber. For most of the generalized Kac-Moody algebras in this paper the Cartan subalgebra has a Lorentzian bilinear form, so that the vectors of norm at most 0 form two solid cones; our sign conventions usually make all the interesting vectors of norm at most 0 lie in the same solid cone.

(4) If a has no zero columns then G is perfect and equal to its own universal central extension. If a is not the direct sum of two smaller matrices, not the 1×1 zero matrix, and not the matrix of an affine Kac-Moody algebra, then G modulo its centre is simple.

(5) Suppose we choose a positive integer n_i for each $i \in I$. Then we can grade G by putting $\deg(e_i) = -\deg(f_i) = n_i$. The degree 0 piece of G is the Cartan subalgebra H.

(6) G has an involution ω with $\omega(e_i) = -f_i, \omega(f_i) = -e_i$, called the Cartan involution.

There is a unique invariant bilinear form $(,)$ on G such that $(e_i, f_i) = 1$ for all i, and it also has the property that $-(g, \omega(g)) > 0$ whenever g is a homogeneous element of nonzero degree. In particular the universal generalized Kac-Moody algebra of any matrix as above is a generalized Kac-Moody algebra.

(7) There is a character formula for the simple lowest weight module M_λ of G with a lowest weight λ in the real vector space of the root lattice such that $(\lambda, r_i) \leq 0$ for $i \in I$ and $2(\lambda, r_i)/(r_i, r_i)$ is integral if the simple root r_i is real. This states that

$$Ch(M_\lambda)e^\rho \prod_{\alpha>0}(1-e^\alpha)^{\mathrm{mult}(\alpha)} = \sum_{w\in W} \det(w) w(e^\rho \sum_\alpha \epsilon(\alpha) e^{\alpha+\lambda})$$

The only case of this we need is for the trivial one dimensional module with $\lambda = 0$, when it becomes the denominator formula

$$e^\rho \prod_{\alpha>0}(1-e^\alpha)^{\mathrm{mult}(\alpha)} = \sum_{w\in W} \det(w) w(e^\rho \sum_\alpha \epsilon(\alpha) e^{\alpha})$$

Here ρ is the Weyl vector, $\alpha > 0$ means α is a positive root, and W is the Weyl group, which is the group of isometries of the root lattice generated by the reflections corresponding to the real simple roots. If $w \in W$ then $\det(w)$ is defined to be $+1$ or -1 depending on whether w is the product of an even or odd number of reflections; if the root lattice is finite dimensional this is just the usual determinant of w acting on it. We define $\epsilon(\alpha)$ for α in the root lattice to be $(-1)^n$ if α is the sum of a set of n pairwise orthogonal imaginary simple roots that are all orthogonal to λ, and 0 otherwise. If G is a Kac-Moody algebra then there are no imaginary simple roots so the sum over α is 1 and we recover the usual character and denominator formulas.

If we have a generalized Kac-Moody algebra G then we choose some universal generalized Kac-Moody algebra mapping to G as in theorem 4.1, and call the Weyl group, root lattice, and so on of the universal generalized Kac-Moody algebra the Weyl group, root lattice and so on of G.

For the generalized Kac-Moody algebras in this paper, the Cartan subalgebra H is usually finite dimensional and its bilinear form is nonsingular. We often think of roots of G as vectors of H by using the natural map from the root lattice to H, taking r_i to h_i. We will often abuse terminology and call the corresponding vectors of H roots. The map from the set of roots to H is not usually injective, so we need to make a few comments to clarify what happens. It is possible for $n > 1$ imaginary simple roots to have the same image r in H; when this happens we say that r is a simple root of multiplicity n. (In general it is possible for the same vector of H to be the image of simple and nonsimple roots, but this does not happen for the Lie algebras in this paper.) The simple roots in H are usually linearly dependent so in general there is no reason why there should exist a Weyl vector ρ in H such that $(\rho, r_i) = -r_i^2/2$ for all real simple roots r_i; however such a vector ρ does exist for the Lie algebras in this paper.

The denominator formula also needs an obvious modification if we think of the roots as elements of H. If a simple root has multiplicity $n > 1$ then the "set" of simple roots should include n copies of it, i.e., the "set" of simple roots is really a "multiset" rather than a set. (A multiset is a "set which may contain several copies of the same object", or more precisely a map from a set to the positive integers.) The expression $\epsilon(\alpha)$ in the character formula is then the sum of terms $(-1)^n$ for all ways of writing α as a sum of a "set" (or more precisely a multiset) of pairwise orthogonal imaginary simple roots that are all orthogonal to λ. For example, if there is only one simple root r of norm 0 and multiplicity n, then $\epsilon(ir) = \binom{n}{i}(-1)^i$ because there are $\binom{n}{i}$ ways of writing ir as a sum of a multiset of pairwise orthogonal simple roots.

Remark. Most of these results can be extended to superalgebras with little difficulty, provided that we interpret roots of negative multiplicity as being "superroots". The only extra detail worth pointing out is that we have to add the condition that all simple superroots are imaginary (and not real). For example, many of the finite dimensional superalgebras are generalized Kac-Moody superalgebras with simple superroots of norm 0. Warning: The Cartan matrix of a finite dimensional superalgebra may depend on the $\mathbf{Z}$-grading chosen.

Any generalized Kac-Moody algebra can be written as a direct sum $E\oplus H\oplus F$ of subalgebras, where H is the Cartan subalgebra and E and F are the subalgebras corresponding to the positive and negative roots. The standard sequence

$$\ldots \to \Lambda^2(E) \to \Lambda^1(E) \to \Lambda^0(E) \to 0$$

whose homology groups are those of the Lie algebra E [10] shows that $\Lambda(E) = H(E)$, where $\Lambda(E)$ is the virtual vector space $\Lambda^0(E)\ominus\Lambda^1(E)\oplus\Lambda^2(E)\ldots$ formed from the alternating sum of the exterior powers of E, and $H(E)$ is the virtual vector space $H_0(E)\ominus H_1(E)\oplus H_2(E)\ldots$ formed from the alternating sum of the homology groups of E with real coefficients. If L is the root lattice of M, then both sides are L-graded virtual vector spaces whose homogeneous pieces are finite dimensional, so these infinite sums are meaningful.

The denominator formula for any generalized Kac-Moody algebra follows from the fact that $\Lambda(E) = H(E)$ as virtual L-graded vector spaces. The character of $\Lambda(E)$ is a product over positive roots. In the case of ordinary Kac-Moody algebras the vector space $H_i(E)$ has a basis corresponding to the elements of the Weyl group of length i, so the character of $H(E)$ is a sum over the Weyl group. If we work out everything explicitly we obtain the denominator formula

$$e^\rho \prod_{\alpha>0}(1-e^\alpha)^{\mathrm{mult}(\alpha)} = \sum_{w\in W}\det(w)w(e^\rho)$$

for Kac-Moody algebras, and a similar but slightly more complicated calculation gives the denominator formula for generalized Kac-Moody algebras. For Kac-Moody algebras this calculation is carried out in Garland and Lepowsky [20] and most of their methods and results apply to generalized Kac-Moody algebras with only minor changes. They obtain a more general result which not only gives the character formula of any highest weight module, but also works if E is replaced by various other radicals of parabolic subalgebras. We do not need these more general results, but they are easily extended to the case of generalized Kac-Moody algebras.

The groups $H_i(E)$ can be calculated for generalized Kac-Moody algebras in the same way that they are calculated for ordinary Kac-Moody algebras in Garland and Lepowsky

[20]. The result we get is that $H_i(E)$ is the subspace of $\Lambda^i(E)$ spanned by the homogeneous vectors of $\Lambda^i(E)$ whose degrees $r \in L$ satisfy $(r+\rho)^2 = \rho^2$. The degree r of any homogeneous vector of $\Lambda^i(E)$ satisfies $(r+\rho)^2 \leq \rho^2$, so $H_i(E)$ can be thought of as a sort of boundary of $\Lambda^i(E)$. These homology groups are easy to work out for any generalized Kac-Moody algebra, provided that we know the simple roots and their multiplicities. For the monster Lie algebra, we carry out this calculation in section 8.

In practice it is sufficient to know the subspace of $H(E)$ of elements whose degree r has the property that $r+\rho$ is in the fundamental Weyl chamber. This subspace is isomorphic to the subspace of $\Lambda(E)$ of all elements that can be written in the form $e_1 \wedge e_2 \wedge \ldots$ where the e_i's are vectors in the root spaces of pairwise orthogonal imaginary simple roots, so that the character of this subspace is just the sum $\sum_\alpha \epsilon(\alpha)e^\alpha$ that appears in the denominator formula. There is a similar description of the homology groups of E with coefficients in any lowest weight module which can be used to prove the character formula for lowest weight modules, but we do not use this.

5 The no-ghost theorem

We prove a slight extension of the no-ghost theorem. The idea of using the no-ghost theorem to prove results about Kac-Moody algebras appears in Frenkel's paper [15], which also contains a proof of the no-ghost theorem. The original proof of Goddard and Thorn [21] works for the cases we need with only trivial modifications. For convenience we give a quick sketch of their proof.

Theorem 5.1. *(The no-ghost theorem.) Suppose that V is a vector space with a nonsingular bilinear form (,) and suppose that V is acted on by the Virasoro algebra in such a way that the adjoint of L_i is L_{-i}, the central element of the Virasoro algebra acts as multiplication by 24, any vector of V is a sum of eigenvectors of L_0 with nonnegative integral eigenvalues, and all the eigenspaces of L_0 are finite dimensional. We let V^i be the subspace of V on which L_0 has eigenvalue i. Assume that V is acted on by a group G which preserves all this structure. We let $V_{II_{1,1}}$ be the vertex algebra of the double cover $\hat{I}I_{1,1}$ of the two dimensional even unimodular Lorentzian lattice $II_{1,1}$ (so that $V_{II_{1,1}}$ is $II_{1,1}$-graded, has a bilinear form (,), and is acted on by the Virasoro algebra as in section 3). We let P^1 be the subspace of the vertex algebra $V \otimes V_{II_{1,1}}$ of vectors v with $L_0(v) = v, L_i(v) = 0$ for $i > 0$, and we let P^1_r be the subspace of P^1 of degree $r \in II_{1,1}$. All these spaces inherit an action of G from the action of G on V and the trivial action of G on $V_{II_{1,1}}$ and $\mathbf{R}^2$. Then the quotient of P^1_r by the nullspace of its bilinear form is naturally isomorphic, as a G module with an invariant bilinear form, to $V^{1-(r,r)/2}$ if $r \neq 0$ and to $V^1 \oplus \mathbf{R}^2$ if $r = 0$.*

The name "no-ghost theorem" comes from the fact that in the original statement of the theorem in [21], V was part of the underlying vector space of the vertex algebra of a positive definite lattice so the inner product on V^i was positive definite, and thus P^1_r had no ghosts (i.e. vectors of negative norm) for r nonzero. The space V^i is the space V_{i-1} used in the rest of this paper.

Sketch of proof (taken from Goddard and Thorn, [21]). Fix some nonzero $r \in II_{1,1}$ and some norm 0 vector w in $II_{1,1}$ with $(r,w) \neq 0$.

We use the following operators. We have an action of the Virasoro algebra on $V \otimes V_{II_{1,1}}$ generated by its conformal vector. The operators L_i of the Virasoro algebra satisfy the relations

$$[L_i, L_j] = (i-j)L_{i+j} + 26(i^3 - i)\delta^i_{-j}/12.$$

and the adjoint of L_i is L_{-i}. (The 26 comes from the 24 in theorem 5.1 plus the dimension of $II_{1,1}$.) We define operators K_i, $i \in \mathbf{Z}$ by $K_i = v_{i-1}$ where v is the element $e^{-w}_{-2}e^w$ of the vertex algebra of $II_{1,1}$, and e^w is an element of the group ring of the double cover of $II_{1,1}$ corresponding to $w \in II_{1,1}$ and e^{-w} is its inverse. (There are in fact two possible choices for e^w which differ by a factor of -1, but it does not matter which we choose because this factor of -1 cancels out in the expression $e^{-w}_{-2}e^w$.) These operators satisfy the relations

$$\begin{aligned}[L_i, K_j] &= -jK_{i+j}\\ [K_i, K_j] &= 0\end{aligned}$$

because w has norm 0, and the adjoint of K_i is K_{-i}.

We define the following subspaces of $V \otimes V_{II_{1,1}}$.

H is the subspace of $V \otimes V_{II_{1,1}}$ of degree $r \in II_{1,1}$. H^1 is its subspace of vectors h with $L_0(h) = h$.
P, is the subspace of H of all vectors h with $L_i(h) = 0$ for $i > 0$. $P^1 = H^1 \cap P$.
S, the space of spurious vectors, is the subspace of H of vectors perpendicular to P. $S^1 = H^1 \cap S$.
N $= S \cap P$ is the radical of the bilinear form of P, and $N^1 = H^1 \cap N$.
T, the transverse space, is the subspace of P annihilated by all the operators $K_i, i > 0$, and $T^1 = H^1 \cap T$.
K is the space generated by the action of the operators $K_i, i \in \mathbf{Z}$ on T.
Ve^r is the subspace $V \otimes e^r$ of H.

We have the following inclusions of subspaces of H:

$$\begin{tikzcd}
S & & P & & K & \\
& N \arrow[ul] \arrow[ur] & & T \arrow[ul] \arrow[ur] & & Ve^r \arrow[ul]
\end{tikzcd}$$

and we construct the isomorphism from $V^{1-(r,r)/2}$ to $P^1/N \cap P^1$ by zigzagging up and down this diagram; more precisely we show that Ve^r and T are both isomorphic to K modulo its nullspace, and then we show that T^1 is isomorphic to P^1 modulo its nullspace $P^1 \cap N$.

Lemma 5.1. *If f is a vector of nonzero norm in T then the vectors of the form*

$$L_{m_1}L_{m_2}\ldots K_{n_1}K_{n_2}\ldots(f)$$

for all sequences of integers with $0 > m_1 \geq m_2 \ldots$, $0 > n_1 \geq n_2 \ldots$ are linearly independent and span a space invariant under the operators K_i and L_i on which the bilinear form is nonsingular.

Sketch of proof: It is possible to order these elements so that the matrix of inner products is upper triangular with nonzero diagonal elements. This implies that they are independent and span a space on which the inner product is nonsingular. The other statements in the lemma are easy to prove.

Lemma 5.2. *The bilinear form on T is nonsingular, and K is the direct sum of T and the nullspace of K.*

Proof. If we choose an orthogonal basis for T, then the set of all vectors generated from them as in Lemma 5.1 is a basis for H. As H is nonsingular, T must therefore also be nonsingular. It now follows that K is the direct sum of its nullspace and T, because K is generated from T by the operators K_i and anything generated from T by these operators is in the nullspace of K.

Lemma 5.3. *Ve^r is naturally isomorphic to T.*

Proof. K is also the subspace of H annihilated by all the operators K_i, $i > 0$ from which it follows that K is the direct sum of Ve^r and the nullspace of K. By lemma 5.2 K is also the direct sum of T and the nullspace of K, so this gives a natural isomorphism from Ve^r to T, because they are both isomorphic to the quotient of K by its nullspace.

Lemma 5.4. *The associative algebra generated by the elements L_i for $i < 0$ is generated by elements mapping S^1 into S.*

Proof. Calculation shows that the operators L_{-1} and $L_{-2}+3L_{-1}^2/2$ have this property, and they generate the algebra generated by all L_i's with $i < 0$. (It is in doing these calculations that we need to use the fact that the center of the Virasoro algebra acts as 24 on V and therefore as 26 on H.)

Lemma 5.5. *P^1 is the direct sum of T^1 and N^1.*

Proof. We have to show that any vector p of P^1 can be written as $p = t+n$ for $t \in T^1$, $n \in N^1$. By lemma 5.3, $p = k + s$ for some unique $k \in K^1$, $s \in S^1$ and by lemma 5.4 k and s are both mapped into K and S by some set of generators of the algebra generated by the L_i's, $i > 0$. As these generators annihilate p, they must also annihilate k and s. Hence k is in $K^1 \cap P^1 = T^1$ and s is in $S^1 \cap P^1 = N^1$, so that $P^1 = T^1 \oplus N^1$.

The no ghost theorem now follows immediately, because by lemma 5.3 $V^{1-(r,r)/2}e^r$ is isomorphic to T^1, and by lemma 5.5 T^1 is isomorphic to the quotient of P^1 by its nullspace.

6 Construction of the Monster Lie algebra.

We construct the monster Lie algebra M in the proof of the following theorem. This is a generalized Kac-Moody algebra acted on by the monster simple group and graded by $II_{1,1} = \mathbf{Z}^2$. Recall that V is the vertex algebra of the monster, so that V is graded with pieces of dimensions 1, 0, 196884, ... , and $V_{II_{1,1}}$ is the vertex algebra of the two dimensional even Lorentzian lattice $II_{1,1}$ with matrix $\left(\begin{smallmatrix}0 & -1\\ -1 & 0\end{smallmatrix}\right)$.

Theorem 6.1. *There exists a Lie algebra M, which we will call the monster Lie algebra, with the following properties.*

(1) M is $II_{1,1}$-graded.

(2) M has a contravariant bilinear form $(,)_0$ which is positive definite on the piece of degree $(m,n) \neq (0,0)$. (By "contravariant bilinear form" we mean that the $II_{1,1}$-graded Lie algebra M has an involution ω which acts as -1 on $II_{1,1}$ and as -1 on

the piece of degree (0,0), such that the form $(u, v) = -(u, \omega(v))_0$ is invariant, and $(u, v) = 0$ unless $\deg(u) + \deg(v) = 0$.)

(3) M is acted on by the monster. As a representation of the monster, the piece of M of degree (m, n) is isomorphic to V_{mn} if $(m, n) \neq (0, 0)$, and to the trivial representation $\mathbf{R}^2$ if $(m, n) = (0, 0)$ where V_n is the piece of the monster vertex algebra V of conformal weight $n + 1$.

Proof. The tensor product $V \otimes V_{II_{1,1}}$ of the vertex algebras V and $V_{II_{1,1}}$ is also a vertex algebra. If P^i is the space of vectors v of this vertex algebra satisfying $L_j(v) = 0$ if $j > 0$, $L_0(v) = v$, then P^1/DP^0 is a Lie algebra with an invariant bilinear form (,), and an involution ω induced by the trivial automorphism of V and the involution ω of $V_{II_{1,1}}$ defined in section 3. We define the monster Lie algebra M to be the quotient of the Lie algebra P^1/DP^0 by the kernel of the form (,). (The kernel of the bilinear form on P^1 is strictly larger than DP^0.)

The $II_{1,1}$ grading of the vertex algebra $V_{II_{1,1}}$ induces a $II_{1,1}$ grading on the Lie algebra M. The no-ghost theorem 5.1 implies that the piece of M of degree $(m, n) \in II_{1,1}$ is isomorphic to the piece of V of degree $1 - (m, n)^2/2 = 1 - mn$ if $v \neq 0$ and to $\mathbf{R}^2$ if $v = 0$, and that $(g, \omega(g)) > 0$ if $g \in M$ is nonzero and homogeneous of nonzero degree in $II_{1,1}$. This proves theorem 6.1.

Remark. The construction of a Lie algebra from a vertex algebra in theorem 6.1 can be carried out for any vertex algebra V with a conformal vector, but it is only when this vector has dimension 24 that we can apply the no-ghost theorem to identify the homogeneous pieces of M with those of V. The important point is that the bilinear form on M is positive definite on any piece of nonzero degree, and this need not be true if the conformal vector has dimension greater than 24, even if the inner product on V is positive definite.

Theorem 6.2. *The monster Lie algebra M is a generalized Kac-Moody algebra.*

Proof: This follows from theorem 6.1. The only condition in the definition of a generalized Kac-Moody algebra that is not immediately obvious from the conclusion of theorem 6.1 is the one about the $\mathbf{Z}$-grading of M. We can $\mathbf{Z}$-grade M in a suitable way by letting elements of M of degree $(m, n) \in II_{1,1}$ have degree $2m + n \in \mathbf{Z}$.

Remark. If V_L is the vertex algebra of any positive definite even lattice L of dimension at most 24 then the bilinear form on the corresponding Lie algebra M_L is still almost positive definite, so M_L is a generalized Kac-Moody algebra. If V_Λ is the vertex algebra of the Leech lattice Λ then M_Λ is (by definition) the fake monster Lie algebra, and its simple roots are described explicitly in [8] (where it is called the monster Lie algebra, or more precisely proved to be isomorphic to something called the monster Lie algebra there). Section 12 contains a summary of results about the fake monster Lie algebra. I have not found any other lattices for which the simple roots of the corresponding Lie algebra can be found explicitly, although for the lattice $E_8 \oplus E_8$ all the simple roots of norm 0, -2, or -4 have multiplicity 0 or 1 so there may be something interesting going on in this case. There are some calculations for the case when V_L is the vertex algebra of $L = E_8$ in Kac, Moody and Wakimoto [24].

The monster Lie algebra can also be constructed as a semi-infinite cohomology group; see [19].

The construction of the monster Lie algebra above looks bizarre at first sight, so we briefly explain some of the motivation behind it. The fake monster vertex algebra M_Λ [8] is the Lie algebra P^1/(kernel of bilinear form) of the vertex algebra of the lattice $II_{25,1}$. This lattice is the sum of the Leech lattice Λ and the lattice $II_{1,1}$, and the vertex algebra of the sum of two lattices Λ and $II_{1,1}$is the tensor product of the vertex algebras V_Λ and $V_{II_{1,1}}$ of the lattices, so the fake monster Lie algebra is the space P^1/kernel of $V_\Lambda \otimes V_{II_{1,1}}$. The monster vertex algebra V is similar to the vertex algebra V_Λ, which suggests replacing V_Λ by V in the construction above, and this gives the monster Lie algebra M.

7 The simple roots of the monster Lie algebra.

We find the simple roots of the monster Lie algebra M constructed in section 6. This algebra turns out to have a Weyl vector, i.e., a vector ρ with $(\rho, r) = -(r,r)/2$ for all simple roots r.

We find the simple roots of the monster Lie algebra by using the following identity, which turns out to be its denominator formula.

Lemma 7.1.

$$p^{-1}\prod_{\substack{m>0\\ n\in\mathbf{Z}}}(1-p^mq^n)^{c(mn)} = j(p)-j(q) \tag{7.1}$$

where $j(q)-744 = \sum_n c(n)q^n = q^{-1}+196884q+\ldots$.

Proof. This is essentially just lemma 2 of section 4 of [8]. For convenience we recall the proof. If we multiply the left hand side by p and take its logarithm we get

$$\begin{aligned}
&-\sum_{m>0}\sum_{n\in\mathbf{Z}}\sum_{k>0} c(mn)p^{mk}q^{nk}/k\\
=&-\sum_{m>0}\sum_{n\in\mathbf{Z}}\sum_{0<k|(m,n)}\frac{1}{k}c(\frac{mn}{k^2})p^mq^n\\
=&-\sum_{m>0}T_m(\sum_{n\in\mathbf{Z}}c(n)q^n)p^m\\
=&-\sum_{m>0}T_m(j(q)-744)p^m\\
=&\sum_{m>0}f_m(q)p^m
\end{aligned}$$

where T_m is the m'th Hecke operator (see Serre [30] proposition 12, chapter VII, section 5) and each f_m is a modular function of level 1, holomorphic on the upper half plane, and therefore a polynomial in $j(q)$. If we exponentiate this we see that the left hand side of 7.1 is of the form $\sum_{m\geq -1} g_m(q)p^m$ where each g_m is a polynomial in $j(q)$. Each coefficient of p^m of the right hand side of (7.1) is either a constant (if $m\neq 0$) or $744-j(q)$ (if $m=0$) and is therefore also a polynomial in $j(q)$. Any polynomial in $j(q)$ is determined by its coefficients of q^n for $n\leq 0$, so to prove the lemma it is sufficient to check that the coefficients of $q^n, n\leq 0$ of both sides are the same, which is easy to do. This proves lemma 7.1.

Remark. The infinite product in (7.1) converges if $|p|, |q| < e^{-2\pi}$ and $p \neq q$, and the infinite series for $j(q)$ converges if $|q| < 1$.

Theorem 7.2. *The simple roots of the monster Lie algebra M are the vectors $(1, n)$ ($n = -1$ or $n > 0$), each with multiplicity $c(n)$.*

Let N be the generalized Kac-Moody algebra with root lattice $II_{1,1}$ whose simple roots are as stated in the theorem. The simple roots of a generalized Kac-Moody algebra (with given Cartan subalgebra and choice of fundamental Weyl chamber) are determined by its root multiplicities because of the denominator formula, so it is sufficient to show that the multiplicity of the root (m, n) of N is equal to the multiplicity $c(mn)$ of the root (m, n) of the algebra M (so N is isomorphic to M). The denominator formula of the Lie algebra N is

$$e^{\rho} \prod_{\substack{m>0 \\ n\in\mathbf{Z}}} (1 - p^m q^n)^{\mathrm{mult}(m,n)} = \sum_{w\in W} \det(w) w(e^{\rho} S) \tag{7.2}$$

where $\mathrm{mult}(m, n)$ is the multiplicity of the root (m, n) of N, p and q are the elements $e^{(1,0)}$ and $e^{(0,1)}$ of the group ring of $II_{1,1}$, W is the Weyl group of N which is of order 2 and whose nontrivial element exchanges p and q, and e^{ρ} is $e^{(-1,0)} = p^{-1}$. By the denominator formula quoted in section 4 the element S is

$$S = \sum_{A} (-1)^{|A|} e^{\Sigma A}$$

where the sum is over all finite subsets A of the set of simple imaginary roots such that any two distinct elements of A are orthogonal, $|A|$ is the number of elements of A, and ΣA is the sum of the elements of A. All the imaginary simple roots of N have nonzero inner product with each other, so S is equal to $1 - \sum_{n>0} c(n) p q^n = 1 - p(j(q) - q^{-1} - 744)$ and hence the right hand side of the denominator formula (7.2) of N is

$$\begin{aligned} e^{\rho} S - w(e^{\rho} S) &= (p^{-1} - j(q) + q^{-1} + 744) - (q^{-1} - j(p) + p^{-1} + 744) \\ &= j(p) - j(q) \end{aligned}$$

where w is the nontrivial element of the Weyl group W. This is the right hand side of (7.1), so that the left hand sides of (7.1) and (7.2) must also be the same, which implies that the multiplicity of the root $(m, n) \neq (0, 0)$ of N is $c(mn)$. This proves theorem 7.2.

Remark. This shows that the action of the monster on M can be extended to an action of the full automorphism group of the graded vector space V on M which still preserves the grading and Lie algebra structure of M. The special property of the action of the monster on M that we use is that the pieces of degree (a, b) and (c, d) of the $II_{1,1}$-graded Lie algebra M are isomorphic as representations of the monster whenever $ab = cd \neq 0$.

8 The twisted denominator formula.

The monster Lie algebra, like any generalized Kac-Moody algebra, can be written as a direct sum $E \oplus H \oplus F$ of subalgebras, where H is the Cartan subalgebra and E and

F are the subalgebras corresponding to the positive and negative roots. We recall from section 4 the equality

$$\Lambda(E) = H(E) \tag{8.1}$$

where in the case of the monster Lie algebra both sides are virtual $II_{1,1}$-graded modules over the monster. In this section we calculate both sides of (8.1) explicitly and use this to obtain some relations between the coefficients of the Thompson series $T_g(q)$.

For any generalized Kac-Moody algebra the homology groups can be calculated as in section 4 provided we know the simple roots. In the case of the monster Lie algebra M the simple roots are given in section 7 and are just the vectors $(1, n)$, $n = -1$ or $n > 0$ with multiplicity $c(n)$, so we can calculate the homology groups $H_i(E)$ as follows. Recall that $H_i(E)$ is the subspace of elements of $\Lambda^i(E)$ whose degree r (in the root lattice) satisfies $(r, r + 2\rho) = 0$. For the monster Lie algebra we can think of the roots as elements of $II_{1,1}$ and can identify the Weyl vector ρ with the norm 0 vector $(-1, 0)$. The condition on r then says that $r + \rho$ has norm 0, i.e., r is a vector of the form $(m, 0)$ or $(1, n)$, so we just have to find the elements of $\Lambda^i(E)$ of these degrees. The answers we get are as follows (where we write $M_{m,n}$ for the subspace of elements of M of degree $(m, n) \in II_{1,1}$).

$H_0(E)$ is one dimensional with character 1, because $\Lambda^0(E) = \mathbf{R}$ is just a one dimensional space of degree $(0, 0)$.

$H_1(E)$ is the subspace of $\Lambda^1(E) = E$ of elements of degree $(m, 0)$ or $(1, n)$. There are no elements of degree $(m, 0)$ and the space of elements of degree $(1, n)$ is the simple root space $M_{1,n} \cong V_n$, so $H_1(E)$ has character $p(j(q) - 744)$ and its piece of degree $(1, n)$ is isomorphic to the n'th head representation V_n of the monster. (Notice that the first homology group $H_1(E)$ is isomorphic to the sum of the simple root spaces; the same is true for any generalized Kac-Moody algebra.)

For $i \geq 2$ there are no elements in $\Lambda^i(E)$ of degree $(1, n)$ because all elements of E have degrees of the form (m, n) with $m \geq 1$. Moreover they all have degrees with $n > 0$ except for the one dimensional space with degree equal to the real simple root $(1, -1)$, so the only way for an element of $\Lambda^i(E)$ to have degree $r = (m, 0)$ is for it to be the exterior product of two elements of E of degrees $(1, -1)$ and $(m - 1, 1)$. Therefore $H_2(E)$ is the sum of pieces of degrees $(m, 0)$ for $m \geq 2$ isomorphic to $M_{m-1,1} = V_{m-1}$, and $H_i(E) = 0$ for $i \geq 3$.

To summarize, the homology groups of E are the following $II_{1,1}$-graded vector spaces, where we use p and q to stand for one dimensional vector spaces of degrees $(1, 0)$ and $(0, 1)$ in $II_{1,1}$, and V_i has degree $0 \in II_{1,1}$ for all i.

$H_0(E) = V_{-1} = \mathbf{R}$ and has character 1.
$H_1(E) = \sum_{n\in\mathbf{Z}} V_n p q^n$ and has character $\sum_{n\in Z} c(n) p q^n = p(j(q) - 744)$.
$H_2(E) = p \sum_{m>0} V_m p^m$ and has character $p(j(p) - 744) - 1$.
$H_i(E) = 0$ if $i \geq 3$.

For most interesting generalized Kac-Moody algebras there are an infinite number of nonzero homology groups. In general the largest n with H_n nonzero is equal to (maximum length of an element of the Weyl group) + (maximum number of pairwise orthogonal imaginary simple roots) which is usually infinite; however for the monster Lie algebra both the terms in parentheses happen to be 1.

The alternating sum $\oplus(-1)^i H_i(E)$ is therefore equal to $p(\sum_m V_m p^m - \sum_n V_n q^n)$, where we use p and q to stand for one dimensional vector spaces of degrees (1,0) and (0,1). If we substitute these values of the homology groups into (8.1) we find that

$$p^{-1}\Lambda(\sum_{m>0,n\in\mathbf{Z}} V_{mn}p^m q^n) = \sum_m V_m p^m - \sum_n V_n q^n \tag{8.2}$$

where V_m is the m'th head representation of the monster simple group. (Both sides of (8.2) are essentially $II_{1,1}$-graded virtual representations of the monster simple group.) For any finite dimensional vector space U, $\Lambda(U)$ is naturally isomorphic to $\exp(-\sum_{i>0}\psi^i(U)/i)$ (where ψ^i is the i'th Adams operation) by the splitting principle, because both expressions are multiplicative in U and are equal if U is one dimensional. (The splitting principle says that two natural operations on representations are equal if they are equal on sums of 1-dimensional representations, i.e., we can pretend that any representation is a sum of 1-dimensional ones, and the Adams operation ψ^i on virtual representations of a group G is defined by $\mathrm{Tr}(g|\psi^i(U)) = \mathrm{Tr}(g^i|U)$; see [2] for more details.) The same is true for infinite dimensional vector spaces U graded by some lattice L provided that the homogeneous pieces are all finite dimensional, and the pieces of degree $a \in L$ vanish unless a is in some fixed closed cone which does not contain any line and has its vertex at the origin; this condition ensures that all the virtual vector spaces $\Lambda(U)$, $\psi^i(U)$, and so on are graded with finite dimensional pieces of each degree and are therefore meaningful. Therefore if we take the trace of some element g of the monster on both sides of (8.2) we find that

$$p^{-1}\exp(-\sum_{i>0}\sum_{m>0,n\in\mathbf{Z}}\mathrm{Tr}(g^i|V_{mn})p^{mi}q^{ni}/i) = \sum_{m\in\mathbf{Z}}\mathrm{Tr}(g|V_m)p^m - \sum_{n\in\mathbf{Z}}\mathrm{Tr}(g|V_n)q^n \tag{8.3}$$

where $\mathrm{Tr}(g|V_n)$ is the trace of g on the vector space V_n.

These relations between the coefficients of the functions $\sum \mathrm{Tr}(g|V_n)q^n$ are the same as those that Norton [28] conjectured to hold for the modular functions associated with elements of the monster in Conway and Norton [13, table 2]. The identities 8.3 imply that the functions $T_g(q)$ are completely replicable in the terminology of [28]; in fact the definition of a completely replicable function in [28] is that the function should satisfy some identities equivalent to 8.3. Norton's conjectures that these modular functions are completely replicable were proved by Koike [25]. In the next section we use this to prove that the functions $\sum_m \mathrm{Tr}(g|V_m)q^m$ are these modular functions.

9 The moonshine conjectures.

In this section we complete the proof of theorem 1.1, i.e., we verify that the monster vertex algebra V satisfies Conway and Norton's moonshine conjectures [13] that the Thompson series of elements of the monster are certain Hauptmoduls. To do this we show that the identities (8.3) in section 8 imply that the Thompson series are determined by their first 5 coefficients $c_g(i)$, $1 \leq i \leq 5$, and then use the fact that the Hauptmoduls listed by Conway and Norton in [13, table 2] satisfy the same identities ([25]) and have the same first five coefficients.

The coefficients $c_g(n) = \mathrm{Tr}(g|V_n)$ of the Thompson series of elements of the monster satisfy the relations (8.3). If we compare the coefficients of p^2 and p^4 of both sides of 8.3 and carry out some elementary algebra we find that the coefficients $c_g(i)$ satisfy the recursion formulas below for $k \geq 1$:

$$\begin{aligned}
c_g(4k) &= c_g(2k+1) + (c_g(k)^2 - c_{g^2}(k))/2 + \sum_{1\leq j<k} c_g(j)c_g(2k-j)\\
c_g(4k+1) &= c_g(2k+3) - c_g(2)c_g(2k) + (c_g(2k)^2 + c_{g^2}(2k))/2\\
&\quad + (c_g(k+1)^2 - c_{g^2}(k+1))/2 + \sum_{1\leq j\leq k} c_g(j)c_g(2k-j+2)\\
&\quad + \sum_{1\leq j<k} c_{g^2}(j)c_g(4k-4j) + \sum_{1\leq j<2k} (-1)^j c_g(j)c_g(4k-j)\\
c_g(4k+2) &= c_g(2k+2) + \sum_{1\leq j\leq k} c_g(j)c_g(2k-j+1)\\
c_g(4k+3) &= c_g(2k+4) - c_g(2)c_g(2k+1)\\
&\quad - (c_g(2k+1)^2 - c_{g^2}(2k+1))/2 + \sum_{1\leq j\leq k+1} c_g(j)c_g(2k-j+3)\\
&\quad + \sum_{1\leq j\leq k} c_{g^2}(j)c_g(4k-4j+2) + \sum_{1\leq j\leq 2k} (-1)^j c_g(j)c_g(4k-j+2)
\end{aligned} \tag{9.1}$$

where $c_g(n) = \mathrm{Tr}(g|V_n)$, $c_{g^2}(n) = \mathrm{Tr}(g^2|V_n)$. In particular if $n = 4$ or $n > 5$ then the coefficient $c_g(n)$ is determined by the coefficients $c_g(i)$ and $c_{g^2}(i)$ for $1 \leq i < n$, so if we know all the coefficients $c_g(n)$ for $n = 1$, 2, 3, and 5 and all elements g of the monster then we can work out all the coefficients $c_g(n)$. (The coefficient $c_g(5)$ is not determined by the recursion relations because they degenerate into $c_g(5) = c_g(5)$. The Thompson series of an element of the monster is not determined by its first 5 coefficients $c_g(i)$, $1 \leq i \leq 5$, but is determined by the coefficients $c_{g^j}(i)$, $1 \leq i \leq 5$ of the Thompson series of all its powers g^j. For example, the Thompson series of the elements $60F$ and $93A$ (in ATLAS [14] notation) have the same first five coefficients $c_g(i)$, $1 \leq i \leq 5$. Norton showed in [28] that any completely replicable function $\sum a(n)q^n$ is determined by its 12 coefficients a_i, $i = 1$, 2, 3, 4, 5, 7, 8, 9, 11, 17, 19, 23.)

For the case of the elliptic modular function $j(q)$, where $g = 1$, these recursion formulas were discovered by Mahler [27]. We do not make any use of the formulas (9.1), apart from the fact that the coefficients for $n = 1$, 2, 3 and 5 determine all the coefficients. (This is easy to check without calculating the formulas (9.1) explicitly. The reason for listing them explicitly is that they are a very efficient way of working out the coefficients c_g on a computer.)

Norton [28] stated and Koike [25] proved that the modular functions associated with elements of the monster in [13, table 2] also satisfy the relations (8.3) (with $\mathrm{Tr}(g|V_m)$ replaced by the coefficient of q^m of the modular function corresponding to g) and therefore also satisfy the recursion relations (9.1) above. To prove that the Thompson series of elements of the monster are these modular functions, it is therefore sufficient to check that the coefficients of q^i, $i \leq 5$ of each function are the same.

The coefficients of q^i, $i \leq 5$ of each modular function are in Conway and Norton [13, table 4], and they define representations of the monster which decompose as stated at the end of section 3. We can work out the coefficients $c_g(i)$, $1 \leq i \leq 5$ of the Thompson series of elements of the monster as follows. Knowing the coefficients $c_g(i)$, $1 \leq i \leq 5$ of the Thompson series is equivalent to knowing how the representations $V_i, 1 \leq i \leq 5$ of the monster decompose into irreducible representations of the monster. The only irreducible representations of the monster with dimension at most that of V_5 are the first seven, with characters χ_i, $1 \leq i \leq 7$ in atlas [14] notation. Therefore we can evaluate the coefficients $c_g(i)$, $1 \leq i \leq 5$ of the Thompson series of all elements of the monster provided we can find seven elements g_j, $1 \leq j \leq 7$ of the monster for which we can evaluate these coefficients, and such that the matrix $\chi_i(g_j)$, $1 \leq i, j \leq 7$ is nonsingular, because this determines the decomposition of V_i, $1 \leq i \leq 5$, into irreducible representations of the monster.

In their book [16] Frenkel, Lepowsky and Meurman give an explicit formula for the Thompson series of any element of the centralizer of an involution of type 2B of the monster. The elements of odd order of $2^{1+24}.Co_1$ correspond to the elements of odd order of the group $2.Co_1$ of automorphisms of the Leech lattice Λ. Frenkel, Lepowsky and Meurman's formula is particularly easy to evaluate if the corresponding automorphism of the Leech lattice is of odd order and fixes no nonzero vectors: it becomes

$$2\sum_n \mathrm{Tr}(g|V_n)q^n = 1/\eta_g(q) + \eta_g(q)/\eta_g(q^2) + \eta_g(q)/\eta_g(q^{1/2}) + \eta_g(q)/\eta_g(-q^{1/2}) \tag{9.2}$$

where $\eta_g(q)$ is the eta function of g acting on the Leech lattice, equal to $\eta(\epsilon_1 q)\dots\eta(\epsilon_{24}q)$ if g has eigenvalues $\epsilon_1, \dots, \epsilon_{24}$ on the vector space $\Lambda \otimes \mathbf{R}$, where $\eta(q) = q^{1/24}\prod_{n>0}(1-q^n)$. If we put $f(\tau) = 1/\eta_g(q)$ (where $q = e^{2\pi i\tau}$) then $f(\tau) - f(0)$ is the modular function of genus 0 that Conway and Norton associate to the element g of the monster in [13, table 2]. The coefficients of the right hand side of the formula above are easy to evaluate explicitly, and we can check that its coefficients of q^i for $i \leq 5$ are equal to those of the modular function $f(\tau) - f(0)$. (The right hand side of 9.2 and $f(\tau) - f(0)$ are of course equal, as we can see directly by observing that the right hand side of (9.2) is $f(\tau) + T_2 f(\tau)/f(\tau)$, where T_2 is a Hecke operator.)

For our seven elements g_j of the monster we choose an element g_1 of conjugacy classes 2B (for which Frenkel, Lepowsky and Meurman explicitly evaluate the Thompson series), and 6 more elements g_i of the monster corresponding to odd order automorphisms of the Leech lattice with no nonzero fixed vectors such that the determinant of the 7×7 matrix $\chi_i(g_j)$ is nonzero. A set of 6 elements satisfying these conditions are those of type

3B, 5B, 7B, 9B, 13B, 15D in the monster (using atlas [14] notation) corresponding to elements in the conjugacy classes 3A, 5A, 7A, 9A, 13A, and 15C of Co_1 with cycle shapes $3^{12}1^{-12}$, $5^{6}1^{-6}$, $7^{4}1^{-4}$, $9^{3}1^{-3}$, $13^{2}1^{-2}$, and $15^{2}3^{-2}$. The determinant of the matrix $\chi_i(g_j)$ is $35672555520 = 2^{22}3^{5}5^{1}7^{1}$ which is nonzero. The modular groups corresponding to these elements of the monster are $\Gamma_0(3)$, $\Gamma_0(5)$, $\Gamma_0(7)$, $\Gamma_0(9)$, $\Gamma_0(13)$, and $\binom{3,0}{0,1}^{-1}\Gamma_0(5)\binom{3,0}{0,1}$. (It is necessary to use at least one element g_i of even order, because the characters of the first seven representations of the monster are linearly dependent when restricted to elements of odd order; in fact the character of $S^2(V_1) - \Lambda^2(V_1) - V_1$ is 0 on all elements of odd order.)

We can use this to verify that the representations V_1, V_2, V_3, and V_5 of the monster decompose as stated at the end of section 3, and this implies that the numbers $\mathrm{Tr}(g|V_n)$ are equal to the coefficients of the corresponding modular functions in [13] for $n = 1$, 2, 3 and 5, and therefore for all n by the recursion relations (9.1). This completes the verification that the Thompson functions $\sum_n \mathrm{Tr}(g|V_n)q^n$ are modular functions of genus 0 and proves theorem 1.1.

10 The monstrous Lie superalgebras.

In the remainder of the paper we describe some Lie algebras similar to the monster Lie algebra. In this section we describe some associated to elements of the monster.

The twisted denominator formula for some diagram automorphism g of a generalized Kac-Moody algebra, which is obtained by taking the trace of g on both sides of the identity $H(E) = \Lambda(E)$, is often the untwisted denominator formula for some generalized Kac-Moody algebra or superalgebra. For example, the twisted denominator formula for E_6 is just the ordinary denominator formula for F_4. We construct a family of Lie algebras and superalgebras whose denominator formulas are twisted denominator formulas of the monster Lie algebra. (Warning: unlike the case of finite dimensional Lie algebras, these are not always subalgebras of the monster Lie algebra; in fact some of them are Lie superalgebras.)

If g is an element (or conjugacy class) of the monster group M then we write $T_g(q)$ for the Thompson series $T_g(q) = \sum c_g(n)q^n = \sum \mathrm{Tr}(g|V_n)q^n$ of g. For example, $T_1(q) + 744$ is the elliptic modular function $j(q)$. The function $T_g(q)$ is the normalized generator for a genus zero function field of a group containing $\Gamma_0(nh)$, where n is the order of g and h is an integer with $h|(24, n)$.

We use the convention that for super vector spaces the dimension is defined to be the dimension of the even part minus the dimension of the odd part. For example, the multiplicity of a root is the dimension of the root space, and is therefore equal to the dimension of the even root space minus the dimension of the odd root space. This provides an interpretation of roots of negative multiplicity. With this convention for multiplicities the denominator formula for generalized Kac-Moody superalgebras is the same as for generalized Kac-Moody algebras.

We define the generalized Kac-Moody superalgebra of an element g of the monster to have root lattice $II_{1,1}$ and simple roots $(1, n)$ with multiplicity $\mathrm{Tr}(g|V_n)$. (These multiplicities are all integers as can be seen in several ways; for example they are rational by the recursion relations 9.1 and algebraic integers because they are character values.) This is really a family of Lie superalgebras rather than a single superalgebra, because for each simple root $(1,n)$ we can choose any two nonnegative integers a and b with $a-b=\mathrm{Tr}(g|V_n)$ and take a even simple roots $(1,n)$ and b odd ones. This only seems to be interesting if all coefficients of T_g are positive, in which case we get a Lie algebra, or if the coefficients alternate in sign, in which case we get a superalgebra such that the super elements are those of degree (m,n) with $m+n$ odd.

We can work out the root multiplicities of these superalgebras because their denominator formulas are the twisted denominator formulas of the monster Lie algebra. The denominator formula for the Lie superalgebra of g is

$$p^{-1}\prod_{m>0,n\in\mathbf{Z}}(1-p^mq^n)^{\mathrm{mult}(m,n)}=\sum_m \mathrm{Tr}(g|V_m)p^m-\sum_n \mathrm{Tr}(g|V_n)q^n=T_g(p)-T_g(q) \quad (10.1)$$

and by (8.3)

$$T_g(p)-T_g(q)=p^{-1}\exp(-\sum_{i>0}\sum_{m>0}\sum_{n\in\mathbf{Z}}\mathrm{Tr}(g^i|V_{mn})p^{mi}q^{ni}/i). \quad (10.2)$$

If we compare the logarithms of (10.1) and (10.2) we find that

$$\sum_{i>0,m>0,n\in\mathbf{Z}}\mathrm{Tr}(g^i|V_{mn})p^{mi}q^{ni}/i=\sum_{i>0,m>0,n\in\mathbf{Z}}\mathrm{mult}(m,n)p^{mi}q^{ni}/i \quad (10.3)$$

and applying the Moebius inversion formula to (10.3) shows that

$$\mathrm{mult}(m,n)=\sum_{ds|(m,n)}\frac{\mu(s)}{ds}\mathrm{Tr}(g^d|V_{mn/d^2s^2}) \quad (10.4)$$

where μ is the Moebius function. If f is any function of n whose value depends only on (n,N) for some N, then the sum $\sum_{ds=k}\mu(s)f(d)$ is 0 unless $k|N$. The trace $\mathrm{Tr}(g^d|V_n)$ depends only on n and (d,N) where N is the order of g, so $\sum_{ds=k}\mu(s)\mathrm{Tr}(g^d|V_{mn/d^2s^2})$ is 0 unless $k|N$, hence (10.4) can be simplified to

$$\mathrm{mult}(m,n)=\sum_{ds|(m,n,N)}\frac{\mu(s)}{ds}\mathrm{Tr}(g^d|V_{mn/d^2s^2}) \quad (10.5)$$

This is the formula for the multiplicity of the roots of the superalgebra of g. The sum on the right of (10.5) can often be simplified by expressing T_{g^d} in terms of T_g. For example, suppose that $N=N_1N_2$ is a squarefree integer such that the group $\Gamma_0(N)+d|N_1$ has genus 0, where $\Gamma_0(N)+d|N_1$ is the group generated by $\Gamma_0(N)=\{\left(\begin{smallmatrix}a&b\\c&d\end{smallmatrix}\right)\in SL_2(\mathbf{Z})|c\equiv 0 \bmod N\}$ together with the Atkin-Lehner involutions of all divisors of N_1. (See [13].) If g is an element of the monster corresponding to one of these groups then so is g^k. By the compression formula of [13] section 8

$$T_{g^p}(\tau)=T_g(\tau)+T_g(\tau/p)+\ldots+T_g((\tau+p-1)/p)$$

for any prime divisor p of N_1, and

$$T_{g^p}(\tau) = T_g(\tau) - T_g(\tau/p^2) - \ldots - T_g((\tau + p^2 - 1)/p^2)$$

for any prime divisor p of N_2. These imply that

$$\mathrm{Tr}(g^d|V_n) = \sum_{d_1|(d,N_1)} \sum_{d_2|(d,N_2)} d_1 d_2^2 \mu(d_2) \mathrm{Tr}(g|V_{d_1 d_2^2 n}) \tag{10.6}$$

by induction on the number of divisors of d. If we substitute (10.6) into (10.5) and rearrange we find that

$$\mathrm{mult}(m,n) = \sum_{d|(m,n,N_1)} \mathrm{Tr}(g|V_{mn/d}) \prod_{p|(m,n,N_2)} (1-p) \tag{10.7}$$

where the product is over all primes p dividing (m, n, N_2).

We get particularly interesting results when N_2 is 1 or 2. First suppose that $N_2 = 1$ so that $N = N_1$ is one of the 44 squarefree integers that are orders of elements in the monster, which are the same as the integers for which $\Gamma_0(N)+$ has genus 0. Let g be an element of the monster corresponding to the group $\Gamma_0(N)+$, so that $T_g(q)$ is the normalized generator of the function field of $\Gamma_0(N)+$. Then (10.7) becomes

$$\mathrm{mult}(m,n) = \sum_{d|(m,n,N)} \mathrm{Tr}(g|V_{mn/d}) \tag{10.8}$$

and if we substitute (10.8) into (10.1) we obtain the formula

$$T_g(p) - T_g(q) = p^{-1} \prod_{m>0, n\in\mathbf{Z}} \prod_{d|N} (1 - p^{dm} q^{dn})^{c_g(dmn)}$$

which generalizes the product formula for the j function. For these cases the coefficients c_g of the Thompson series $T_g(q)$ are always nonnegative, so the algebras we get are Lie algebras rather than Lie superalgebras. This seems to happen whenever the corresponding subgroup of $PGL_2(R)$ contains the Fricke involution $\tau \to -1/N\tau$. More generally, Norton has observed ([29]) that the result of applying the Fricke involution to a Thompson series always has nonnegative coefficients.

Similarly suppose that $N_2 = 2$ so that N_1 is one of the squarefree integers 1, 3, 5, 7, 11, or 15 for which $\Gamma_0(2N_1) + d|N_1$ has genus 0. Then (10.7) becomes

$$\mathrm{mult}(m,n) = (-1)^{(m-1)(n-1)} \sum_{d|(m,n,N_1)} \mathrm{Tr}(g|V_{mn/d}).$$

The coefficients of the Thompson series for these six cases alternate in sign, so the multiplicity of (m, n) is at least 0 or at most 0 depending on whether $m + n$ is even or odd. Therefore the root (m, n) is an even root or an odd (super) root depending on the parity of $m + n$. The same is true for any element whose Thompson series has coefficients that alternate in sign. If the coefficients of a Thompson series are neither at least 0 nor alternating in sign, then the root space of some root (m, n) is in general a sum of an even space and an odd space, and the multiplicity of the root is the difference of the dimensions of these two spaces. However the Lie superalgebras are probably not very interesting unless the coefficients are either all positive or alternating in sign.

11 Some modular forms.

We verify some identities involving modular forms of level 2 that we use later. This section can be missed out if the reader is willing to assume these identities.

The modular forms in this section are usually forms of level 2, i.e. modular forms for the group $\Gamma(2) = \{\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in SL_2(\mathbf{Z}) | \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \equiv \left(\begin{smallmatrix} 1 & 0 \\ 0 & 1 \end{smallmatrix}\right) \bmod 2\}$. We recall a few facts about this group from [22]. The group $\Gamma(2)$ has no elliptic elements, 3 cusps (represented by 0, 1, and ∞), genus 0, and has index 6 in $SL_2(\mathbf{Z})$. The dimension of the space of forms of even nonnegative weight $2k$ is equal to $k+1$ and if f and g are two linearly independent forms of weight 2 then every form can be written uniquely as a polynomial in f and g. Two modular forms of level 2 and weight $2k$ are equal if and only if their coefficients of q^0, $q^{1/2}$, q^1, ... , q^k are equal. The group $\Gamma(2)$ is conjugate to the group $\Gamma_0(4) = \{\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in SL_2(\mathbf{Z}) | c \equiv 0 \bmod 4\}$, and $f(q)$ is a modular form for $\Gamma_0(4)$ if and only if $f(q^{1/2})$ is a modular form for $\Gamma(2)$.

We list several modular forms of level 2, together with enough of their Fourier coefficients to verify the identities we use in later sections. Recall that to prove that two modular forms are equal it is sufficient to check that sufficiently many of their Fourier coefficients are equal.

The following are some forms of weight 4 and level 2.

$$\begin{aligned}
\theta_{E_8}(q) &= 1 + 240(q + 9q^2 + 28q^3 + \ldots + \sigma_3(n)q^n + \ldots) \\
\theta_{2E_8}(q) &= 1 + 240q^2 + \ldots \\
\theta_{2E_8+v_1}(q) &= 2q^{1/2} + 56q^{3/2} + 252q^{5/2} + \ldots \\
\theta_{2E_8+v_2}(q) &= 16q + 128q^2 + 448q^3 + \ldots \\
\eta(q)^{16}\eta(q^{1/2})^{-8} &= q^{1/2} + 8q + 28q^{3/2} + 64q^2 + 126q^{5/2} + 224q^3 + \ldots \\
\eta(q)^{16}\eta(-q^{1/2})^{-8} &= -q^{1/2} + 8q - \ldots \\
\eta(q)^{16}\eta(q^2)^{-8} &= 1 - 16q + 112q^2 - 448q^3 + \ldots
\end{aligned}$$

The form $\theta_{E_8}(q)$ is the theta function of the E_8 lattice, and the form $\theta_{2E_8+v_i}$ is the theta function of the coset of $2E_8$ containing a vector v_i of norm i in the dual of $2E_8$ but not in E_8 (where $2E_8$ is the E_8 lattice with all norms doubled).

Lemma 11. 1. *If* $\eta_{2+}(q) = \eta(q)^8\eta(q^2)^8$ *then*

$$\begin{aligned}
\theta_{2E_8}(q)/\Delta(q) &= 1/\eta_{2+}(q) + 1/\eta_{2+}(q^{1/2}) + 1/\eta_{2+}(-q^{1/2}) \\
\theta_{2E_8+v_1}(q)/\Delta(q) &= 1/\eta_{2+}(q^{1/2}) - 1/\eta_{2+}(-q^{1/2}) \\
\theta_{2E_8+v_2}(q)/\Delta(q) &= 1/\eta_{2+}(q^{1/2}) + 1/\eta_{2+}(-q^{1/2})
\end{aligned}$$

Proof: If we multiply both sides by $\Delta(q)$ then both sides are modular forms of level 2 and weight 4, so it is sufficient to check that the coefficients of q^0, $q^{1/2}$, and q^1 of both sides are equal, which we can do using the expressions above.

The following are some forms of weight 8 and level 2.

$$\begin{aligned}
\theta_{\Lambda_2}(q) &= 1 + 4320q^2 + \dots \\
\theta_{\Lambda_2}(q^{1/2}) &= 1 + 4320q^1 + 61440q^{3/2} + 522720q^2 + \dots \\
\theta_{\Lambda_2}(-q^{1/2}) &= 1 + 4320q - 61440q^{3/2} + 522720q^2 + \dots \\
\eta(q)^{32}\eta(q^2)^{-16} &= 1 - 32q + 480q^2 - 4480q^3 + \dots \\
\eta(q)^{32}\eta(q^{1/2})^{-16} &= q + 16q^{3/2} + 120q^2 + 576q^{5/2} + 2060q^3 + \dots \\
\eta(q)^{32}\eta(-q^{1/2})^{-16} &= q - 16q^{3/2} + 120q^2 \dots
\end{aligned}$$

The form $\theta_{\Lambda_2}(q)$ is the theta function of the Barnes-Wall lattice Λ_2 of dimension 16, and is a modular form for $\Gamma_0(2)+$. The forms $\theta_{\Lambda_2+v_i}$ are defined in the same way as for the lattice $2E_8$.

Lemma 11. 2. *Let $\eta_{2-}(q)$ be the modular form $\eta(q)^{-8}\eta(q^2)^{16}$. Then*

$$\begin{aligned}
\theta_{\Lambda_2}(q)/\Delta(q) &= 1/\eta_{2-}(q) - 1/\eta_{2-}(q^{1/4}) - 1/\eta_{2-}(iq^{1/4}) - 1/\eta_{2-}(-q^{1/4}) - 1/\eta_{2-}(-iq^{1/4}) \\
\theta_{\Lambda_2+v_3}/\Delta(q) &= 1/\eta_{2-}(q^{1/4}) + 1/\eta_{2-}(iq^{1/4}) + 1/\eta_{2-}(-q^{1/4}) + 1/\eta_{2-}(-iq^{1/4}) \\
\theta_{\Lambda_2+v_2}/\Delta(q) &= 1/\eta_{2-}(q^{1/4}) - 1/\eta_{2-}(iq^{1/4}) + 1/\eta_{2-}(-q^{1/4}) - 1/\eta_{2-}(-iq^{1/4})
\end{aligned}$$

Proof. If we multiply both sides by $\Delta(q)$ then both sides are modular forms of weight 8 and level 2, so it is sufficient to check that the coefficients of q^0, $q^{1/2}$, q^1, $q^{3/2}$, and q^2 of both sides are equal.

12 The fake monster Lie algebra.

In the next section we construct a family of superalgebras whose denominator formulas are twisted versions of the denominator formula of the fake monster Lie algebra, in the same way that we constructed a family of algebras from the monster Lie algebra. To do this we need a detailed description of the fake monster Lie algebra, which we give in this section.

As the Leech lattice Λ is an even lattice, it has a unique central extension

$$0 \to \{1, -1\} \to \hat{\Lambda} \to \Lambda \to 0$$

by a group of order 2, such that the commutator of any inverse images of $r, s \in \Lambda$ is $(-1)^{(r,s)}$. This central extension is unique up to nonunique isomorphism, and its group of automorphisms $\mathrm{Aut}(\hat{\Lambda})$ preserving the inner product is a nonsplit extension $2^{24}.\mathrm{Aut}(\Lambda)$. (The double cover of this nonsplit extension is isomorphic to the double cover of a centralizer of an involution of type 2B in the monster simple group.)

We start by recalling some results about the fake monster Lie algebra from [8] (where it is called the monster Lie algebra). The root lattice of the fake monster Lie algebra is the 26 dimensional even unimodular Lorentzian lattice $II_{25,1} = \Lambda \oplus II_{1,1}$, where the norm of an element $(\lambda, m, n) \in \Lambda \oplus II_{1,1}$ is defined to be $\lambda^2 - 2mn$. The real simple roots are the norm 2 vectors of the form $(\lambda, 1, \lambda^2/2-1)$, and the imaginary simple roots are the positive multiples $n\rho$ of the Weyl vector $\rho = (0, 0, 1)$, each with multiplicity 24. A nonzero vector $r \in II_{25,1}$ is a root if and only if $r^2 \leq 2$, in which case it has multiplicity $p_{24}(1 - r^2/2)$ where $p_{24}(n)$ is the number of partitions of n into parts of 24 colours. The fake monster Lie algebra is essentially the space of physical vectors of the vertex algebra of $\hat{II}_{25,1}$, and can be constructed from the vertex algebra V_Λ of $\hat\Lambda$ in the same way that the monster Lie algebra M was constructed from the monster vertex algebra V in section 6.

The fake monster Lie algebra is acted on by the group of affine automorphisms of the Leech lattice which is a split extension $\Lambda.\mathrm{Aut}(\Lambda)$, because its Dynkin diagram may be interpreted as the Leech lattice as it has one real simple root $(\lambda, 1, \lambda^2/2 - 1)$ for each Leech lattice vector λ. However this is the wrong group of automorphisms to use. A more useful group of automorphisms of the fake monster Lie algebra is the nonsplit extension $2^{24}.\mathrm{Aut}(\Lambda) = \mathrm{Aut}(\hat\Lambda)$, which acts naturally on the vertex algebra of the central extension $\hat\Lambda$ of the Leech lattice Λ, and therefore on the fake monster Lie algebra. The point is that we can use the no-ghost theorem 5.1 to describe how the group $\mathrm{Aut}(\hat\Lambda)$ acts on the root spaces of the fake monster Lie algebra, and it is not obvious how we could do this if we used the group $\mathrm{Aut}(\Lambda)$.

We now describe what the fake monster Lie algebra M_Λ looks like as a module over $\mathrm{Aut}(\hat\Lambda) = 2^{24}\mathrm{Aut}(\Lambda)$. If we forget the Λ in the $II_{25,1} = \Lambda \oplus II_{1,1}$ grading of M_Λ then we can consider M_Λ to be a $II_{1,1}$-graded Lie algebra. The piece of M_Λ of degree $(m, n) \in II_{1,1}$ is then isomorphic as a Λ-graded $2^{24}\mathrm{Aut}(\Lambda)$ module to the weight $1 - mn$ piece of the vertex algebra V_Λ of $\hat\Lambda$ by theorem 6.1, so it is sufficient to describe V_Λ explicitly, which we can do as follows.

We let $S = S(\oplus_{i>0}\Lambda_i)$ be the symmetric algebra on the sum of a countable number of copies Λ_i of the Leech lattice Λ, and grade this by letting the elements of Λ_i have weight i. The dimension of the subspace of S of weight n is then equal to $p_{24}(n)$, the number of partitions of n into parts of $24 = \dim(\Lambda)$ colours, which is the coefficient of q^{n-1} of $1/\Delta(q) = q^{-1}\prod_{i>0}(1 - q^i)^{-24}$. We let $\mathbf{Z}(\hat\Lambda)$ be the twisted group ring of Λ, which is the group ring of $\hat\Lambda$ quotiented out by the ideal $(1 + \epsilon)$ where ϵ is the element of the group ring of $\hat\Lambda$ corresponding to $-1 \in \hat\Lambda$, and grade it by letting e^v have weight $(v, v)/2$ for $v \in \hat\Lambda$. (This grading does not have the property that $\deg(ab) = \deg(a) + \deg(b)$.) Finally the graded space V_Λ is isomorphic to $\mathbf{Z}(\hat\Lambda) \otimes S$. The group $2^{24}\mathrm{Aut}(\Lambda) = \mathrm{Aut}(\hat\Lambda)$ acts naturally on both $\hat\Lambda$ and on Λ_i, and so acts on V_Λ. Finally the Λ grading on V_Λ comes from the Λ grading on $\mathbf{Z}(\hat\Lambda)$. (The Λ-grading on S is the trivial one such that everything has degree 0.) This gives a complete description of V_Λ as a Λ-graded $\mathrm{Aut}(\hat\Lambda)$ module, and therefore describes M_Λ as a $II_{25,1}$-graded $\mathrm{Aut}(\hat\Lambda)$ module.

We need a lemma to construct some elements of $\mathrm{Aut}(\hat\Lambda)$ from elements of $\mathrm{Aut}(\Lambda)$.

Lemma 12.1. *Let σ be an automorphism of Λ of order n, let Λ^σ the vectors of Λ fixed by σ, and let $\hat\Lambda^\sigma$ be the inverse image of Λ^σ in $\hat\Lambda$. If n is odd then σ can be lifted to an element $\hat\sigma \in \mathrm{Aut}(\Lambda)$ of order n which fixes all elements of $\hat\Lambda^\sigma$. If n is even then σ can be lifted to an element $\hat\sigma \in \mathrm{Aut}(\Lambda)$ which fixes all elements of $\hat\Lambda^\sigma$. The automorphism $\hat\sigma^n$ multiplies any element v of $\hat\Lambda$ by $\epsilon^{(v,\sigma^{n/2}(v))}$, and in particular $\hat\sigma$ has order n if $(v, \sigma^{n/2}(v))$ is even for all v, and has order $2n$ otherwise.*

Proof. If n is odd this result is obvious because σ has lifts of the same odd order, and any lift of odd order must fix all elements of $\hat{\Lambda}^g$. If n is even then we can multiply any lift of σ by some element of 2^{24} to get an element $\hat{\sigma}$ which fixes all elements of $\hat{\Lambda}^\sigma$. The element $v\sigma(v)\ldots\sigma^{n-1}(v)$ is fixed by σ as it is in $\hat{\Lambda}^\sigma$ and is therefore equal to $\sigma(v)\ldots\sigma^n(v)$. Hence $v=\sigma^n(v)$ if and only if v commutes with $\sigma(v)\ldots\sigma^{n-1}(v)$, which is true if and only if $(v,\sigma(v))+\ldots(v,\sigma^{n-1}(v))$ is even, which is true if and only if $(v,\sigma^{n/2}v)$ is even because $(v,\sigma^i(v))=(v,\sigma^{n-i}(v))$. Therefore $\sigma^n(v)$ fixes v if and only if $(v,\sigma^{n/2}(v))$ is even, and therefore multiplies v by $\epsilon^{(v,\sigma^{n/2}(v))}$. This proves lemma 12.1.

For example, if σ is an involution of $\mathrm{Aut}(\Lambda)$ whose lattice Λ^σ has dimension 8 or 16 then it is easy to check that $(v,\sigma(v))$ is even for all $v\in\Lambda$, so σ can be lifted to an element $\hat{\sigma}\in\mathrm{Aut}(\hat{\Lambda})$ which has order 2 and fixes all elements of $\hat{\Lambda}^\sigma$. This is not possible if σ is an involution with Λ^σ 12-dimensional, because there are vectors v such that $(v,\sigma(v))$ is odd.

The homology $H(E)$ of the subalgebra E of M_Λ corresponding to the positive roots can be described as follows. We let e^ρ stand for a one dimensional $II_{25,1}$-graded vector space of degree $\rho\in II_{25,1}$. Then the virtual vector space $e^\rho H(E)$ is antisymmetric under the Weyl group, so it is only necessary to describe the subspace of it generated by elements whose degrees are in the Weyl chamber of $II_{25,1}$. By the remarks at the end of section 4 this subspace is naturally isomorphic to the virtual vector space $\Lambda(\oplus_{i>0}\Lambda_i)$, where Λ_i is a copy of the vector space of Λ with degree $i\rho\in II_{25,1}$. This follows from the fact that the imaginary simple roots of M_Λ are the positive multiples of ρ each with multiplicity 24, so all imaginary simple roots are orthogonal to each other, so the subspace of the homology group that we need is just the exterior power of the sum of the root spaces of the imaginary simple roots.

13 The denominator formula for fake monster Lie algebras.

We can now calculate a twisted denominator formula for each element of $\mathrm{Aut}(\hat{\Lambda})$, which is often the denominator formula for some other Lie algebra or superalgebra. In this section we calculate a few examples of these Lie algebras.

We let g be some element of $\mathrm{Aut}(\hat{\Lambda})=2^{24}\mathrm{Aut}(\Lambda)$ of order N, and we let L be the sublattice of Λ fixed by g. The projection of Λ into the vector space of L is the dual lattice L' of L because Λ is unimodular. For simplicity we assume that any power g^n of g fixes all elements of $\hat{\Lambda}$ which are in the inverse image of any vector of Λ fixed by g^n. (If we do not assume this condition we can still carry out most of the work here, but we would have to put more effort into keeping track of signs.) Lemma 12.1 provides us with plenty of examples of such elements g; for example any element of odd order.

We consider both sides of the formula

$$\Lambda(E)=H(E)$$

to be L'-graded virtual g modules. We calculate the trace of g on both sides, which can be thought of as an element of some completion of the group ring of L'. We can calculate the trace of g on $\Lambda(E)$ provided we know exactly how g acts on E, and we can calculate the trace of g on $H(E)$ if we know exactly how g acts on the simple root spaces of M_Λ.

We first calculate the trace of g on $\Lambda(E) = \exp(-\sum_{i>0}\psi^i(E)/i)$ (where ψ^i are the Adams operations). This trace is equal to

$$\exp(-\sum_{v\in L'}\sum_{i>0}\mathrm{Tr}(g^i|E_v)e^{iv}/i) \tag{13.1}$$

where E_v is the subspace of E whose L'-degree is v. (Note added May 1999: the published version of this formula incorrectly had a term E_{iv} instead of E_v.) We wish to express the trace of g in the form $\prod(1-e^r)^{\mathrm{mult}(r)} = \exp - \sum_r\sum_{i>0}e^{ir}\mathrm{mult}(r)/i$ for some numbers $\mathrm{mult}(r)$. By applying the Moebius inversion formula to (13.1) as in section 11 we see that the numbers $\mathrm{mult}(r)$ are given by

$$\mathrm{mult}(r) = \sum_{ds|((r,L),N)}\mu(s)\mathrm{Tr}(g^d|E_{r/ds})/ds \tag{13.2}$$

where (r, L) is the highest common factor of the numbers (r, a) for $a \in L$.

By theorem 2.2 of [6] there is a reflection group W^g acting on the lattice L, which may be taken as any of the following groups.

1 The subgroup of W of elements that commute with g.

2 The subgroup of W of elements that map ρ into L.

3 The subgroup of W of elements mapping L into L.

The positive roots of W^g are the vectors which are the sums of the conjugates of some positive real root of $II_{25,1}$. The simple roots of W^g are the sums of orbits of simple roots of W that have positive norm, and they are also the roots of W^g satisfying $(r,\rho) = -r^2/2$, so ρ is a norm 0 Weyl vector for W^g. (Warning: W^g is not always the full reflection group of L.)

From (13.2) we can see that any 2 positive vectors of L' conjugate under W^g have the same multiplicity. If r is a real simple root of W^g then an easy calculation using (13.2) shows that $\mathrm{mult}(r)$ is 1, so $\mathrm{mult}(r)$ is 1 for any positive real root of W^g, because any such root is conjugate under W^g to a simple root of W^g. If r has positive norm but is not a root of W^g then $\mathrm{mult}(r) = 0$.

The product

$$e^\rho\prod_{r\in L}(1-e^r)^{\mathrm{mult}(r)}$$

is therefore antisymmetric under the reflection group W^g, so it is equal to $\sum_{w\in W^g}\det(w)w(e^\rho S)$ for some S with $e^\rho S$ in the Weyl chamber of W^g. (The determinant of w means its determinant as an automorphism of L, rather than as an automorphism of Λ.) This sum is also equal to the trace of g on $e^\rho H(E)$ because it is equal to the trace of g on $e^\rho\Lambda(E)$, so S is the trace of g on the subspace of $H(E)$ in the Weyl chamber of W^g. This subspace is isomorphic to $\Lambda(\oplus_{i>0}\Lambda_i)$ where Λ_i is a copy of the Leech lattice with degree $i\rho \in II_{25,1}$. The trace of g on this subspace is just $e^{-\rho}\eta_g(e^\rho)$ where $\eta_g(q)$ is defined to be $\eta(\epsilon_1 q)\ldots\eta(\epsilon_{24}q)$ if g has eigenvalues ϵ_1, ... , ϵ_{24} on the vector space of Λ. (If G has generalized cycle shape $a_1^{b_1}a_2^{b_2}\ldots$ then $\eta_g(q) = \eta(q^{a_1})^{b_1}\eta(q^{a_2})^{b_2}\ldots$.) Therefore we finally get

$$e^\rho\prod_{r\in L}(1-e^r)^{\mathrm{mult}(r)} = \sum_{w\in W^g}\det(w)w(\eta_g(e^\rho)). \tag{13.3}$$

The right hand side of this is exactly the denominator formula for a generalized Kac-Moody superalgebra with the following simple roots.

1 The real simple roots are the simple roots of the reflection group W^g, which are the roots r with $(r,\rho) = -(r,r)/2$.

2 The imaginary simple roots are the positive multiples $i\rho$ of the Weyl vector ρ, with multiplicity equal to

$$\mathrm{mult}(i\rho) = \sum_{ja_k=i} b_k$$

if g has generalized cycle shape $a_1^{b_1}a_2^{b_2}\ldots$.

Therefore the left hand side is the left hand side of the denominator formula for this generalized Kac-Moody superalgebra, so its positive roots have multiplicity $\mathrm{mult}(r)$.

14 Examples of fake monster Lie algebras.

We now evaluate both sides of the denominator formula (13.3) for several elements of $\mathrm{Aut}(\hat\Lambda)$, so we get several example of generalized Kac-Moody algebras whose simple roots and root multiplicities are known explicitly.

Example 1. The fake baby monster Lie algebra of rank 18. For this example we let $g \in \mathrm{Aut}(\hat\Lambda)$ be an element of order 2 which is the lift of an element of order 2 of $\mathrm{Aut}(\Lambda)$ which fixes a 16 dimensional sublattice Λ^g of Λ, such that g fixes all elements of $\hat\Lambda^g$. By lemma 12.1 such an element g exists, and the lattice Λ^g is the Barnes-Wall lattice of dimension 16 and determinant 2^8 [12]. The root lattice L is the sum of Λ^g and the two dimensional even Lorentzian lattice $II_{1,1}$. The Barnes-Wall lattice Λ^g has no roots, so by theorem 3.1 of [6] the group W^g is the full reflection group of L.

We can calculate the multiplicities $\mathrm{mult}(r)$ explicitly. The result we get is that $\mathrm{mult}(r) = p_g(1-r^2/2)$ if $r \in L$ and $r \notin 2L'$, $\mathrm{mult}(r) = p_g(1-r^2/2) + p_g(1-r^2/4)$ if $r \in 2L'$, and $\mathrm{mult}(r) = 0$ otherwise, where $p_g(1+n)$ is the coefficient of q^n in $1/\eta_g(q) = q^{-1}\prod_{i>0}(1-q^i)^{-8}(1-q^{2i})^{-8} = q^{-1} + 8 + 44q + \ldots$. If $r \in L'$ then $\mathrm{Tr}(g|E_r)$ is 0 if $r \notin L$ and equal to the coefficient of $q^{-r^2/2}$ in $1/\eta_g(q)$ if $r \in L$. The value of $\mathrm{Tr}(g^2|E_r)$ is just the dimension of E_r, which is the coefficient of $q^{-r^2/2}$ in $\theta_{\Lambda^{g\perp}+r^\perp}(q)/\Delta(q)$ where $\theta_{\Lambda^{g\perp}+r^\perp}(q)$ is the theta function of the coset $\Lambda^{g\perp}+r^\perp$ of the lattice $\Lambda^{g\perp}$ and where $r^\perp$ is a vector such that $r + r^\perp$ is in $II_{25,1}$. If we substitute these values into the formula

$$\mathrm{mult}(r) = \mathrm{Tr}(g|E_r) - \mathrm{Tr}(g|E_{r/2})/2 + \mathrm{Tr}(g^2|E_{r/2})/2$$

we find that $\mathrm{mult}(r)$ is equal to the coefficient of $q^{-r^2/2}$ in

$$\begin{aligned} 0 &\text{ if } r \notin L\\ 1/\eta_g(q) &\text{ if } r \in L, r \notin 2L'\\ 1/\eta_g(q) + \theta_{\Lambda^{g\perp}+r^\perp}(q^4)/\Delta(q^4) &\text{ if } r \in 2L', r \notin 2L\\ 1/\eta_g(q) - 1/\eta_g(q^4)/2 + \theta_{\Lambda^{g\perp}}(q^4)/\Delta(q^4)/2 &\text{ if } r \in 2L. \end{aligned}$$

By lemma 11.1 this implies that if $r \in 2L'$ then $\mathrm{mult}(r)$ is equal to the coefficient of $q^{-r^2/2}$ of $1/\eta_g(q) + 1/\eta_g(q^2)$. Therefore the explicit version of the product formula for the fake baby monster Lie algebra is

$$e^\rho \prod_{r\in L^+}(1-e^r)^{p_g(1-r^2/2)}\prod_{r\in 2L'^+}(1-e^r)^{p_g(1-r^2/4)} = \sum_{w\in W^g}\det(w)w(e^\rho\prod_{i>0}(1-e^{i\rho})^8(1-e^{2i\rho})^8)$$

where L is the Lorentzian lattice which is the sum of the Barnes-Wall lattice Λ^g and the two dimensional even Lorentzian lattice, W^g is its reflection group which has Weyl vector ρ, and L' is the dual of L.

Example 2. We can construct a similar Lie algebra for any of the primes $p = 2$, 3, 5, 7, 11, or 23 with $(p+1)|24$. We let g be an element of $\mathrm{Aut}(\hat\Lambda)$ of order p corresponding to an element of $M_{24}\subset \mathrm{Aut}(\Lambda)$ of cycle shape $1^{24/(p+1)}p^{24/(p+1)}$. We assume that the lattice Λ^g of dimension $48/(p+1)$ has no roots and if $r\in\Lambda^{g\perp\prime}$ then

$$\theta_{\Lambda^{g\perp}+r}(q) = \eta(q)^{24p/(p+1)}(\eta(q^p)^{-24/(p+1)}\delta(r\in\Lambda^{g\perp}) + \sum_{0\le i<p}\epsilon^{-ipr^2/2}\eta(\epsilon^i q^{1/p})^{-24/(p+1)})$$

where ϵ is a primitive p'th root of 1 and where $\delta(r\in\Lambda^{g\perp})$ is 1 if $r\in\Lambda^{g\perp}$ and 0 otherwise. These assumptions are in principle not difficult to prove if they are true, as they are essentially just identities between modular forms. (For $p = 2$ they are just lemma 12.1.)

Assuming these identities, an argument similar to the one above for $p = 2$ shows that the denominator formula for the Lie algebra of G is

$$\begin{aligned} &e^\rho\prod_{r\in L^+}(1-e^r)^{p_g(1-r^2/2)}\prod_{r\in pL'^+}(1-e^r)^{p_g(1-r^2/2p)}\\ =&\sum_{w\in W^g}\det(w)w(e^\rho\prod_{i>0}(1-e^{i\rho})^{24/(p+1)}(1-e^{pi\rho})^{24/(p+1)}) \end{aligned}$$

where $\sum_{i>0}p_g(1+i)q^i = 1/\eta_g(q)$. For p= 2, 3, 5, 7, and 11 these Lie algebras seem to correspond to the baby monster, the Fischer group Fi_{24}, the Harada Norton group, the Held group and the Mathieu group M_{12} in the same way that the fake monster Lie algebra corresponds to the monster simple group.

Example 3. The fake Conway Lie superalgebra of rank 10. This is the algebra described at the end of section 2, and seems to correspond to Conway's simple group Co_1. We let $g\in\mathrm{Aut}(\hat\Lambda)$ be an element of order 2 which is the lift of an element of order 2 of $\mathrm{Aut}(\Lambda)$ which fixes a lattice Λ^g of Λ of dimension 8. This lattice Λ^g is isomorphic to the E_8 lattice with all norms doubled, so if we halve all the norms of the lattice $\Lambda^g\oplus II_{1,1}$ we get the nonintegral lattice of determinant 1/4 which is the dual of the sublattice of even vectors of $I_{9,1}$. A calculation similar to that in example 1 but using lemma 11.2 shows that the denominator formula of this Lie superalgebra is

$$e^\rho\prod_{r\in\Pi^+}(1-e^r)^{\mathrm{mult}(r)} = \sum_{w\in W}\det(w)w(e^\rho\prod_{n>0}(1-e^{n\rho})^{(-1)^n 8})$$

where the multiplicity of the root $r = (v, m, n)\in L$ is equal to

$$\mathrm{mult}(r) = (-1)^{(m-1)(n-1)}p_g((1-r^2)/2) = (-1)^{m+n}|p_g((1-r^2)/2)|,$$

and $p_g(n)$ is defined by

$$\sum p_g(n)q^n = q^{-1/2}\prod_{n>0}(1-q^{n/2})^{-(-1)^n 8}.$$

15 Open questions

We list a few conjectures and open questions about the Lie algebras and superalgebras we have constructed.

(1) Prove the assumptions about the modular forms used in example 2 in section 14. In principle this should be easy (at least when they are true) because they just involve checking a finite number of identities between modular forms.

(2) Investigate the Lie algebras and superalgebras coming from other elements of the monster or $\mathrm{Aut}(\Lambda)$ and write down their denominator formulas explicitly in some nice form.

(3) Find a natural construction for these Lie algebras and superalgebras (i.e. other than by generators and relations). We used natural constructions for the monster Lie algebra and the fake monster Lie algebra from vertex algebras, but I do not know of any similar constructions for most of the other Lie algebras. The easiest case is the superalgebra of rank 10 which can be constructed from superstrings on a 10-dimensional torus. (The even part of the rank 10 superalgebra was constructed in [3, 4]; the odd part is more difficult to construct.) A natural construction should give actions of various finite groups on these Lie algebras; for example the double cover of the baby monster should act on the baby monster Lie algebra.

(4) Describe the Lie bracket from $V_{ab}\otimes V_{cd}$ to $V_{(a+c)(b+d)}$ of the monster Lie algebra explicitly in terms of the vertex algebra operations on V.

(5) Is the baby monster Lie algebra a subalgebra of the monster Lie algebra in a way that preserves the action of the double cover of the baby monster? Similarly for the other monstrous Lie algebras.

(6) Are there any generalized Kac-Moody algebras, other than the finite dimensional, affine, monstrous or fake monstrous ones, whose simple roots and root multiplicities can both be described explicitly? The monstrous and fake monstrous algebras are both finite families, each with a few hundred members, corresponding roughly to the conjugacy classes in the monster and in $\mathrm{Aut}(\hat{\Lambda})$. One example of a denominator formula for a Lie superalgebra of rank 3 is the identity

$$\sum_{i+j+k=0}(-p)^{jk}(-q)^{ik}(-r)^{ij} = \prod_{i+j+k>0}((1-p^iq^jr^k)/(1+p^iq^jr^k))^{c(ij+jk+ki)}$$

where $c(i)$ is defined by $\sum_n c(n)q^n = \prod_{n>0}(1+q^n)/(1-q^n) = 1+2q+4q^2+8q^3+14q^4+\ldots$.

(7) Find all completely replicable functions. (The ones with integral coefficients were found by computer in [1].) Are nontrivial completely replicable functions always modular functions of genus 0? A proof of this conjecture of Norton's [28] which was not a case by case verification would be much neater than the argument in section 9.

(8) Is it possible to say anything interesting from Lie algebras constructed from the vertex algebras of lattices (other than the Leech lattice) as in section 6? The two obvious

candidates are the lattices E_8 and $E_8 \oplus E_8$, so that the corresponding Lie algebras have root lattices $II_{9,1}$ and $II_{17,1}$. The real simple roots of these Lie algebras are the Dynkin diagrams of the reflection groups of the lattices, which were described by Vinberg. There are some calculations connected with the Lie algebra of $II_{9,1}$ in [24].

In this paper we complete the proof of Ryba's modular moonshine conjectures [R] that was started in [B-R]. We do this by applying Hodge theory to the cohomology of the monster Lie algebra over the ring of p-adic integers in order to calculate the Tate cohomology groups of elements of the monster acting on the monster vertex algebra.

Contents.

7. Open problems and conjectures.

1. Introduction.

This paper is a continuation of the earlier paper [B-R] so we will only briefly recall results that are discussed there in more detail. In [B-R] we constructed a modular superalgebra for each element of prime order in the monster, and worked out the structure of this superalgebra for some elements in the monster. In this paper we work out the structure of this superalgebra for the remaining elements of prime order.

Ryba conjectured [R] that for each element of the monster of prime order p of type pA there is a vertex algebra ${}^gV$ defined over the finite field $\mathbf{F}_p$ and acted on by the centralizer $C_M(g)$ of g in the monster group M, with the property that the graded Brauer character $\mathrm{Tr}(h|{}^gV) = \sum_n \mathrm{Tr}(h|{}^gV_n)q^n$ is equal to the Hauptmodul $\mathrm{Tr}(gh|V) = \sum_n \mathrm{Tr}(g|V_n)q^n$ (where V is the graded vertex algebra acted on by the monster constructed by Frenkel, Lepowsky and Meurman [FLM]). In [B-R] the vertex superalgebra ${}^gV$ was defined for any element $g \in M$ of odd prime order to be the sum of the Tate cohomology groups $\hat{H}^0(g, V[1/2]) \oplus \hat{H}^1(g, V[1/2])$ for a suitable $\mathbf{Z}[1/2]$ form $V[1/2]$ of V, and it was shown that $\mathrm{Tr}(h|{}^gV) = \mathrm{Tr}(h|\hat{H}^0(g, V[1/2])) - \mathrm{Tr}(h|\hat{H}^1(g, V[1/2]))$ was equal to the Hauptmodul of $gh \in M$. Hence to prove the modular moonshine conjecture for an element g of type pA it is enough to prove that $\hat{H}^1(g, V[1/2]) = 0$. In [B-R] this was shown by explicit calculation for the elements of type pA for $p \leq 11$, using the fact that these elements commute with an element of type $2B$. For $p \geq 13$ this method does not work as these elements do not commute with an element of type $2B$. The first main theorem of this paper is theorem 4.1 which states that if g is an element of prime order $p \geq 13$ not of type $13B$ then $\hat{H}^1(g, V[1/2]) = 0$ (assuming a certain condition about the monster Lie algebra, whose proof should appear later). Hence Ryba's conjectures are proved for all elements of M of type pA. (Actually this is not quite correct, because the proof for $p = 2$ in [B-R] assumes an unproved technical hypothesis.) The proof we give fails for exactly the cases already proved in [B-R].

We can also ask what happens for the other elements of order less than 13. The cases of elements of types $2B$ or $3C$ are also treated in [B-R]: for type $3C$, $\hat{H}^1(g, V[1/2])$ is again zero, and for type $2B$, $\hat{H}^1(g, V[1/2])$ is zero in even degree and $\hat{H}^0(g, V[1/2])$ is zero in odd degree. This leaves the cases where g is of type $3B$, $5B$, $7B$, or $13B$, when the Tate cohomology groups $\hat{H}^0(g, V[1/2])$ and $\hat{H}^1(g, V[1/2])$ are usually both nonzero in each degree. In these cases the structure of the cohomology groups is determined by our second main result, theorem 6.1, which states that the unique element σ of order 2 in the center of

---

$C_M(g)/O_p(C_M(g))$ acts as 1 on $\hat{H}^0(g,V[1/2])$ and as -1 on $\hat{H}^1(g,V[1/2])$. This determines the modular characters of both cohomology groups because $\mathrm{Tr}(h|\hat{H}^0(g,V[1/2]) + \mathrm{Tr}(h|\hat{H}^1(g,V[1/2]))$ is then given by $\mathrm{Tr}(h\sigma|\hat{H}^0(g,V[1/2])) - \mathrm{Tr}(h\sigma|\hat{H}^1(g,V[1/2]))$ which is the Hauptmodul of the element $gh\sigma \in M$. Hence both $\mathrm{Tr}(h|\hat{H}^0(g,V[1/2]))$ and $\mathrm{Tr}(h|\hat{H}^1(g,V[1/2]))$ can be written explicitly as linear combinations of two Hauptmoduls for any p-regular element $h \in C_M(g)$. We get two new modular vertex superalgebras acted on by double covers of sporadic groups when g has type $3B$ or $5B$: a vertex superalgebra over $\mathbf{F}_3$ acted on by $2.Suz$, and a vertex superalgebra over $\mathbf{F}_5$ acted on by $2.HJ$. For elements of types $7B$ and $13B$ the vertex superalgebras we get are acted on by the double covers $2.A_7$ and $2.A_4$ of alternating groups.

In particular if the integral form V of the monster vertex algebra discussed in [B-R] exists and has the properties conjectured there then all the cohomology groups $\hat{H}^i(g,V)$ are now known for all elements g of prime order in M.

We now discuss the proofs of the two main theorems. We first quickly dispose of the second main theorem: if an element $g \in M$ of odd order commutes with an element of type $2B$ then it is easy to work out its action on the $\mathbf{Z}[1/2]$-form of the monster vertex algebra and hence the Tate cohomology groups $\hat{H}^*(g,V[1/2])$ can be calculated by brute force, which is what we do in sections 5 and 6 for the elements of types $3B$, $5B$, $7B$, and $13B$.

The elements g of prime order $p \geq 13$ do not commute with any elements of type $2B$ (except when g has type $13B$ or $23AB$) so we cannot use the method above. Instead we adapt the proof of the moonshine conjectures in [B]. By using a $\mathbf{Z}_p$-form of the monster Lie algebra rather than a $\mathbf{Q}$-form we can find some complicated relations between the coefficients of the series $\sum_n \mathrm{Tr}(h|\hat{H}^0(g,V[1/2]_n))q^n$ and $\sum_n \mathrm{Tr}(h|\hat{H}^1(g,V[1/2]_n))q^n$. The reason we get more information by using $\mathbf{Z}_p$-forms rather than $\mathbf{Q}_p$-forms is that the group ring $\mathbf{Z}_p[\mathbf{Z}/p\mathbf{Z}]$ has 3 indecomposable modules which are free over $\mathbf{Z}_p$, while the group ring $\mathbf{Q}_p[\mathbf{Z}/p\mathbf{Z}]$ only has 2 indecomposable modules which are free over $\mathbf{Q}_p$, and this extra indecomposable module provides the extra information. The relations between the coefficients we get are similar to the relations defining completely replicable functions, except that some of the relations defining completely replicable functions (about "$(2p-1)/p^2$" of them) are missing. If p is large (≥ 13) we show that these equations have only a finite number of solutions. We then use a computer to find all the solutions, and see that the only solutions imply that $\hat{H}^1(g,V[1/2]) = 0$ for all g of prime order at least 13 other than those of type $13B$. This proof could probably be made to work for some smaller values of p such as 7 and 11, but the difficulty of showing that there are no extra solutions for the equations of the coefficients increases rapidly as p decreases, because for smaller p there are more equations missing.

Y. Martin [Ma] has recently found a conceptual proof that any completely replicable function is a modular function. Cummins and Gannon [CG] have greatly generalized this result using different methods, and showed that the functions are Hauptmoduls. It seems possible that their methods could be extended to replace the computer calculations in section 4, although Cummins has told me that this would probably require adding in some "missing" relations corresponding to the case $(p,mn) \neq 0$ in proposition 3.4.

We summarize the results of this paper and of [B-R] about the vertex superalgebras ${}^gV$ for all elements g of prime order p in the monster. If g is of type pA, or pB for $p > 13$, or $3C$, then ${}^gV$ is just a vertex algebra and not a superalgebra. If $p \geq 13$ this is proved in this paper by an argument which works for any self dual form of the monster vertex algebra but which relies on computer calculations and on a so far unpublished argument about integral forms of the monster Lie algebra. For $p < 13$ (or $p = 23$) this is proved in [B-R] by calculating explicitly for a certain $\mathbf{Z}[1/2]$ form of the monster vertex algebra; this avoids computer calculations but only works for one particular form of the monster vertex algebra. Also, if $p = 2$ the calculation depends on an as yet unproved technical assumption about the Dong-Mason-Montague construction of the monster vertex algebra from an element of type $3B$ ([DM] or [M]). If g is of type pB for $2 \leq p \leq 13$ then the super part of ${}^gV$ does not vanish. If $p = 2$ then ${}^gV$ is calculated explicitly in [B-R] (again using the unproved technical assumption) and it turns out that its ordinary part vanishes in odd degrees and its super part vanishes in even degrees. If $3 \leq p \leq 13$ then ${}^gV$ is calculated in this paper, and we find that there is an element in $C_M(g)$ acting as -1 on the super part and as 1 on the ordinary part of ${}^gV$. In all cases we have explicitly described the modular characters of $C_M(g)$ acting on the ordinary or super part of any degree piece of ${}^gV$ in terms of the coefficients of certain Hauptmoduls.

Notation.

$[A]$ is the element of K represented by the module A.

A, B, C	*G-modules.*
A_n	*The alternating group on n symbols.*
Aut	*The automorphism group of something.*
$c_g^+(n)$	*The n'th coefficient of the Hauptmodul of $g \in M$, equal to* $\mathrm{Tr}(1\vert^g V_n) = \dim(\hat{H}^0(g, V[1/2]_n)) - \dim(\hat{H}^1(g, V[1/2]_n))$.
$c_g^-(n)$	$\dim(\hat{H}^0(g, V[1/2]_n)) + \dim(\hat{H}^1(g, V[1/2]_n))$.
$c_{m,n}$	*Defined in proposition 4.3.*
$\mathbf{C}$	*The complex numbers.*
$C_M(g)$	*The centralizer of g in the group M.*
Co_1	*Conway's largest sporadic simple group.*
E	*The positive subalgebra of the monster Lie algebra.*
F	*The negative subalgebra of the monster Lie algebra.*
$\mathbf{F}_p$	*The finite field with p elements.*
f	*A homomorphism from K to $\mathbf{Q}$ defined in lemma 2.3.*
g	*An element of G, usually of order p.*
g_i	*The element g^i of G, used when it is necessary to distinguish the multiplication in the group ring from some other multiplication.*
$\langle g \rangle$	*The group generated by g.*
G	*A group, often cyclic of prime order p and generated by g.*
$h(A), h_n$	*See section 5.*
H	*The Cartan subalgebra of the monster Lie algebra.*
$\hat{H}^i(G, A)$	*A Tate cohomology group of the finite group G with coefficients in the G-module A.*
$\hat{H}^i(g, A)$	*means $\hat{H}^i(\langle g \rangle, A)$, where $\langle g \rangle$ is the cyclic group generated by g.*
$\hat{H}^*(g, A)$	*The sum of the Tate cohomology groups $\hat{H}^0(g, A)$ and $\hat{H}^1(g, A)$, considered as a super module.*
HJ	*The Hall-Janko sporadic simple group (sometimes denoted J_2).*
I	*The indecomposable module of dimension $p-1$ over $\mathbf{Z}_p[G]$, isomorphic to the kernel of the natural map from $\mathbf{Z}_p[G]$ to $\mathbf{Z}_p$ and to the quotient $\mathbf{Z}_p[G]/N_G\mathbf{Z}_p$.*
Im	*The image of a map.*
K	*A ring which is a free $\mathbf{Q}$-module with a basis of 3 elements $[\mathbf{Z}_p] = 1$, $[\mathbf{Z}_p[G]]$, and $[I]$.*
Ker	*The kernel of a map.*
$\Lambda, \hat{\Lambda}$	*The Leech lattice and a double cover of the Leech lattice.*
$\Lambda^n(A)$	*The n'th exterior power of A.*
$\Lambda^*(A)$	*The exterior algebra $\oplus_n \Lambda^n(A)$ of A.*
L	*An even lattice.*
$\mathbf{m}$	*The monster Lie algebra.*
M	*The monster simple group.*
N_G	*The element $\sum_{g \in G} g$ of $\mathbf{Z}_p[G]$.*
$O_p(G)$	*The largest normal p-subgroup of the finite group G.*
p	*A prime, usually the order of g.*
$\mathbf{Q}, \mathbf{Q}_p$	*The rational numbers and the field of p-adic numbers.*
ρ	*The Weyl vector of the monster Lie algebra.*
$\mathbf{R}$	*The real numbers.*
R_p	*A finite extension of the p-adic integers.*
$R(i)$	*Defined just before lemma 3.2.*
σ	*An automorphism of type $2B$ in the monster or the automorphism -1 of the Leech lattice.*
S_n	*A symmetric group.*
$S^n(A)$	*The n'th symmetric power of A.*
$S^*(A)$	*The symmetric algebra $\oplus_n S^n(A)$ of A.*
Suz	*Suzuki's sporadic simple group.*
Tr	$\mathrm{Tr}(g\vert A)$ *is the usual trace of g on a module A if A is a module over a ring of characteristic 0, and the Brauer trace if A is a module over a field of finite characteristic.*
$V[1/n]$	*A $\mathbf{Z}[1/n]$-form of the monster vertex algebra.*
V_Λ	*The integral form of the vertex algebra of $\hat{\Lambda}$.*

V_n *The degree n piece of V.*
V^n *An eigenspace of some group acting on V.*
${}^gV$ *A modular vertex algebra or superalgebra given by $\hat{H}^*(g, V[1/n])$ for some n coprime to $|g|$.*
$\mathbf{Z}$ *The integers.*
$\mathbf{Z}_p$ *The ring of p-adic integers.*
ω *A cube root of 1 or a conformal vector.*
Ω *The Laplace operator on $\Lambda^*(E)$.*

2. Representations of $\mathbf{Z}_p[G]$.

We give some auxiliary results about modules over $\mathbf{Z}_p[G]$ where G is a cyclic group generated by g of prime order p, and in particular calculate the exterior and symmetric algebras of all indecomposable modules. All modules will be free over $\mathbf{Z}_p$ and will be either finitely generated or $\mathbf{Z}$ graded with finitely generated pieces of each degree. All tensor products will be taken over $\mathbf{Z}_p$.

Recall from [B-R section 2] that there are 3 indecomposable modules over $\mathbf{Z}_p[G]$, which are $\mathbf{Z}_p$, the group ring $\mathbf{Z}_p[G]$, and the module I of $\mathbf{Z}_p[G]$ that is isomorphic to the kernel of the natural map from $\mathbf{Z}_p[G]$ to $\mathbf{Z}_p$ and to the quotient $\mathbf{Z}_p[G]/N_G\mathbf{Z}_p$ (where $N_G = 1 + g + g^2 + \cdots + g^{p-1}$). Their Tate cohomology groups are given by $\hat{H}^0(g, \mathbf{Z}_p) = \mathbf{Z}/p\mathbf{Z}$, $\hat{H}^1(g, \mathbf{Z}_p) = 0$, $\hat{H}^0(g, \mathbf{Z}_p[G]) = 0$, $\hat{H}^1(g, \mathbf{Z}_p[G]) = 0$, $\hat{H}^0(g, I) = 0$, and $\hat{H}^1(g, I) = \mathbf{Z}/p\mathbf{Z}$.

Lemma 2.1. *The tensor products of these modules are given as follows:*

$$\begin{aligned}\mathbf{Z}_p \otimes X &= X \ \textit{(for any } X\textit{)}\\ \mathbf{Z}_p[G] \otimes X &= \mathbf{Z}_p[G]^{\dim(X)} \ \textit{(the sum of } \dim(X) \textit{ copies of } \mathbf{Z}_p[G]\textit{)}\\ I \otimes I &= \mathbf{Z}_p[G]^{p-2} \oplus \mathbf{Z}_p.\end{aligned}$$

Proof. The case $\mathbf{Z}_p \otimes X$ is trivial. If X has a basis $x_1, \ldots, x_n$ then for any fixed i the elements $g^j \otimes g^j(x_i)$ ($0 \le j < p$) form a basis for a submodule of $\mathbf{Z}_p[G] \otimes X$ isomorphic to $\mathbf{Z}_p[G]$, and $\mathbf{Z}_p[G] \otimes X$ is the direct sum of these submodules for all i, which proves the result about $\mathbf{Z}_p[G] \otimes X$. For the case $I \otimes I$ we look at the cohomology sequence of the short exact sequence

$$0 \to I \otimes I \to I \otimes \mathbf{Z}_p[G] \to I \otimes \mathbf{Z}_p \to 0$$

to see that $\hat{H}^0(I \otimes I) = \mathbf{Z}/p\mathbf{Z}$ and $\hat{H}^1(I \otimes I) = 0$, which implies that $I \otimes I$ must be the sum of $\mathbf{Z}_p$ and some copies of $\mathbf{Z}_p[G]$. The number of copies can be worked out by looking at the dimensions of both sides. This proves lemma 2.1.

Corollary 2.2. *If A and B are $\mathbf{Z}_p[G]$-modules then $\hat{H}^*(g, A \otimes B) = \hat{H}^*(g, A) \otimes \hat{H}^*(g, B)$.*

Proof. Check each of the 9 cases when A and B are indecomposable modules using lemma 2.1. This proves corollary 2.2.

We form the ring K which is a free $\mathbf{Q}$-module with a basis of 3 elements $[\mathbf{Z}_p] = 1$, $[\mathbf{Z}_p[G]]$, and $[I]$ corresponding to the indecomposable modules of $\mathbf{Z}_p[G]$, whose addition and multiplication are those induced by tensor products and direct sums of modules. If A is a $\mathbf{Z}_p[G]$-module then we write $[A]$ for the element of K represented by A. Notice that this is not the same as the (tensor product with $\mathbf{Q}$ of the) Grothendieck ring of finitely generated projective $\mathbf{Z}_p[G]$ modules because we do not assume the relations given by nonsplit short exact sequences. The Grothendieck ring (tensored with $\mathbf{Q}$) is a quotient of our ring K by the ideal generated by $[\mathbf{Z}_p] + [I] - [\mathbf{Z}_p[G]]$.

Lemma 2.3. *There are exactly 3 ring homomorphisms* $\dim$, $\mathrm{Tr}(g|.)$, *and f from K to $\mathbf{Q}$ (which correspond to the 3 elements of the spectrum of K). They are given by*

1. $\dim([\mathbf{Z}_p]) = 1$, $\dim([\mathbf{Z}_p[G]]) = p$, $\dim([I]) = p - 1$.
2. $\mathrm{Tr}(g|[\mathbf{Z}_p]) = 1$, $\mathrm{Tr}(g|[\mathbf{Z}_p[G]]) = 0$, $\mathrm{Tr}(g|[I]) = -1$.
3. $f([\mathbf{Z}_p]) = 1$, $f([\mathbf{Z}_p[G]]) = 0$, $f([I]) = 1$.

Proof. From corollary 2.2 we know that the products in the ring K are given by $[\mathbf{Z}_p[G]][\mathbf{Z}_p[G]] = p[\mathbf{Z}_p[G]]$, $[\mathbf{Z}_p[G]][I] = (p-1)[\mathbf{Z}_p[G]]$, and $[I][I] = (p-2)[\mathbf{Z}_p[G]] + 1$. Hence if $x \in \mathbf{Q}$ and $y \in \mathbf{Q}$ are the images of $[\mathbf{Z}_p[G]]$ and I under some homomorphism they must satisfy $x^2 = px$, $xy = (p-1)x$, and $y^2 = (p-2)x+1$. The only solutions to these equations are $(x,y) = (p, p-1)$, $(0,1)$, or $(0,-1)$. This proves lemma 2.3.

The first two homomorphisms in lemma 2.3 are the homomorphisms which factor through the Grothendieck ring and will not be very interesting to us. We can use them in place of f in the arguments in the rest of the paper, but this only leads to relations between the coefficients of $\sum_n \dim(V_n)q^n$ and $\sum_n \mathrm{Tr}(g|V_n)q^n$, which are essentially the relations already used in [B] to determine these functions. It is the third homomorphism f which detects the integral structure on $V[1/2]$ which will give us enough extra information to prove theorem 4.1.

In general, taking the trace of any fixed element of a group gives a homomorphism from a representation ring of a group to some field, and quite often (e.g., for the complex representation ring of a group) this gives a 1:1 correspondence between homomorphisms and (certain sorts of) conjugacy classes of the group. Lemma 2.3 gives an example of a homomorphism f not constructed in this way.

A permutation module is a module for G with a basis acted on by G. We recall from [B-R] that a module A is a permutation module if and only if $\hat{H}^1(g, A) = 0$, which in turn is equivalent to saying that A is a sum of copies of $\mathbf{Z}_p$ and $\mathbf{Z}_p[G]$.

Lemma 2.4. *If A is a permutation module over any ring for any finite group g then so are the symmetric powers $S^n(A)$. If all elements of G act on a basis of A as products of cycles of odd length then the exterior powers $\Lambda^n(A)$ are also permutation modules.*

Proof. For symmetric powers this is proved in [B-R]. For the proof for exterior powers, let $a_1, \ldots, a_n$ be a basis for A acted on by G. Then G acts on the set of all elements of the form $\pm a_{i_1} \wedge \cdots \wedge a_{i_n}$, which consists of all elements of a basis together with their negatives. If the action of G on the basis of A has the property that all elements of G are products of cycles of odd length, then there is no element of G that maps any element of the form $\pm a_{i_1} \wedge \cdots \wedge a_{i_n}$ to its negative. This means that we can find a G-invariant subset of these elements which forms a basis for $\Lambda^n(A)$. This proves lemma 2.4.

Lemma 2.5. *The exterior powers of indecomposable modules are given by*

$$\begin{aligned}
\Lambda^0(\mathbf{Z}_p) &= \mathbf{Z}_p \\
\Lambda^1(\mathbf{Z}_p) &= \mathbf{Z}_p \\
\Lambda^n(\mathbf{Z}_p) &= 0 \textit{ if } n \neq 0, 1 \\
\Lambda^0(\mathbf{Z}_p[G]) &= \mathbf{Z}_p \\
\Lambda^p(\mathbf{Z}_p[G]) &= \mathbf{Z}_p \textit{ if } p \textit{ is odd, and } I \textit{ if } p = 2 \\
\Lambda^n(\mathbf{Z}_p[G]) &= \mathbf{Z}_p[G]^{\binom{p-1}{n}} \textit{ if } 1 \leq n \leq p-1 \\
\Lambda^n(\mathbf{Z}_p[G]) &= 0 \textit{ if } n > p \\
\Lambda^n(I) &= \mathbf{Z}_p \oplus \mathbf{Z}_p[G]^{(\binom{p-1}{n}-1)/p} \textit{ if } n \textit{ is even and } 0 \leq n < p \\
\Lambda^n(I) &= I \oplus \mathbf{Z}_p[G]^{(\binom{p-1}{n}+1-p)/p} \textit{ if } n \textit{ is odd and } 0 \leq n < p \\
\Lambda^n(I) &= 0 \textit{ if } n \geq p
\end{aligned}$$

Proof. For the exterior powers of $\mathbf{Z}_p[G]$ with p odd we apply lemma 2.4 to see that all exterior powers are sums of $\mathbf{Z}_p$ and $\mathbf{Z}_p[G]$, and the exterior powers can then be identified by checking the dimension and the trace of g. The cohomology groups of the exterior powers of I can then be worked out by induction using the exact sequence

$$0 \to \Lambda^n(I) \to \Lambda^n(\mathbf{Z}_p[G]) \to \Lambda^{n-1}(I) \to 0.$$

The cohomology groups determine how many copies of $\mathbf{Z}_p$ and I occur in the decomposition into indecomposable modules, so we can work out the exterior powers of I from this. The remaining cases of lemma 2.5 are trivial, so this proves lemma 2.5.

These exterior powers induce operators on the ring K which we also denote by Λ^n. For example, we can use these operators to define Adams operations ψ^n on the ring K by

$$\sum_{n \in \mathbf{Z}} (-1)^n \Lambda^n([A])q^n = \exp(-\sum_{n \in \mathbf{Z}} \psi^n([A])q^n/n).$$

Corollary 2.6. *If p is odd then*

$$\sum_{n\in\mathbf{Z}}(-1)^n f([\Lambda^n(\mathbf{Z}_p)])q^n = 1-q$$

$$\sum_{n\in\mathbf{Z}}(-1)^n f([\Lambda^n(\mathbf{Z}_p[G])])q^n = 1-q^p$$

$$\sum_{n\in\mathbf{Z}}(-1)^n f([\Lambda^n(I)])q^n = (1+q^p)/(1+q)$$

Proof. This follows immediately from lemma 2.5 and lemma 2.3.

Lemma 2.7. *The symmetric powers of indecomposable modules are given by*

$$S^n(\mathbf{Z}_p) = \mathbf{Z}_p \text{ if } n\geq 0$$

$$S^n(\mathbf{Z}_p[G]) = \mathbf{Z}_p[G]^{\binom{p+n-1}{n}/p} \text{ if } (p,n)=1$$

$$S^n(\mathbf{Z}_p[G]) = \mathbf{Z}_p[G]^{(\binom{p+n-1}{n}-1)/p}\oplus\mathbf{Z}_p \text{ if } p|n$$

$$S^n(I) = \mathbf{Z}_p\oplus\mathbf{Z}_p[G]^{(\binom{p+n-2}{n}-1)/p} \text{ if } p|n$$

$$S^n(I) = I\oplus\mathbf{Z}_p[G]^{(\binom{p+n-2}{n}+1-p)/p} \text{ if } n\equiv 1 \bmod p$$

$$S^n(I) = \mathbf{Z}_p[G]^{(\binom{p+n-2}{n})/p} \text{ if } n\not\equiv 0,1 \bmod p$$

Proof. For symmetric powers of $\mathbf{Z}_p$ this is trivial and for symmetric powers of $\mathbf{Z}_p[G]$ it can be proved in the same way as in lemma 2.5. If $p=2$ then the case of I is easy to do as I is just one dimensional. For the case of I when p is odd we let N_G be the element $1+g+\cdots+g^{p-1}\in\mathbf{Z}_p[G]$ and consider the quotient of the symmetric algebra $S^*(\mathbf{Z}_p[G])$ by the ideal (N_G). This is the universal commutative algebra generated by $\mathbf{Z}_p[G]/N_G\mathbf{Z}_p$, so it is $S^*(\mathbf{Z}_p[G]/N_G\mathbf{Z}_p)$ which is isomorphic to $S^*(I)$ because $\mathbf{Z}_p[G]/N_G\mathbf{Z}_p$ is isomorphic to I. Therefore there is an exact sequence

$$0\rightarrow S^{n-1}(\mathbf{Z}_p[G])\rightarrow S^n(\mathbf{Z}_p[G])\rightarrow S^n(I)\rightarrow 0.$$

Using the known cohomology groups of the symmetric powers of $\mathbf{Z}_p[G]$ and the exact sequence of cohomology groups of this exact sequence gives the cohomology groups of $S^n(I)$ and hence the number of times that $\mathbf{Z}_p$ and I occur in the decomposition of $S^n(I)$. This proves lemma 2.7.

Corollary 2.8. *The cohomology rings of the symmetric algebras of indecomposable modules are give as follows.*

$\hat{H}^*(S^*(\mathbf{Z}_p))$ *is a polynomial algebra with one ordinary generator of degree 1.*

$\hat{H}^*(S^*(\mathbf{Z}_p[G]))$ *is a polynomial algebra with one ordinary generator of degree p.*

$\hat{H}^*(S^*(I))$ *is the tensor product of a polynomial algebra with one ordinary generator of degree p and an exterior algebra with one super generator of degree 1 if p is odd. (If p is even then* $\hat{H}^*(S^*(I))$ *is a polynomial algebra on one super generator of degree 1, but we do not need this case.)*

Proof. This follows from the calculation of the symmetric powers in lemma 2.7. The product structure on the symmetric algebras can be worked out using the formula $d(ab)=(da)b\pm a(db)$ relating the cup product with the map d from $\hat{H}^i(C)$ to $\hat{H}^{i+1}(A)$ associated to the exact sequence $0\rightarrow A\rightarrow B\rightarrow C\rightarrow 0$. This proves corollary 2.8.

Lemma 2.9. *Suppose that* $A_{-1}=0, A_0,\ldots,A_n,A_{n+1}=0$ *is a sequence of modules and we have maps* d *from* A_i *to* A_{i+1} *and* d^* *from* A_{i+1} *to* A_i *for all* i *such that* $d^2=0$, $d^{*2}=0$, *and* $dd^*+d^*d=k$ *for some fixed integer* k *coprime to* p. *Then*

$$[A_0]-[A_1]+[A_2]-\cdots+(-1)^n[A_n]=0.$$

Proof. The fact that k is a unit in $\mathbf{Z}_p$ implies that A_i is the direct sum $dd^*(A_i)\oplus d^*d(A_i)$ and that d is an isomorphism from $d^*d(A_i)$ to $dd^*(A_{i+1})$. The lemma follows from this because the sequence splits as the sum of these isomorphisms. (Notice that the relation between the $[A_i]$'s does not follow just from the exactness of d; for example, look at the short exact sequence $0\rightarrow I\rightarrow\mathbf{Z}_p[G]\rightarrow\mathbf{Z}_p\rightarrow 0$. It is easy to check that in this case there is a map d^* with $d^{*2}=0$ and $dd^*+d^*d=p$, so the condition that $(k,p)=1$ is also necessary.) This proves lemma 2.9.

Lemma 2.10. *Suppose that A is a finitely generated free module over $\mathbf{Z}$ or $\mathbf{Z}_p$ with a symmetric self dual form (,). Then this induces a symmetric self dual form (defined in the proof) on any exterior power $\Lambda^n(A)$.*

Proof. We define the bilinear form on $\Lambda^n(A)$ by

$$(a_1 \wedge \cdots \wedge a_n, b_1 \wedge \cdots \wedge b_n) = \sum_{\sigma \in S_n} \chi(\sigma)(a_1, b_{\sigma(1)}) \cdots (a_n, b_{\sigma(n)})$$

where $\chi(\sigma)$ is 1 or -1 depending on whether σ is an even or odd permutation. This obviously defines a symmetric bilinear form on $\Lambda^n(A)$ with values in $\mathbf{Z}$ or $\mathbf{Z}_p$, and we have to check it is unimodular. The determinant of $\Lambda^n(A)$ is equal to $a \det(A)^b$ for some constants a and b depending on n, but not on A. We can work out a by letting A be the lattice with a base of orthogonal elements $a_1, a_2, \ldots$ with norms ± 1, when we see that $\Lambda^n(A)$ also has an orthogonal base of elements $a_{i_1} \wedge a_{i_2} \cdots$ with $i_1 < i_2 < \cdots$ with norms ± 1, so both A and $\Lambda^n(A)$ have discriminant 1 and so $a = 1$. Hence if A is self dual then $\Lambda^n(A)$ has discriminant 1 and must also be self dual. This proves lemma 2.10. (It is easy to check that the constant b is equal to $\dim(\Lambda^n(A))/\dim(A)$ but we do not need this.)

The analogue of this lemma for symmetric powers is false. The proof breaks down because the element $a_{i_1} a_{i_2} \cdots$ with $i_1 \leq i_2 \leq \cdots$ does not have norm ± 1 if some of the i_j's are equal. In section 5 we will construct a graded algebra $h(A)$, such that the homogeneous components of $h(A)$ have self dual symmetric bilinear forms if A does, and $h(A) \otimes \mathbf{Q}_p$ is a sum of tensor products of symmetric powers of A.

The following corollary is purely for entertainment and is not used elsewhere in the paper.

Corollary 2.11. *There is a 28-dimensional self dual positive definite lattice with no roots, acted on by the orthogonal group $O_8^+(\mathbf{F}_2)$.*

Proof. By lemma 2.10 the lattice $\Lambda^2(E_8)$ is self dual, and is obviously acted on by the automorphism group of the E_8 lattice modulo -1, which is just $O_8^+(\mathbf{F}_2)$. It is easy to check that this lattice has no roots either by calculation or by observing that there is no suitable root lattice acted on by $O_8^+(\mathbf{F}_2)$. This proves lemma 2.11.

The lattice $\Lambda^2(E_8)$ has theta function

$$\sum_{\lambda \in \Lambda^2(E_8)} q^{\lambda^2/2} = 1 + 2240q^{3/2} + 98280q^{4/2} + 1790208q^{5/2} + 19138560q^{6/2} + \cdots.$$

The vectors of norm 3 are just the 2240 vectors generating one of the 1-dimensional sublattices of the form $\Lambda^2(L)$ where L is one of the 1120 sublattices of E_8 isomorphic to A_2.

3. The $\mathbf{Z}[1/2]$-form of the monster Lie algebra.

We find some relations between the dimensions of the Tate cohomology groups $\hat{H}^i(g, V[1/2])$ by studying the Lie algebra cohomology of the positive subalgebra of a $\mathbf{Z}_p$-form of the monster Lie algebra. In the next section we will use these relations to compute the cohomology groups in the case when g has order at least 13. We recall that $V[1/2]$ is the self dual $\mathbf{Z}[1/2]$-form of Frenkel, Lepowsky, and Meurman's monster vertex algebra [FLM] described in [B-R] (but the arguments in this section work for any self dual $\mathbf{Z}_p$-form of the monster vertex algebra).

This section should really be about the integral form of the monster Lie algebra, but this has not been constructed yet because of the lack of a construction of a self dual integral form of the monster vertex algebra. However, as we are only looking at the action of elements of odd order p in the monster and tensoring everything with $\mathbf{Z}_p$, a $\mathbf{Z}[1/2]$-form is just as good as an integral form.

We briefly recall some properties of the monster Lie algebra $\mathbf{m}$ from [B]. This is a $II_{1,1}$-graded Lie algebra acted on by the monster, where $II_{1,1}$ is the 2-dimensional even self dual Lorentzian lattice whose element (m, n) has norm $-2mn$. The piece of degree (m, n) of $\mathbf{m}$ is isomorphic to V_{mn} if $(m, n) \neq (0, 0)$ and to $\mathbf{R}^2$ if $(m, n) = (0, 0)$. The Lie algebra $\mathbf{m}$ is the sum of 3 subalgebras E, F, and H, where the Cartan subalgebra H is the piece of degree $(0, 0)$ of $\mathbf{m}$, E is the sum of all pieces of degree (m, n) of $\mathbf{m}$ for $m > 0$, and F is the sum of all pieces of degree (m, n) of $\mathbf{m}$ for $m < 0$.

The $\mathbf{Z}[1/2]$ form on V induces a self dual $\mathbf{Z}[1/2]$-form and hence a $\mathbf{Z}_p$-form on $\mathbf{m}$. From now on we will write $\mathbf{m}[1/2]$ for this $\mathbf{Z}[1/2]$-form. In the preprint version of this paper I implicitly assumed that the degree (m, n) piece of $\mathbf{m}$ was self dual and isomorphic as a module over the monster to V_{mn}. At the last moment I realized that this is not at all clear. The problem is that although the no-ghost theorem gives an isomorphism of both spaces tensored with $\mathbf{Q}$, and both spaces have $\mathbf{Z}[1/2]$-forms, there is no obvious reason why this isomorphism should map one $\mathbf{Z}[1/2]$ form to the other. (In fact for the fake monster Lie algebra the corresponding isomorphism does not preserve the integral forms.) Fortunately in this paper we only need the following weaker statement:

Assumption. *If $m < p$ then the degree (m, n) piece of $\mathbf{m} \otimes \mathbf{Z}_p$ is self dual under the natural bilinear form and isomorphic to $V_{mn} \otimes \mathbf{Z}_p$ as a $\mathbf{Z}_p$ module acted on by the monster.*

I believe I have a proof of this; if all goes well it will appear in a paper provisionally titled "The fake monster formal group". Until this paper appears all the statements in sections 3 and 4 and the modular moonshine conjectures for elements of type pA ($p \geq 13$) should have this assumption added as a hypothesis.

I do not know if the condition $m < p$ in the assumption above is necessary; if it is not, then this condition (usually added in parentheses) can be missed out of some of the following lemmas. It seems very likely that self duality still holds without it, but I am not so sure about the action of the monster being the same if both m and n are divisible by p.

The monster Lie algebra has a Weyl vector ρ, i.e., a vector in the root lattice $II_{1,1}$ such that $(\rho, \alpha) = -(\alpha, \alpha)/2$ for every simple root α. This follows from [B, theorem 7.2] which states that this simple roots are the vectors $(1, n)$ for $n \geq 0$ or $n = -1$, with multiplicities $c(n)$. Hence the Weyl vector is $\rho = (1, 0)$.

We recall some facts about Hodge theory applied to Lie algebra cohomology. The self dual symmetric bilinear form on the monster Lie algebra identifies E with the dual space of F, and using the Cartan involution which maps F to E we see that we have a symmetric bilinear form on the Lie algebra E (which is the restriction of the contravariant form of the monster Lie algebra to E) and in particular we can identify E with its dual. The Lie algebra cohomology is the cohomology of an operator d which maps each space $\Lambda^i(E)$ to $\Lambda^{i+1}(E)$. The adjoint of this operator is denoted by d^*, and we define the Laplace operator Ω by $\Omega = dd^* + d^*d$. As for any generalized Kac-Moody algebra with a Weyl vector, the action of the Laplace operator $\Omega = dd^* + d^*d$ on the degree $\alpha = (m, n) \in II_{1,1}$ piece of $\Lambda^*(E)$ is given by multiplication by $(\alpha, \alpha + 2\rho)/2 = (m-1)n$. The Lie algebra cohomology group $H^i(E)$ of E can be identified with the zero eigenspace of Ω on $\Lambda^i(E)$. The Laplace operator restricted to $\Lambda^1(E) = E$ is half the partial Casimir operator Ω_0 defined in [K, section 2.5]; the extra factor of $1/2$ is necessary to make things work well over rings not containing $1/2$, but this is not important in this paper as we work over the ring of p-adic integers for odd p which always contains $1/2$.

Proposition 3.1. *The operators d and d^* act on the $\mathbf{Z}[1/2]$-form $\Lambda^*(E[1/2]) \subset \Lambda^*(E)$ of the exterior algebra (in all degrees (m, n) with $m < p$).*

Proof. The main point is that all homogeneous pieces of the $\mathbf{Z}[1/2]$-form of the exterior algebra are self dual under the contravariant bilinear form. This follows from lemma 2.10 and the fact that each homogeneous component is a finite sum of tensor products of exterior powers of the homogeneous components of $E[1/2]$. The result now follows from the fact that if d is a homomorphism of finite dimensional free $\mathbf{Z}[1/2]$-modules from A to B and A and B have self dual symmetric inner products then the adjoint d^* from B to A is well defined. This proves proposition 3.1.

We let $R(0)$ be the ring of formal Laurent series $K[[r, q]][1/r, 1/q]$ with coefficients in K, and we let $R(1)$ be the space of power series in $R(0)$ only involving monomials $r^m q^n$ with $p|mn$, and we let $R(2)$ be the subring of $R(0)$ of power series only involving powers of r^p and q^p. So we have the inclusions $R(2) \subset R(1) \subset R(0)$ and $R(1)$ is a module over $R(2)$ (but is not a ring itself). (We can also define $R(0)$, $R(1)$, and $R(2)$ for arbitrary generalized Kac-Moody algebras, in particular for the fake monster Lie algebra: $R(0)$ is a completion of the group ring of the root lattice, $R(1)$ is a subspace corresponding to the elements α of the root lattice with $p|(\alpha, \alpha)/2$, and $R(2)$ is the subring corresponding to p times the root lattice.) If A is a $\mathbf{Z}[1/2]$-module then we write $[A]$ for $[A \otimes_{\mathbf{Z}[1/2]} \mathbf{Z}_p]$.

Lemma 3.2. *If $(p, (m-1)n) = 1$ (and $m < p$) then the piece of degree (m, n) of*

$$[\Lambda^*(E[1/2])] = [\Lambda^0(E[1/2])] - [\Lambda^1(E[1/2])] + [\Lambda^2(E[1/2])] - \cdots$$

vanishes. In other words

$$r^{-1}\Lambda^*(\sum_{m>0,n\in\mathbf{Z}} r^m q^n[V_{mn}])$$

lies in $R(1)$.

Proof. The Laplace operator $\Omega = dd^* + d^*d$ acts as multiplication by $(m-1)n$ on the degree (m,n) piece of $\Lambda^*(E[1/2])$, so the result follows from lemma 2.9 if we let A_i be the degree (m,n) piece of $\Lambda^i(E[1/2])$. This proves lemma 3.2.

Lemma 3.3. *If A is a $\mathbf{Z}_p[G]$-module with $\mathrm{Tr}(g|A) = c^+$, $f([A]) = c^-$, (and $m < p$) then*

$$f(\Lambda^*(r^m q^n A)) = (1 - r^m q^n)^{(c^+ + c^-)/2}(1 + r^m q^n)^{(c^+ - c^-)/2} U$$

where U is a unit of the ring $R(2)$.

Proof. It is sufficient to prove this for an indecomposable module A because both sides are multiplicative. We just check each of the three possibilities for A using lemma 2.6.

If $A = \mathbf{Z}_p$ then $c^+ = c^- = 1$ and $f(\Lambda^*(r^m q^n[\mathbf{Z}_p])) = 1 - r^m q^n$, so lemma 3.3 is true in this case.

If $A = \mathbf{Z}_p[G]$ then $c^+ = c^- = 0$ and $f(\Lambda^*(r^m q^n[\mathbf{Z}_p[G]])) = 1 - r^{mp} q^{np}$ which is a unit in $R(2)$, so lemma 3.3 is true in this case.

If $A = I$ then $c^+ = -1$, $c^- = 1$ and

$$f(\Lambda^*(r^m q^n[I])) = (1 + r^{mp} q^{np})/(1 + r^m q^n) = U(1 + r^m q^n)^{-1},$$

so lemma 3.3 is also true in this case. This proves lemma 3.3.

We define integers $c_g^+(n)$ and $c_g^-(n)$ by

$$\begin{aligned}
c_g^+(n) &= \mathrm{Tr}(g|V_n) = \dim(\hat{H}^0(g, V[1/2]_n)) - \dim(\hat{H}^1(g, V[1/2]_n))\\
c_g^-(n) &= f(V[1/2]_n) = \dim(\hat{H}^0(g, V[1/2]_n)) + \dim(\hat{H}^1(g, V[1/2]_n)).
\end{aligned}$$

We use the numbers $c_g^+(n)$ and $c_g^-(n)$ rather than the apparently simpler numbers $\dim(\hat{H}^0(g, V[1/2]_n))$ and $\dim(\hat{H}^1(g, V[1/2]_n))$ because they turn out to be coefficients of Hauptmoduls, and because $c_g^+(n)$ is already known.

Proposition 3.4. *If $(p, mn) = 1$ (and $m < p$) then the coefficient of $r^m q^n$ in*

$$r^{-1} \prod_{m>0,n\in\mathbf{Z}} (1 - r^m q^n)^{(c_g^-(mn) + c_g^+(mn))/2}(1 + r^m q^n)^{(c_g^+(mn) - c_g^-(mn))/2}$$

vanishes. In other words this power series lies in $R(1)$.

Proof. We apply the homomorphism f to the expression in lemma 3.2 and use lemma 3.3. We find that the expression in this proposition is equal to an element of $R(1)$ times a unit in $R(2)$, and is therefore still an element of $R(1)$. Therefore its coefficients of $r^m q^n$ vanish unless $p|mn$. This proves proposition 3.4.

Proposition 3.4 can be generalized in the obvious way to any generalized Kac-Moody algebra which has a self dual $\mathbf{Z}_p$-form, a Weyl vector, and an integral root lattice.

We can also ask whether or not the coefficients of $r^m q^n$ in proposition 3.4 vanish when $p|mn$. Some numerical calculations suggest that they usually do not.

4. The modular moonshine conjectures for $p \geq 13$.

In this section we prove the following theorem, which completes the proof of the modular moonshine conjectures of [R section 6] (apart from a small technicality in the case $p = 2$.)

Theorem 4.1. *If $g \in M$ is an element of prime order $p \geq 17$ or an element of type $13A$ then $\hat{H}^1(g, V[1/2]) = 0$.*

This implies that ${}^gV = \hat{H}^0(g, V[1/2]) = \hat{H}^*(g, V[1/2])$ is a vertex algebra whose modular character is given by Hauptmoduls, and whose homogeneous components have the characters of [R definition 2].

The proof of this theorem will occupy the rest of this section. We have to show that the numbers $c_g^-(n)$ of proposition 3.4 are equal to the numbers $c_g^+(n)$, because the difference is twice the dimension of $\hat{H}^1(g, V[1/2]_n)$. We start by summarizing what we know about these numbers.

Lemma 4.2.

1. *The numbers $c_g^-(n)$ and $c_g^+(n)$ satisfy the relations given in proposition 3.4.*
2. *The numbers $c_g^-(n)$ are integers, with $c_g^-(n) \equiv c_g^+(n) \bmod 2$.*
3. *$c_g^-(n) \geq |c_g^+(n)|$ and $(p-2)c_g^+(n) + pc_g^-(n) \leq 2c_1^+(n)$, (where $c_1^+(n)$ is the coefficient of q^n in the elliptic modular function).*
4. *The numbers $c_g^+(n)$ are the coefficients of the Hauptmodul of the element $g \in M$.*

Proof. These properties follow easily from proposition 3.4 together with the fact that $\mathbf{Z}_p \otimes V_n$ has dimension $c_1^+(n)$ and is the sum of $(c_g^-(n) + c_g^+(n))/2$ copies of $\mathbf{Z}_p$, $(c_g^-(n) - c_g^+(n))/2$ copies of I, and some copies of $\mathbf{Z}_p[G]$. This proves lemma 4.2.

We will prove theorem 4.1 by showing that if g satisfies the conditions of theorem 4.1 then the conditions 1 to 4 in lemma 4.2 imply that $c_g^-(n) = c_g^+(n)$. We find a finite set of possible solutions of conditions 1, 2, and 4 of lemma 4.2, and find that for each p only one of these satisfies the condition 3. (There are often several solutions not satisfying condition 3.) The proof is just a long messy calculation and the reader should not waste time looking at it.

We first put the relations into a more convenient form.

Proposition 4.3. *There are integers $c_{m,n}$ defined for $m, n > 0$ (and $m < p$) with the following properties.*

1.
$$-\log\left(1 + \sum_{m>0,n>0} c_{m,n} r^m q^n\right) \equiv \sum_{m>0,n>0} \sum_{d|(m,n)} \frac{c_g^{(-)^d}(mn/d^2)}{d} r^m q^n \bmod r^p$$

2. *If $(p, mn) = 1$ then $c_{m+1,n} = c_{m,n+1}$.*

Proof. This follows from proposition 3.4 if we multiply both sides by $(r-q)/rq$ and then take the logarithm of both sides. This proves proposition 4.3.

Lemma 4.4. *If $p > 13$ then the values of $c_g^-(n)$ for $n \leq 21$, $c_g^-(2n)$ for $2n \leq 32$, and $c_g^-(36)$ and $c_g^-(45)$ are given by polynomials in the numbers $c_g^-(i)$ for $i = 1, 2, 4, 5$ with coefficients in $\mathbf{Z}_3$.*

Proof. We can evaluate the elements $c(n), n \leq 21$ and $c(2n), n \leq 16$ using the argument for cases 1 and 2 of lemma 4.7 below. We can evaluate $c(36)$ by looking at the coefficient of r^4q^9 in proposition 4.3 and using the fact that we know $c_{m,n}$ for $m \leq 3$, $n \leq 8$. Similarly we can evaluate $c(45)$ by looking at the coefficient of r^5q^9. Notice that the term $(\sum_{m,n} c_{m,n} r^m q^n)^3/3$ has 3's only in the denominators of coefficients of $r^m q^n$ when $3|m$ and $3|n$, so we do not get problems from this for the coefficients of r^4q^9 and r^5q^9 (but we do get problems from this if we try to work out $c_g^-(27)$ using the same method). This proves lemma 4.4.

If $p = 13$ we run into trouble when we try to determine $c_g^-(26)$; this is why the argument in lemma 4.4 does not work in this case. Also the argument breaks down if we try to work out $c(27)$, because when we look at the coefficient of r^3q^9 we get an extra term $c_g^-(3)/3$ which does not have coefficients in $\mathbf{Z}_3$. This is why we use the coefficients $c_g^-(1)$, $c_g^-(2)$, $c_g^-(4)$, and $c_g^-(5)$ rather than $c_g^-(1)$, $c_g^-(2)$, $c_g^-(3)$, and $c_g^-(5)$.

Lemma 4.4 is the reason why our arguments do not work for $p < 13$ (and do not work so smoothly for $p = 13$). As p gets smaller we have fewer relations to work with and it gets more difficult to determine all coefficients in terms of the $c_g^-(m)$'s for small m. It is probably possible to extend lemma 4.4 to cover some smaller primes with a lot of effort. Fortunately it is not necessary to do the cases $p < 13$ because these cases have already been done by explicit calculations in [B-R].

Lemma 4.5. *If $c_g^-(1)$, $c_g^-(2)$, $c_g^-(4)$, and $c_g^-(5)$ are known mod 3^n for some $n \geq 1$, and $p > 13$, and $(c_g^-(1), 3) = 1$ if $p = 13$, then these values of $c_g^-(m)$ are determined mod 3^{n+1}.*

Proof. By lemma 4.4 we see that we can determine the values mod 3^n of $c_g^-(n)$ for $n \leq 16$, $c_g^-(2n)$ for $2n \leq 32$, and $c_g^-(36)$ and $c_g^-(45)$.

But now if we look at the coefficient of r^3q^{3m} of 3.4 with $m = 1, 2, 4$, or 5, we see that $c_g^-(9m) + c_g^+(2m)/2 + c_g^-(m)/3 = c_g^-(m)^3/3+$ (some polynomial in known $c_g^-(i)$'s with coefficients that are 3-adic integers). But $c_g^-(m)^3/3$ mod 3^n depends only on $c_g^-(m)$ mod 3^n if $n \geq 1$, so we can determine $c_g^-(m)/3$ mod 3^n and hence $c_g^-(m)$ mod 3^{n+1}. This proves lemma 4.5.

This lemma is the reason that we use 3-adic rather than 2-adic approximation. If we try to prove the lemma above for 2^{n+1} instead of 3^{n+1}, all we find is that we can determine the $c_g^+(m)$'s mod 2^{n+1}, which is useless because we already know these numbers.

Proposition 4.6. *If the numbers $c_g^-(n)$ satisfy the conditions 1, 2, and 4 of lemma 4.2 then the numbers $c_g^-(1)$, $c_g^-(2)$, $c_g^-(4)$, and $c_g^-(5)$ are congruent mod 3^{29} to the coefficients of q, q^2, q^4, and q^5 of one of the following power series. (The second column is a genus zero group whose Hauptmodul appears to be the function with coefficients $c_g^-(n)$. This has not been checked rigorously as it is not necessary for the proof of theorem 4.1.)*

$p = 71$	$\Gamma_0(71)+$	q^{-1}	$+q$	$+q^2$	$+q^3$	$+q^4$	$+2q^5$	$+\cdots$
$p = 59$	$\Gamma_0(59)+$	q^{-1}	$+q$	$+q^2$	$+2q^3$	$+2q^4$	$+3q^5$	$+\cdots$
$p = 47$	$\Gamma_0(47)+$	q^{-1}	$+q$	$+2q^2$	$+3q^3$	$+3q^4$	$+5q^5$	$+\cdots$
$p = 47$	$\Gamma_0(94)+$	q^{-1}	$+q$		$+q^3$	$+q^4$	$+q^5$	$+\cdots$
$p = 41$	$\Gamma_0(41)+$	q^{-1}	$+2q$	$+2q^2$	$+3q^3$	$+4q^4$	$+7q^5$	$+\cdots$
$p = 41$	$\Gamma_0(82\mid 2)+$	q^{-1}			$+q^3$		$+q^5$	$+\cdots$
$p = 31$	$\Gamma_0(31)+$	q^{-1}	$+3q$	$+3q^2$	$+6q^3$	$+9q^4$	$+13q^5$	$+\cdots$
$p = 31$	$\Gamma_0(62)+$	q^{-1}	$+q$	$+q^2$	$+2q^3$	$+q^4$	$+3q^5$	$+\cdots$
$p = 29$	$\Gamma_0(29)+$	q^{-1}	$+3q$	$+4q^2$	$+7q^3$	$+10q^4$	$+17q^5$	$+\cdots$
$p = 29$	$\Gamma_0(58\mid 2)+$	q^{-1}	$+q$		$+q^3$		$+q^5$	$+\cdots$
$p = 23$	$\Gamma_0(23)+$	q^{-1}	$+4q$	$+7q^2$	$+13q^3$	$+19q^4$	$+33q^5$	$+\cdots$
$p = 23$	$\Gamma_0(46) + 23$	q^{-1}		$-q^2$	$+q^3$	$-q^4$	$+q^5$	$+\cdots$
$p = 23$	$\Gamma_0(46)+$	q^{-1}	$+2q$	$+q^2$	$+3q^3$	$+3q^4$	$+5q^5$	$+\cdots$
$p = 19$	$\Gamma_0(19)+$	q^{-1}	$+6q$	$+10q^2$	$+21q^3$	$+36q^4$	$+61q^5$	$+\cdots$
$p = 19$	$\Gamma_0(38)+$	q^{-1}	$+2q$	$+2q^2$	$+5q^3$	$+4q^4$	$+9q^5$	$+\cdots$
$p = 19$	$\Gamma_0(38\mid 2)+$	q^{-1}	$+2q$		$+q^3$		$+3q^5$	$+\cdots$
$p = 17$	$\Gamma_0(17)+$	q^{-1}	$+7q$	$+14q^2$	$+29q^3$	$+50q^4$	$+92q^5$	$+\cdots$
$p = 17$	$\Gamma_0(34)+$	q^{-1}	$+3q$	$+2q^2$	$+5q^3$	$+6q^4$	$+12q^5$	$+\cdots$
$p = 17$	$\Gamma_0(34\mid 2)+$	q^{-1}	$+q$		$+3q^3$		$+4q^5$	$+\cdots$
$p = 13$	$\Gamma_0(13)+$	q^{-1}	$+12q$	$+28q^2$	$+66q^3$	$+132q^4$	$+258q^5$	$+\cdots$
$p = 13$	$\Gamma_0(26)+$	q^{-1}	$+4q$	$+4q^2$	$+10q^3$	$+12q^4$	$+26q^5$	$+\cdots$
$p = 13$	$\Gamma_0(26\mid 2)+$	q^{-1}	$+2q$		$+4q^3$		$+6q^5$	$+\cdots$

It is also possible (but unlikely) that there are other solutions for $p = 13$ for which $c_g^-(1)$ does not satisfy the inequalities $0 \leq c_g^-(1) < 3^{10}$.

Proof. For each prime p we use a computer to test all 81 possibilities for $c_g^-(1)$, $c_g^-(2)$, $c_g^-(4)$, and $c_g^-(5)$ mod 3. If $p > 13$ then we can calculate the p-adic expansion of all the coefficients $c_g^-(n)$ recursively using lemma 4.5 above, and we reach a contradiction by looking at coefficients of proposition 4.3 except in the cases above. For $p = 13$ this does not quite work as we have not shown the values mod 3^n determine those mod 3^{n+1}, so we can adopt the crude procedure of just testing all 3^4 possibilities for the $c_g^-(i)$'s mod 3^{n+1} for each solution mod 3^n we have found, and checking to see which of them leads to contradictions. There were some cases for $p = 13$ where this did not lead to a contradiction but did at least lead to the conclusion that $c_g^-(1) < 0$ or $c_g^-(1) \geq 3^{10}$. (If $c_g^-(1)$ is not divisible by 3 then even when $p = 13$ the numbers $c_g^-(i)$ mod 3^n determine the numbers $c_g^-(n)$ mod 3^{n+1}. When $c_g^-(1)$ was divisible by 3, there were several cases where the coefficient $c_g^-(5)$ was not determined mod 3^{n+1} by the identities used by the computer program. However in all the cases looked at by the computer with $3|c_g^-(1)$, the values of $c_g^-(1)$, $c_g^-(2)$, $c_g^-(4)$, and $3c_g^-(5)$ mod 3^n uniquely determined their values mod 3^{n+1}.) This proves proposition 4.6, at least if one believes the computer calculations. (Anyone who does not like computer calculations in a proof is welcome to redo the calculations by hand.)

Lemma 4.7. *If the coefficients $c_g^-(1)$, $c_g^-(2)$, $c_g^-(4)$, and $c_g^-(5)$ are equal to the coefficients $c_g^+(1)$, $c_g^+(2)$, $c_g^+(4)$, and $c_g^+(5)$ for g an element of prime order $p > 13$ or an element of type $13A$ then all the coefficients are determined by the relations of proposition 3.4.*

Proof. This proof is just a long case by case check using induction. We will repeatedly use the fact that the coefficients of $r^m q^n$ of both sides of proposition 4.3 are equal.

Case 1. $c_g^-(2n)$ for $2n \not\equiv 0 \bmod p$. By looking at the coefficient of $r^2 q^n$ and using the fact that $c_{2,n} = c_{1,n+1}$ (as $(p, n) = 1$) we see that $c_g^-(2n)$ can be written as a polynomial in $c(n + 1)$ and $c(i)$ for $1 \le i < n$.

Case 2. $c_g^-(2n+1)$ for $2n+1 \not\equiv \pm 1 \bmod p$. By looking at the coefficient of $r^2 q^{2n}$ we can express $c_g^-(2n+1)$ in terms of $c_g^-(4n)$ and known quantities. But $c_g^-(4n)$ can be evaluated by looking at the coefficient of $r^4 q^n$ and using the fact that $c_{4,n} = c_{3,n+1} = c_{2,n+2}$ (as $2n + 1 \not\equiv \pm 1 \bmod p$).

The recursion formulas given by cases 1 or 2 can be written out explicitly and are given in [B, (9.1)]. In that paper they are sufficient to determine all coefficients because the analogues of the relations in proposition 3.4 hold whenever $mn \neq 0$.

The remaining cases of the proof are unusually tedious so we only sketch them briefly.

Case 3. $c_g^-(2n)$ for $2n \equiv 0 \bmod p$, n odd. We can express this in terms of $c_{2,n} = c_{3,n-1}$, which we can evaluate by calculating $c_g^-(3(n-1)) = c_g^-(2(3(n-1)/2))$ using case 1.

For the rest of the proof it is convenient to evaluate the cluster of elements $c_g^-(2pn - 1)$, $c_g^-(2pn + 1)$, and $c_g^-(4pn)$, simultaneously. (These are the only cases left to do.)

Case 4. $2np \equiv 2 \bmod 3$. We evaluate $c_g^-(2np + 1)$ in terms of $c_{3,(2np+1)/3}$. We evaluate $c_g^-(2np - 1)$ by expression $c_g^-(2np - 1)c(2)$ in terms of $c_{2,2np+1}$ and evaluating the latter by comparing it with $c_{3,2(2np+1)/3}$. We evaluate $c_g^-(4np)$ by expressing $c_{3,2np+2}$ in terms of $c_g^-(2)c_{2,2np}$ and evaluating the latter by comparing it with $c_{2,3np+3}$.

Case 5. $2np \equiv 1 \bmod 3$. We evaluate $c_g^-(2np-1)$ in terms of $c_{3,(2np-1)/3}$. We evaluate $c_{1,2np+5}$ by using $c_{3,(2np+5)/3}$ and then evaluate in turn $c_{2,2np+4} = c_{1,2np+5}$, $c_g^-(1)c_{1,2np+3}$ (using the coefficient of $r^2 q^{2np+4}$), $c_{2,2np+3} = c_{1,2np+3}$, $c_g^-(1)c_{1,2np+1}$ which gives us the value of $c_{1,2np+1}$. We evaluate $c_{2,2np}$ as in case 4.

Case 6. $2np \equiv 0 \bmod 3$. By looking at $c_{2,2np+2}$ and $c_{2,2np+3}$ we can find expressions for the linear combinations $c_g^-(1)c_g^-(2np + 1) + c_g^-(3)c_g^-(2np - 1)$ and $c_g^-(2)c_g^-(2np + 1) + c_g^-(4)c_g^-(2np - 1)$. If $p \neq 59$ or 71 then these two linear equations are independent so we can solve for $c_g^-(2np + 1)$ and $c_g^-(2np - 1)$, and then find $c_{2,2np}$ as in case 4. If $p = 59$ or 71 then an even more tedious argument using $c_{2,2np+2}$, $c_{3,2np+2}$, and $c_{3,2np+3}$ produces 3 independent linear relations between $c_g^-(2pn - 1)$, $c_g^-(2pn + 1)$, and $c_g^-(4pn)$, so we can solve for them.

This proves lemma 4.7.

We can now complete the proof of theorem 4.1. If we look at the possible solutions for the coefficients $c_g^-(n)$ given by proposition 4.6, we see that all the solutions except those congruent mod 3^{29} to the Hauptmoduls of the elements $g \in M$ are ruled out by the inequalities of lemma 4.2. As $3^{29} > c_1^+(i) > c_g^-(i) \ge 0$ for $i \le 5$ we see that $c_g^+(i) = c_g^-(i)$ for $i \le 5$. The coefficients $c_g^+(n)$ also satisfy the identities of proposition 4.3 satisfied by the $c_g^-(n)$'s; for example, this follows easily from the identity

$$\sum_{n\in\mathbf{Z}} c_g^+(n)r^n - \sum_{n\in\mathbf{Z}} c_g^+(n)q^n = r^{-1} \prod_{m>0,n\in\mathbf{Z}} (1 - r^m q^n)^{c_g^+(mn)}(1 - r^{pm}q^{pn})^{c_g^+(pmn)}$$

[B, page 434]. Therefore $c_g^-(n) = c_g^+(n)$ for all n by lemma 4.7 because they both have the same values for $n \le 5$ and both satisfy the same recursion relations given in proposition 3.4. This proves theorem 4.1.

5. Calculation of some cohomology groups.

In this section we calculate the Tate cohomology groups of some spaces that appear in the construction of the monster vertex algebra. In the next section we will use these calculations to find the Tate cohomology $\hat{H}^*(g, V[1/2])$ for elements g of types $3B$, $5B$, $7B$ and $13B$.

We will write $g_0, g_1, \ldots, g_{p-1}$ for the elements $1, g, \ldots, g^{p-1}$ of the group ring $\mathbf{Z}_p[G]$ to avoid confusing the group ring multiplication with the multiplication in other rings containing it.

Suppose that A is a free $\mathbf{Z}_p$-module. We write $h(A)$ for the $\mathbf{Z}$-graded $\mathbf{Z}_p$-algebra generated by elements $h_n(a)$ of degree n for $a \in A$, $n \geq 0$ with the relations

1. $h_n(\lambda a) = \lambda^n h_n(a)$ if $\lambda \in \mathbf{Z}_p$.
2. $h_0(a) = 1$, $h_n(a) = 0$ if $n < 0$.
3. $h_n(a+b) = \sum_{i \in \mathbf{Z}} h_i(a) h_{n-i}(b)$.

If A has a basis $a_1, \ldots, a_m$ then $h(A)$ is the polynomial algebra generated by elements $h_n(a_i)$ for $n > 0$, $1 \leq i \leq m$. An action of G on A induces an action of G on $h(A)$ in the obvious way.

Lemma 5.1. *The cohomology ring $\hat{H}^*(g, h(\mathbf{Z}_p[G]))$ is the polynomial algebra over $\mathbf{F}_p$ generated by the ordinary elements $h_n(g_0) + h_n(g_1) + \cdots + h_n(g_{p-1})$ for $n > 0$.*

Proof. This follows from the fact that $h(\mathbf{Z}_p[G])$ is the tensor product of the rings A_n, where A_n is the polynomial algebra generated by the elements $h_n(g_i)$ for $0 \leq i < p$. We see that A_n is isomorphic to the symmetric algebra $S^*(\mathbf{Z}_p[G])$ whose cohomology is given by lemma 2.8, and we then apply corollary 2.2 to finish the proof. (Notice that the space spanned by the elements $h_n(g_i)$ for $0 \leq i < p$ is not $h_n(\mathbf{Z}_p[G])$; in fact, the latter is not even a $\mathbf{Z}_p$-module.) This proves lemma 5.1.

Proposition 5.2. *The cohomology ring $\hat{H}^*(g, h(I))$ is isomorphic to the free exterior algebra with one super generator in each positive degree not divisible by p. The automorphism -1 of I multiplies each generator by -1 and hence acts as -1 on $\hat{H}^1(g, h(I))$ and as 1 on $\hat{H}^0(g, h(I))$.*

Proof. The algebra $h(I)$ is the quotient of $h(\mathbf{Z}_p[G])$ by the ideal generated by the elements $h_n(N_G)$. We let R_m be the quotient of $h(\mathbf{Z}_p[G])$ by the elements $h_n(N_G)$ for $n \leq m$, and we will prove by induction on m that $\hat{H}^*(R_m)$ is the tensor product of the free polynomial algebra generated by the ordinary elements $h_n(g_0) + h_n(g_1) + \cdots + h_n(g_{p-1})$ (of degree n) for $n > m/p$ and the free exterior algebra generated by super elements of each degree n with $0 < n \leq m$, $(p, n) = 1$ (of degree n).

To do this we look at the exact sequence

$$0 \to R_{m-1} \to R_{m-1} \to R_m \to 0$$

where the map from R_{m-1} to R_{m-1} is given by multiplication by $h_m(N_G)$, and work out the cohomology of R_m using the cohomology exact sequence of this short exact sequence. We have to consider the cases $p|m$ and $(p, m) = 1$ separately.

If $(p, m) = 1$ then multiplication by $h_m(N_G)$ induces the zero map on cohomology, so that $\hat{H}^*(g, R_m)$ is the sum of $\hat{H}^*(g, R_{m-1})$ and $\hat{H}^*(g, R_{m-1})$ with the degree shifted by m and with the ordinary and super parts exchanged. In other words, $\hat{H}^*(g, R_m)$ is the tensor product of $\hat{H}^*(g, R_{m-1})$ with an exterior algebra generated by one super element of degree m. This proves the induction step when $(p, m) = 1$.

If $p|m$ then multiplication by $h_m(N_G)$ induces an injective map on cohomology, so that $\hat{H}^*(g, R_m)$ is the quotient of $\hat{H}^*(g, R_{m-1})$ by the image of $h_m(N_G)$, in other words it is just $\hat{H}^*(g, R_{m-1})$ with a polynomial generator of degree m killed off.

Hence we see that to go from $\hat{H}^*(h(R_{m-1}))$ to $\hat{H}^*(h(R_m))$ we either kill off a polynomial generator or add an exterior algebra generator. This proves the statement about $\hat{H}^*(h(R_m))$ for all m by induction, and hence proves proposition 5.2.

For completeness we remark that the cohomology ring $\hat{H}^*(g, h(\mathbf{Z}_p))$ is a polynomial algebra over $\mathbf{F}_p$ with one ordinary generator of each positive degree.

For any $\mathbf{Z}_p$-module A we define ω to be the automorphism of $h(A)$ taking $h_n(a)$ to $(-1)^n h_n(-a)$. We define $h_\omega(A)$ to be the largest quotient ring of $h(A)$ on which the automorphism ω acts trivially. (Notice that this is smaller than the largest quotient module on which ω acts trivially.)

Lemma 5.3. *The cohomology ring $\hat{H}^*(g, h_\omega(\mathbf{Z}_p[G]))$ is the polynomial ring on ordinary generators of degrees $(2n+1)p$ for $n \geq 0$.*

Proof. The algebra $h_\omega(\mathbf{Z}_p[G])$ is the polynomial algebra generated by the elements $h_{2n+1}(g_i)$ for $0 \leq i < p$, $n \geq 0$, and lemma 5.3 follows from this.

Lemma 5.4. *The cohomology ring $\hat{H}^*(g, h_\omega(I))$ is the exterior algebra on generators of degrees $(2n+1)$ for $n \geq 0$, $(n,p) = 1$. In particular it is generated (as a ring) by super elements of odd degrees, so that $\hat{H}^0(g, h_\omega(I))$ vanishes in odd degrees and $\hat{H}^1(g, h_\omega(I))$ vanishes in even degrees.*

This follows from lemma 5.3 in the same way that lemma 5.2 follows from 5.1.

Remark. The ring $h(\mathbf{Z}_p)$ can be identified with the ring of symmetric functions over $\mathbf{Z}_p$ if we identify $h_n(1)$ with the n'th complete symmetric function. In this case the automorphism ω taking $h_n(1)$ to $(-1)^n h_n(-1)$ is just the automorphism ω of [Mac, p. 14] taking the complete symmetric functions to the elementary symmetric functions.

Remark. More generally we can form a quotient ring associated to any automorphism ω of A of order n prime to p such that $h_\omega(A)$ is the quotient ring associated to the automorphism $\omega = -1$ of A. To do this we let R_p be the unramified extension of $\mathbf{Z}_p$ generated by a primitive n'th root of unity ζ. We then form the largest quotient ring of $h(A) \otimes R_p$ whose elements are fixed by the automorphism taking $h_n(a)$ to $\zeta^n h_n(\omega(a))$. For example this space appears when we try to construct the monster vertex algebra from a fixed point free automorphism ω of the Leech lattice Λ.

The extraspecial group 2^{1+24} occurring in the centralizer of an element of type $2B$ in M has a unique 2^{12}-dimensional irreducible module A over $\mathbf{Z}[1/2]$. Any element of odd order in $\mathrm{Aut}(\Lambda)$ has an induced action on 2^{1+24} and on A.

Lemma 5.5. *If g is an element of order 3, 5, 7, or 13 acting on the Leech lattice Λ with no nonzero fixed vectors then as a $\mathbf{Z}_p[G]$-module, $A \otimes \mathbf{Z}_p$ is the sum of $\mathbf{Z}_p$ and some copies of $\mathbf{Z}_p[G]$.*

Proof. We let B be the 2^{24}-dimensional 2^{1+24}-module $A \otimes A$. This is isomorphic to the group ring of 2^{24}. The element g acts fixed point freely on the group $2^{24} = \Lambda/2\Lambda$ because it acts fixed point freely on Λ and has odd order, so as a module over G, $B \otimes \mathbf{Z}_p$ is the sum of $\mathbf{Z}_p$ and some copies of $\mathbf{Z}_p[G]$, and the Tate cohomology groups are therefore $\hat{H}^0(g, B \otimes \mathbf{Z}_p) = \mathbf{Z}/p\mathbf{Z}$, $\hat{H}^1(g, B \otimes \mathbf{Z}_p) = 0$. As $\hat{H}^*(g, B \otimes \mathbf{Z}_p) = \hat{H}^*(g, A \otimes \mathbf{Z}_p) \otimes \hat{H}^*(g, A \otimes \mathbf{Z}_p)$ we see that $\hat{H}^*(g, A \otimes \mathbf{Z}_p)$ is either an ordinary or a super vector space over $\mathbf{F}_p$ of dimension 1.

Therefore as a G module, $A \otimes \mathbf{Z}_p$ is the sum of some copies of $\mathbf{Z}_p[G]$ and either $\mathbf{Z}_p$ or I. But $\dim(A) = 2^{12} \equiv 1 \bmod p$ as $(p-1)|12$ which rules out the second possibility. Therefore $\hat{H}^0(g, A \otimes \mathbf{Z}_p)) = \mathbf{Z}/p\mathbf{Z}$, $\hat{H}^1(g, A \otimes \mathbf{Z}_p) = 0$. This proves lemma 5.5.

A similar argument can be used to calculate $\hat{H}^*(g, A)$ for any element g of odd prime order p in $\mathrm{Aut}(\Lambda)$. If $2n$ is the dimension of the subspace of Λ fixed by g then n is an integer with $2^n \equiv \pm 1 \bmod p$. Exactly one of the two cohomology groups $\hat{H}^*(g, A)$ vanishes and the other has dimension 2^n over $\mathbf{F}_p$. The group $\hat{H}^1(g, A)$ vanishes if $2^n \equiv 1 \bmod p$, and the group $\hat{H}^0(g, A)$ vanishes if $2^n \equiv -1 \bmod p$. There are some cases where it is $\hat{H}^0(g, A)$ and not $\hat{H}^1(g, A)$ that vanishes; for example, if g is the element of order 5 with trace -1 on Λ then $\hat{H}^0(g, A) = 0$ and $\hat{H}^1(g, A) = (\mathbf{Z}/5\mathbf{Z})^4$.

6. Elements of type $3B$, $5B$, $7B$, and $13B$.

We use the result of the previous section to calculate the cohomology groups $\hat{H}^i(g, V[1/2])$ when $g \in M$ has type $3B$, $5B$, $7B$, or $13B$.

Theorem 6.1. *If $g \in M$ has type $3B$, $5B$, $7B$, or $13B$ and σ is the element of order 2 generating the center of $C_M(g)/O_p(C_M(g))$ then $O_p(C_M(g))$ acts trivially on ${}^gV$ and σ fixes the ordinary part of ${}^gV$ and acts as -1 on the super part.*

Proof. We prove this by calculating the action of σ on $\hat{H}^*(g, V[1/2])$ explicitly. We recall from [B-R] that the $\mathbf{Z}[1/2]$-form $V[1/2]$ of Frenkel, Lepowsky and Meurman's monster vertex algebra [FLM] is the sum of two pieces V^0 and V^1 which are the $+1$ and -1 eigenspaces of an element σ of type $2B$. (Unfortunately the details for the construction of this $\mathbf{Z}[1/2]$-form have not been published anywhere.) We now show that $\hat{H}^0(g, V^1) = \hat{H}^1(g, V^0) = 0$.

The space V^0 is the subspace of $V_\Lambda[1/2]$ fixed by the automorphism induced by -1 acting on the Leech lattice Λ, where $V_\Lambda[1/2] = V_\Lambda \otimes \mathbf{Z}[1/2]$, and V_Λ is the integral form of the vertex algebra of the Leech lattice, described in [B-R]. As in [B-R], the space V_Λ is the tensor product of a twisted group ring $\mathbf{Z}[\hat{\Lambda}]$ and a space isomorphic to $h(\Lambda)$. The cohomology $\hat{H}^*(g, \mathbf{Z}[\hat{\Lambda}])$ is just $\mathbf{Z}/p\mathbf{Z}$ as in [B-R] because g acts fixed point freely on Λ. By proposition 5.2, the element -1 of $\mathrm{Aut}(\hat{\Lambda})$ acts as $+1$ on $\hat{H}^0(g,h(\Lambda))$ and as -1 on $\hat{H}^1(g,h(\Lambda))$. Therefore $\hat{H}^1(g,V^0)$ vanishes because it is isomorphic to the subspace of $\hat{H}^1(g,h(\Lambda))$ fixed by $-1\in\mathrm{Aut}(\Lambda)$.

The space V^1 is the subspace of elements of integral weight of the tensor product $A\otimes h_\omega(\Lambda\otimes\mathbf{Z}_p)$, where A is the 2^{12} dimensional module for 2^{1+24} and $h_\omega(\Lambda\otimes\mathbf{Z}_p)$ has its grading halved and then shifted by 3/2. By lemma 5.5, $\hat{H}^*(g,A)=\mathbf{F}_p$, so $\hat{H}^*(g,A\otimes h_\omega(\Lambda\otimes\mathbf{Z}_p))=\hat{H}^*(g,h_\omega(\Lambda\otimes\mathbf{Z}_p))$. By lemma 5.4 the cohomology ring $\hat{H}^*(g,h_\omega(\Lambda\otimes\mathbf{Z}_p))$ is generated by super elements of odd degree, so $\hat{H}^1(g,h_\omega(\Lambda\otimes\mathbf{Z}_p))$ vanishes in even degrees and $\hat{H}^1(g,h_\omega(\Lambda\otimes\mathbf{Z}_p))$ vanishes in odd degrees. Therefore $\hat{H}^0(g,A\otimes h_\omega(\Lambda\otimes\mathbf{Z}_p))$ vanishes in integral degrees, so $\hat{H}^0(g,V^1)=0$.

This shows that the element σ acts as 1 on $\hat{H}^0(g,V[1/2])=\hat{H}^0(g,V_\Lambda)=\hat{H}^0(g,h(\Lambda\otimes\mathbf{Z}_p))$ and as -1 on $\hat{H}^1(g,V[1/2])=\hat{H}^1(g,A\otimes h_\omega(\Lambda\otimes\mathbf{Z}_p))$.

Finally we show that $O_p(C_M(g))$ acts trivially on ${}^gV$. The element σ acts trivially on the center $\langle g\rangle$ of the extraspecial group $p^{1+24/(p-1)}$ and acts as -1 on the quotient $p^{24/(p-1)}$. The element g acts trivially on ${}^gV$ so we get an action of $p^{24/(p-1)}$ on ${}^gV$. As σ acts as 1 on the even part of ${}^gV$ and as -1 on the odd part, it commutes with all automorphisms of ${}^gV$, so the group $p^{24/(p-1)}$ must act trivially on ${}^gV$. This proves theorem 6.1.

The group $C_M(g)$ has structure $3^{1+12}.2.Suz$, $5^{1+6}.2.HJ$, $7^{1+4}.2.A_7$, or $13^{1+2}.2.A_4$, so we get modular vertex superalgebras acted on faithfully by the groups $2.Suz$, $2.HJ$, $2.A_7$, and $2.A_4$ whose modular characters are given by Hauptmoduls. We can calculate the characters of both the ordinary and super parts of these superalgebras by using the fact that the characters of their sum and difference are both given in terms of known Hauptmoduls.

It seems likely that if g has type $2B$ then the vertex superalgebra acted on by $2^{24}.Co_1$ constructed in [B-R] is acted on trivially by the 2^{24} subgroup, but this has not yet been proved. The proof given above for the corresponding fact for elements of odd prime order fails for order 2 because an automorphism mapping each element of 2^{24} to its inverse is still the identity automorphism.

As an example, we work out the dimensions of the ordinary and super parts of ${}^gV$ in the case when g has type $3B$. The function $\sum_n\mathrm{Tr}(1|{}^gV)$ is equal to the Hauptmodul of the element g of type $3B$ in the monster, which is

$$q^{-1}+54q-76q^2-243q^3+1188q^4-1384q^5-\cdots,$$

and the function $\sum_n\mathrm{Tr}(\sigma|{}^gV)$ is equal to the Hauptmodul of the element σg of type $6B$ in the monster, which is

$$q^{-1}+78q+364q^2+1365q^3+4380q^4+12520q^5+\cdots$$

so we find that the dimension of the ordinary part of ${}^gV_n$ is the coefficient of q^n of

$$q^{-1}+66q+144q^2+561q^3+2784q^4+5568q^5+\cdots$$

and the dimension of the super part of ${}^gV_n$ is the coefficient of q^n of

$$12q+220q^2+804q^3+1596q^4+6952q^5\cdots.$$

These series can be written as sums of dimensions of ordinary representations of the groups $3.Suz$ and $6.Suz$ as

$$q^{-1}+66q+(1+143)q^2+(429+66+66)q^3+(66+66+78+429+2145)q^4+(4\times1+4\times143+2\times780+3432)q^5+\cdots$$

and

$$12q+220q^2+(780+12+12)q^3+(780+780+12+12+12)q^4+(4\times220+2\times572+4928)q^5+\cdots.$$

(Some of the decompositions are ambiguous; for example $1+143$ could be $66+78$. We have chosen $1+143$ instead of $66+78$ for a reason that will appear in a moment.) At first sight this seems to rule out a vertex algebra structure on any lift to characteristic 0, as the homogeneous components V_n, $V_{n+1},\ldots$ have to increase. However we can get around this by rescaling the grading by a factor of 1/3. The data above seem consistent with the existence of a $\frac{1}{3}\mathbf{Z}$-graded vertex superalgebra $W=\sum_{3n\in\mathbf{Z}}W_n$ such that the mod

3 reduction of W_n is V_{3n}. The vertex superalgebra W is probably acted on by $6.Suz$, with the element of order 3 in the center acting as ω^{3n} on W_n.

There is a second modular vertex super algebra acted on by each of the groups $2.Suz$, $2.HJ$, $2.A_7$, and $2.A_4$, which can be constructed as $\hat{H}^*(g, V_\Lambda)$ where g is a fixed point free automorphism of order 3, 5, 7, or 13 of the Leech lattice Λ. The ordinary part of this superalgebra is the same as the ordinary part of the superalgebra constructed from the monster vertex algebra, but its super part is different; for example, its degree 0 piece does not vanish.

7. Open problems and conjectures.

For more open problems in this area see section 7 of [B-R].

At the end of section 6 we saw that the vertex superalgebra of an element of type $3B$ looks as if it might be the reduction mod 3 of a superalgebra in characteristic 0. More generally something similar seems to happen for some other elements of the monster, as described in the following conjecture.

Conjecture. *For each element $g \in M$ of order n there is a $\frac{1}{n}\mathbf{Z}$-graded super module ${}^g\hat{V} = \sum_{i \in \frac{1}{n}\mathbf{Z}} V_i$ over the ring $\mathbf{Z}[e^{2\pi i/n}]$ with the following properties.*

1. *${}^g\hat{V}$ is often a vertex superalgebra with a conformal vector and a self dual invariant symmetric bilinear form. (For example, it seems to be a vertex algebra when g is of type $1A$, $2B$, $3B$, $5B$, $7B$, $13B$, or $3C$, but possibly not if g has type $2A$ or $3A$.)*
2. *${}^1\hat{V}$ is a self dual integral form of the monster vertex algebra (probably the one conjecturally described in lemma 7.1 of [B-R]).*
3. *If g has prime order then the reduction mod p of ${}^g\hat{V}$ is the modular vertex superalgebra ${}^gV$ associated to g (at least when its grading is multiplied by n.)*
4. *If all coefficients of the Hauptmodul of g are nonnegative then the super part of ${}^g\hat{V}$ vanishes. In this case ${}^g\hat{V}$ should be the same as the "twisted sector" of g that appears in Norton's generalized moonshine conjectures [N]. (But notice that if the Hauptmodul of g has negative coefficients then ${}^g\hat{V}$ is certainly not the twisted sector of g; for example, ${}^g\hat{V}$ is a super vector space and has a nontrivial piece of degree 0.)*
5. *${}^g\hat{V}$ is acted on by a central extension $(\mathbf{Z}/n\mathbf{Z}).C_M(g)$ of $C_M(g)$ by $\mathbf{Z}/n\mathbf{Z}$. This central extension contains an element of order 1 or 2 acting as -1 on the super part of ${}^g\hat{V}$ and as 1 on the ordinary part.*
6. *If g and h are commuting elements of M of coprime orders and $\hat{g}$ is the lift of g to the central extension of $C_M(h)$ with the same order as g, then*
$$\mathrm{Tr}(\hat{g}|{}^h\hat{V}) = \mathrm{Tr}(gh|{}^1\hat{V}).$$
(This identity is often false if the orders of g and h are not coprime.)
7. *If g and h commute then $\hat{H}^*(\hat{g}, {}^h\hat{V})$ is (essentially) the reduction mod $|g|$ of ${}^{gh}V$. (Actually this is not quite correct as stated, because the reduction mod $|g|$ will be defined over some nilpotent extension of $\mathbf{Z}/|g|\mathbf{Z}$, and we should then take the tensor product over this ring with $\mathbf{Z}/|g|\mathbf{Z}$.)*

These conjectures are similar to Norton's generalized moonshine conjectures [N] because both associate some graded space with each element g of the monster. However they treat the problem of negative coefficients in the Hauptmodul $T_g(\tau)$ in a different way: Norton's conjectures use the fact that $T_g(-1/\tau)$ has nonnegative coefficients, which are supposed to be the dimensions of some vector spaces, while the conjectures above allow super vector spaces which may have negative super dimension. Perhaps both Norton's conjectures and the conjectures above are special cases of some conjecture which associates a $\mathbf{Z}/n\mathbf{Z} \times \mathbf{Z}$-graded super space acted on by a central extension $\mathbf{Z}/n\mathbf{Z}.C_M(g)$ to each element $g \in M$ of order n.

We finish by listing a few other questions.

1. Is the group $C_M(g)/O_p(C_M(g))$ the full automorphism group of the modular vertex algebra ${}^gV$? If g has type $3C$ it seems possible that it is not, and the full automorphism group may be $E_8(\mathbf{F}_3)$. Notice that if g has type $2B$ then it is not yet known that $O_2(C_M(g))$ acts trivially on ${}^gV$.
2. Replace the revolting argument of section 4 that involves computer calculations with a more conceptual proof. More generally, suppose we have coefficients $c(n)$ of some function such that the coefficient of r^mq^n in
$$r^{-1}\prod_{m>0, n\in\mathbf{Z}}(1-r^mq^n)^{c(mn)}$$

vanishes whenever $(mn, N) = 1$ for some fixed integer N. What does this imply about the coefficients $c(n)$? (There are many solutions to this given by taking the $c(n)$'s to be the coefficients of some Hauptmodul of level N.)

3. What happens when we apply the argument of section 3 to some automorphism of prime order of the fake monster Lie algebra? Do the infinite products we get represent interesting functions?
4. In [B section 10] it was suggested that there should be Lie superalgebras associated with elements g of the monster, but it was not clear what the dimensions of homogeneous components of these superalgebras should be in the cases when the coefficients of the Hauptmodul of g were neither all positive nor alternating in sign. The results of section 6 suggest what to do in this case: the sum of the dimensions of the ordinary and super parts should also be given by the coefficients of another Hauptmodul.

Abstract

We present a microscopic index formula for the degeneracy of dyons in four-dimensional $N = 4$ string theory. This counting formula is manifestly symmetric under the duality group, and its asymptotic growth reproduces the macroscopic Bekenstein-Hawking entropy. We give a derivation of this result in terms of the type II five-brane compactified on $K3$, by assuming that its fluctuations are described by a closed string theory on its world-volume. We find that the degeneracies are given in terms of the denominator of a generalized super Kac-Moody algebra. We also discuss the correspondence of this result with the counting of D-brane states.

1. INTRODUCTION

In this paper we will study the dyonic spectrum of $N=4$ string theory in 4 dimensions. This theory has two perturbative formulations: one in terms of the toroidally compactified heterotic string, and a dual formulation in terms of type II strings compactified on $K3 \times T^2$. To describe the set of charged states we will take the point of view of the heterotic string, so that we have 28 electric charges q_e and 28 magnetic charges q_m which both lie on the $\Gamma^{22,6}$ lattice. This theory is conjectured [1, 2, 3] to have as its exact duality group

$$SL(2,\mathbf{Z}) \times SO(22,6,\mathbf{Z}) \tag{1.1}$$

with $SL(2,\mathbf{Z})$ being the electric-magnetic duality symmetry. The perturbative heterotic string states carry only electric charge, so that states with magnetic charge arise necessarily non-perturbatively as solitons.

Most accessible to computations is the spectrum of BPS states. These states are annihilated by some subset of the 16 supersymmetry charges and therefore many of their properties are protected in perturbation theory. The purely electric states are special in the sense that they preserve 1/2 of the supercharges and their degeneracies are easily determined, since they simply correspond to the heterotic string states that are in the right-moving ground state. Hence a BPS heterotic string state is described by specifying the 28 charges $q_e \in \Gamma^{22,6}$ together with the occupation numbers N_l^I ($I = 1, \ldots, 24$, $l > 0$), subject to the level-matching condition

$$\tfrac{1}{2} q_e^2 + \sum_{l,I} l N_l^I = 1. \tag{1.2}$$

Here the subscript l to N_l^I denotes the world-sheet oscillation number of the coordinate field X^I, and q_e^2 is defined using the $SO(22,6)$ invariant inner product on the $\Gamma^{22,6}$ lattice. The number of such states is given by[*]

$$d(q_e) = \oint d\sigma \, \frac{e^{i\pi\sigma q_e^2}}{\eta(\sigma)^{24}} \tag{1.3}$$

where the 'contour' integral over σ is from 0 to 1 and $\eta(\sigma)$ is the Dedekind η-function.

The conjectured electric-magnetic $SL(2,\mathbf{Z})$-duality predicts that there should also exist a solitonic version of the heterotic string that carries pure magnetic charge $q_m \in \Gamma^{22,6}$, and thus that a similar formula counts the pure magnetically charged 1/2 BPS states. The generic dyonic states, however, preserve only 1/4 of the supersymmetries and are more mysterious. In the following we will give a concrete proposal for the exact degeneracy of these dyonic BPS states. To be more precise, we will present a formula for the number of bosonic minus the number of fermionic BPS-multiplets for a given electric and magnetic charge. The basic idea is the following. We like to think of the dyonic states as some kind of bound state of an electric heterotic string with a dual magnetic heterotic string. The formula that counts these states, should therefore be a suitable generalization of (1.3), that will contain (1.3) as a special subcase. In addition it has to satisfy other non-trivial consistency checks, such as invariance under the full duality group, while it also has to reproduce the correct asymptotic growth as predicted from the macroscopic entropy formulas of extremal dyonic black holes [4, 5].

---

[*] Here and in the subsequent we omit a factor of 16, and therefore count the number of 1/2 BPS multiplets rather than individual states.

After presenting our formula and illustrating some of its features, we will show that the complete duality invariant dyon spectrum has a unified and natural interpretation in terms of strings on the five-brane. We will also discuss the correspondence with the counting of BPS-states that follows from a D-brane description [6, 7, 8, 9].

2. The degeneracy formula

To write the proposed dyonic index formula, it will be convenient to combine the electric and magnetic charge vectors q_e and q_m into a vector as follows

$$\boldsymbol{q} = \begin{pmatrix} q_m \\ q_e \end{pmatrix} \tag{2.1}$$

Accordingly we introduce the 2×2 matrix

$$\Omega = \begin{pmatrix} \rho & \upsilon \\ \upsilon & \sigma \end{pmatrix} \tag{2.2}$$

generalizing the single modulus σ in (1.3). The degeneracy formula will then take the following form

$$d(q_e, q_m) = \oint d\Omega \, \frac{e^{i\pi \boldsymbol{q}\cdot\Omega\cdot\boldsymbol{q}}}{\Phi(\Omega)}. \tag{2.3}$$

The integrals over the moduli parameters σ, ρ and υ again all run over the domain from 0 to 1, and impose level matching conditions analogous to (1.2).

In the above suggestive form, it is natural to identify the matrix Ω with the period matrix of a genus two Riemann surface. In the result that we will obtain, the denominator $\Phi(\Omega)$ indeed will turn out to be a genus two modular form. More precisely, it is the unique automorphic form of weight 10 of the modular group $Sp(2, \mathbf{Z})$ (represented by

4×4 matrices) and can be expressed as the squared product of all genus 2 theta functions with even spin structure

$$\Phi(\Omega) = 2^{-12} \prod_{\alpha=even} \theta[\alpha](\Omega)^2. \tag{2.4}$$

$\Phi(\Omega)$ also happens to be equal to the denominator in the Weyl-Kac-Borcherds character formula for a generalized super Kac-Moody algebra, and as such it is a special case of the automorphic forms constructed in [10]. The $SL(2,\mathbf{Z})$ duality transformations are identified with the subgroup of $Sp(2,\mathbf{Z})$ that leave the genus two modular form $\Phi(\Omega)$ invariant, and thus the presented degeneracies are manifestly duality symmetric. In addition, the formula satisfies a number of other non-trivial consistency checks, that we will now discuss. Subsequently, we will turn to the derivation and more detailed description of this result.

To make our formula somewhat more explicit, we can expand the integrand as a formal Fourier series expansion

$$\frac{1}{\Phi(\Omega)} = \sum_{k,l,m} D(k,l,m) e^{-2\pi i(k\rho + l\sigma + m\upsilon)} \tag{2.5}$$

with k, l, m integers. The coefficients $D(k,l,m)$ are all integers, that via (2.3) give us the degeneracy for a given electric and magnetic charge as

$$d(q_m, q_e) = D(\tfrac{1}{2}q_m^2, \tfrac{1}{2}q_e^2, q_e \cdot q_m) \tag{2.6}$$

Note that the normalization of (2.4) is chosen such that $d(0,0) = 1$.

Correspondence with the heterotic string

As we will explain in the following, the parameter υ couples to the helicity m of the dyonic states. The integral over υ thus projects on dyons with helicity equal to zero. However, instead of integrating over υ we can also put it to fixed value, like $\upsilon = 0$. The resulting formula will then correspond to a helicity trace $(-1)^m$, which will project out all 1/4 BPS representations, except for the purely electric or magnetic 1/2 BPS representations. Hence, for $\upsilon \to 0$ the integrand in formula (2.3) should match with the degeneracy formula (1.3) for the heterotic string BPS spectrum.

To make this correspondence explicit, we note that the function $1/\Phi(\Omega)$ is in fact identical to the chiral half of the bosonic string partition function (or rather, that of 24 massless scalars) on the corresponding genus two curve (see [11]). This means in particular that, if we factorize the genus two surface parametrized by Ω into two separate genus one surfaces with moduli ρ and σ, we indeed recover the separate 1/2 BPS partition sums. In

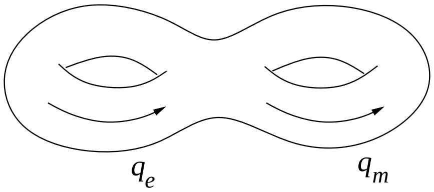

Fig. 1: *The dyon counting can be represented in terms of a genus two partition sum. The electric and magnetic charges of the dyon correspond to the loop momenta through the two handles of the Riemann surface.*

this analogy the electric and magnetic charges correspond to the loop momenta through the two handles, as in *fig.* 1.

Concretely, this factorization corresponds to taking the limit $\upsilon \to 0$, under which the function $1/\Phi(\Omega)$ reduces to

$$\frac{e^{i\pi \boldsymbol{q}\cdot\Omega\cdot\boldsymbol{q}}}{\Phi(\Omega)} \quad\longrightarrow\quad \frac{1}{\upsilon^2}\,\frac{e^{i\pi\rho q_m^2}}{\eta(\rho)^{24}}\,\frac{e^{i\pi\sigma q_e^2}}{\eta(\sigma)^{24}} \tag{2.7}$$

The diverging factor $1/\upsilon^2$ corresponds to the 'tachyon pole,' and reflects the emergence of two non-compact translational zero-modes for $\upsilon = 0$. In the other factors we recover the separate electric and magnetic heterotic string contributions. The above correspondence is a necessary boundary condition on any (candidate) dyonic degeneracy formula.

Asymptotic growth and black hole entropy

As a further non-trivial boundary condition, the formula (2.3) also matches the asymptotic behavior for large charges that one obtaines by comparing with the results for the macroscopic Bekenstein-Hawking entropy of extremal 4-dimensional black holes. This correspondence predicts that the statistical entropy of states with charge (q_e, q_m) is given by [5]

$$S = \pi\sqrt{q_e^2 q_m^2 - (q_e\cdot q_m)^2}. \tag{2.8}$$

The asymptotic growth of the degeneracies $d(q_e, q_m)$ indeed agrees with this predicted entropy, as it can be shown that in the large charge limit

$$d(q_e, q_m) \sim e^{\pi\sqrt{q_e^2 q_m^2 - (q_e\cdot q_m)^2}}. \tag{2.9}$$

A formal derivation of this result is outlined in the Appendix, and makes use of the zeroes of the function Φ. These zeroes lead to poles in the integrand in (2.3). In our case the leading contribution to the integral comes from the pole at $\rho\sigma - \upsilon^2 + \upsilon = 0$(which is an appropriate $Sp(2, \mathbf{Z})$-transform of the above described 'tachyon pole'). After evaluating the residue at this pole one can perform the remaining integration by means of a saddle-point approximation, and this immediately reproduces the above formula for the asymptotic growth of $d(q_e, q_m)$. We will give an alternative explanation of this result at the end of the next section, after we have reinterpreted the degeneracy formula (2.3) in terms of strings living on a five-brane.

3. DERIVATION FROM THE QUANTUM FIVEBRANE

It is known that the heterotic string arises as a soliton in type II string theory that can be described as a five-brane wrapped around the internal $K3$ manifold [12]. $SL(2, \mathbf{Z})$ symmetry in the type II formulation is a consequence of T-duality, and thus string-string duality implies that both the electric and magnetic heterotic string can be considered as five-branes wrapped around $K3$. Based on the above the degeneracy formula, we will argue in the following that this correspondence can be naturally extended to all dyonic states.

Heterotic string from the five-brane

The five-brane we will consider arises as a soliton in the 10-dimensional type II effective string theory [13]. The long-wavelength fields on its world-volume are given by an $N = (2,0)$ supermultiplet consisting of a tensor with self-dual 3-index field strength T_3, 4 chiral fermions and 5 scalar fields. These fields represent the zero modes of the 10-dimensional massless fields on the five-brane background, which, via the standard adiabatic argument, are allowed to vary along the five-brane world-volume.

The relation of the five-brane with the heterotic string can be derived by dimensionally reducing the six-dimensional chiral field theory on the world-volume to two dimensions on $K3$. In this way the self-dual tensor field reduces to 19 left-moving and 3 right-moving scalars. Together with the additional five scalars and fermions, this gives exactly the world-sheet fields of the heterotic string. Moreover, the string momentum lattice $\Gamma^{20,4}$ corresponds to the cohomology lattice of $K3$. In particular, the fluxes of the self-dual tensor field T_3 are identified with the electric charges

$$q_e^A = \int_{S^1 \times \Sigma^A} T_3 \tag{3.1}$$

where S^1 is one of the cycles of T^2 and Σ^A is a basis of two-cycles in $K3$.

In our setup, we would in fact like to take this correspondence one step further, by replacing the standard world-sheet theory of the heterotic string by the 5+1-dimensional world-volume theory of the five-brane wrapped around $K3$. Concretely this means that in counting the states of this generalized heterotic string, we wish to take seriously the possible fluctuations of the five-brane in the internal $K3$. At first sight this would appear to imply a very drastic extension of the world-sheet degrees of freedom, but it turns out that for purely electrically charged BPS states nothing has changed: when one imposes the BPS conditions one automatically finds that the allowed fluctuations of the five-brane are the usual left-moving heterotic string oscillations [14]. We will outline this calculation in a moment, after we have explained our general set-up.

Idea of the computation

We would like to extend the above description to include dyonic states. As we will argue in the following, these dyonic states will naturally arise as 1/4 BPS configurations of the five-brane, provided we make one important new assumption. Namely, we will assume that the world volume description of the five-brane is not described by a field theory, but rather by an appropriate closed string theory. This world-volume string theory must satisfy the condition that the usual massless collective fields should correspond to the ground states of this string, in direct analogy with the standard relation between the space-time effective field theory and the ground states of the type II string. In this sense, we wish to think about the strings on the five-brane as essentially the original type II string, but restricted to the world-volume. The effective field theory of the string ground states is sufficient to describe the long-wavelength fluctuations of the five-brane, but at short distance we will also take into account the other string modes, including winding configurations and excitations.

Our aim is eventually to determine the degeneracy of BPS states. We will do this by considering the partition function of the 5+1-dimensional world-volume string theory with target space $K3 \times T^2$.[*] In a light-cone gauge in which the transversal space is taken to be the $K3$ manifold, the worldsheet theory on this string is a $N = (4,4)$ superconformal field theory with $SU(2)_L \times SU(2)_R$ current algebra [15, 14]. The eight supercharges on the world-sheet describe the unbroken part of the space-time supersymmetry. (The broken space-time supersymmetries give rise to zero-modes on the five-brane.)

The five-brane BPS partition function $\mathcal{Z}$ essentially counts the number of BPS states of this second quantized string theory. In computing this quantity, we will neglect string interactions. The justification for this should come from the fact that the BPS-condition in combination with the large number of supersymmetries severely restricts the possible interactions. This expectation will indeed find concrete support in our analysis, as it will turn out that for the relevant string partition sums on the target space $K3 \times T^2$, there are no higher loop correction to the free energy. Hence the fivebrane BPS partition sum can be computed by taking the exponent of the relevant one-loop free energy of the string on the world-volume, provided one also adds an appropriate zero-mode contribution

---

[*] This calculation is the direct analog of the conventional counting of string states by means of a conformal field theory partition function on a world-sheet of topology T^2.

$$\mathcal{Z} = \exp\Big[\mathcal{F}^{string}_{1-loop} + \mathcal{F}_{0-modes}\Big]. \tag{3.2}$$

The concrete form of this zero-mode contribution follows from considering the free energy of the fluxes of the low-energy massless field theory on the five-brane world-volume. The partition sum $\mathcal{Z}$ will depend in particular on the moduli that parametrize the shape and size of world-volume manifold.

To obtain the number of BPS states for given electric and magnetic charge, one finally needs to identify the corresponding contribution to the partition sum. In our formalism, this identification is automatically implemented via the integral over an appropriate set of world-volume moduli, which act as Lagrange multipliers that impose 'level-matching conditions' analogous to the $L_0 - \overline{L}_0 = 0$ condition in string theory. We will now explain and motivate this procedure in more detail for the 1/2 BPS states, in which case we should recover the before-mentioned classical correspondence with the electric and magnetic heterotic string.

Electric and magnetic fivebrane states

To count the states that respect half of the supersymmetries we have to restrict to the string ground states. This turns the 6-dimensional string into a topological string for which we can simply compute its one-loop free energy $\mathcal{F}$. The one-loop computation is well-known [16]. There are 24 ground states on $K3$, corresponding to the harmonic forms. We further add the momenta and winding numbers in the T^2 direction, which take value in the lattice $\Gamma^{2,2}$ parametrised by the moduli ρ, σ. Here ρ parametrize the size and B-field on the two-torus and σ parametrizes the complex structure. We then compute [16]

$$\begin{aligned}\mathcal{F} &= \tfrac{1}{2}\int \frac{d^2\tau}{\tau_2} \sum_{(p_L,p_R)\in\Gamma^{2,2}} e^{i\pi(\tau p_L^2 - \overline{\tau} p_R^2)} \cdot 24 \\ &= 24 \log\Big(\rho_2^{1/2}|\eta(\rho)|^2\Big) + 24\log\Big(\sigma_2^{1/2}|\eta(\sigma)|^2\Big) + cnst.\end{aligned} \tag{3.3}$$

Here the first term represents the contribution of the winding modes of the strings that couple to the parameter ρ and the second term the contribution of the momentum modes that couple to the parameter σ. The occurrence of these two terms reflects a $\mathbf{Z}_2$ symmetry, which is an $R \to 1/R$ symmetry applied to the world-volume of the five-brane. This transformation interchanges momentum and winding modes. So, even at the level of the string ground states, we encounter a pure stringy effect.

To obtain the 1/2 BPS partition function there are two more steps to be taken. First, we have to take only the holomorphic part of the above expression in ρ and σ, and secondly, we need to include the zero-mode contributions. Specifically, we must replace the factor σ_2 in $\mathcal{Z} = e^{\mathcal{F}}$ by the appropriate theta-function representing the summation of the fluxes over the lattice $\Gamma^{22,6}$, see [17]. Combined with the momentum contribution $1/\eta(\sigma)^{24}$ this then gives the left-moving partition function of the heterotic string with modular parameter σ. This is in accord with the expected one-to-one correspondence between 1/2 BPS states of the five-brane and those of the heterotic string.

To restore the $\mathbf{Z}_2$ symmetry between ρ and σ, we also need to replace the powers of ρ_2 by a lattice sum with a new set of charges. It seems natural to identify these new charges with the magnetic charges $q_m \in \Gamma^{22,6}$. This identification finds support from the heterotic-type II string duality, as follows. The electric-magnetic duality map that interchanges q_e and q_m acts on the type IIA side as a T-duality on the T^2. Since the five-brane we consider is wrapped around $K3$ and a one-cycle in T^2, this transformation will act non-trivially on its world-volume via an $R \to 1/R$ transformation on the S^1. As we have just discussed, this is a symmetry of the world-volume string theory that interchanges the world-volume parameter ρ and the parameter σ.

Hence, we conclude that by representing the world-volume degrees of freedom on the five-brane as strings, we are able to describe the electrically charged heterotic string and the magnetically charged heterotic string both in terms of one single fivebrane.

Dyonic fivebrane states

We now wish to consider five-brane states that carry both electric and magnetic charge. These dyonic states necessarily break 3/4 of the 16 supercharges. Concretely this means that the dyonic BPS five-branes carry more degrees of freedom than the purely electric or magnetic configurations.

As already noted, the 8 unbroken supercharges of the five-brane are realized on the world-sheet of the string as the 4 left-moving and 4 right-moving generators of an $N = (4,4)$ superconformal algebra. So to keep 4 unbroken charges we must restrict the string states to be in the ground state of either the right-moving or the left-moving sector. For definiteness, we will choose the right-moving one. The index that counts these string states is given by the elliptic genus of $K3$ [18], which is defined as the weighted trace in the RR-sector of the superconformal sigma-model

$$\chi_{\tau,z}(K3) = \mathrm{Tr}\,(-1)^{F_L+F_R} e^{2\pi i(\tau(L_0-\frac{c}{24})+zF_L)} \tag{3.4}$$

with $c = 6$ for $K3$. The fermion numbers F_L and F_R can be identified with the zero-modes of the left-moving and right-moving $U(1) \subset SU(2)$ current algebras.

As we restrict to right-moving ground states, F_R only takes the values $0, \pm 1$, while F_L can a priori take all integer values and gives us a conserved quantum number m. Since the corresponding $SU(2)$-symmetry is part of the space-time Lorentz symmetry, this conserved quantum number can be interpreted as the helicity in space-time, *cf* [19, 20]. In the following we will treat it on equal footing with the momentum and winding numbers of the string around T^2. This turns the Narain lattice $\Gamma^{2,2}$ of the two-torus into the lattice $\Gamma^{3,2}$. Moreover, it allows us to extend the set of world-brane parameters ρ, σ by another complex parameter υ that couples to the helicity quantum number m. Technically, υ has an interpretation as a Wilson loop on the world-volume that parametrizes the $SU(2)_L$ bundle over T^2. Together, ρ, σ and υ parametrize the lattice $\Gamma^{3,2}$, and transform in a vector representation of the $SL(2,\mathbf{Z})$ subgroup of the corresponding $SO(3,2;\mathbf{Z})$ T-duality group. (See Appendix.)

We now need to compute the following one-loop integral

$$\mathcal{F} = \frac{1}{2}\int \frac{d^2\tau}{\tau_2} \sum_{\substack{(p_L,p_R)\,\in\,\Gamma^{3,2} \\ n\,\in\,4\mathbf{Z}-\epsilon}} e^{i\pi(\tau p_L^2 - \bar\tau p_R^2)} \cdot c(n) e^{i\pi\tau n/2} \tag{3.5}$$

where $\epsilon = 0, 1$ depending on whether the helicity quantum number m is even or odd, and the coefficients $c(n)$ are defined by the expansion of the $K3$ elliptic genus as[†]

$$\chi_{\tau,z}(K3) = \sum_{h\geq 0,\, m\in\mathbf{Z}} c(4h - m^2) e^{2\pi i(h\tau + mz)} \tag{3.6}$$

It turns out that precisely the integral (3.5) has been computed recently by T. Kawai in the context of $N = 2$ heterotic string compactifications [21] along the lines of [22]. The answer obtained in [21] reads

$$\mathcal{F} = -\log\left[(\rho_2\sigma_2 - \upsilon_2^2)^{10}|\Phi(\rho,\sigma,\upsilon)|^2\right] + const. \tag{3.7}$$

where the holomorphic part has the following product representation

$$\Phi(\rho,\sigma,\upsilon) = e^{2\pi i(\rho+\sigma+\upsilon)} \prod_{(k,l,m)>0} \left(1 - e^{2\pi i(k\rho + l\sigma + m\upsilon)}\right)^{c(4kl-m^2)}. \tag{3.8}$$

Here $(k,l,m) > 0$ means that $k, l \geq 0$ and $m \in \mathbf{Z}$, $m < 0$ for $k = l = 0$. (Note further that $c(n) = 0$ for $n < -1$).

[†] Up to normalization this is the unique weak Jacobi form of index 1 and weight 0.

Now, following the same logic as for the 1/2 BPS states, we define the partition sum for the dyonic 1/4 BPS states by $\mathcal{Z} = e^{\mathcal{F}}$, where again we have to include separately the zero-mode contributions and restrict to the holomorphic sector. So the denominator of the partition function is given by $\Phi(\rho, \sigma, \upsilon)$ and represents the contribution from multi-string states that describe the fluctuations of the five-brane preserving the BPS condition. From the appearance of the factor $\rho_2\sigma_2 - \upsilon_2^2 = \det \operatorname{Im} \Omega$ it is clear that the zero-modes must be included by a factor

$$\exp\Big[i\pi(q_m^2\rho + q_e^2\sigma + 2q_e \cdot q_m\upsilon)\Big] \tag{3.9}$$

Combining all ingredients, and continuing the parallel with the heterotic string discussion of the introduction, we finally arrive at the announced result for the (bosonic minus fermionic) degeneracy formula

$$d(q_e, q_m) = \oint d\rho d\sigma d\upsilon \, \frac{e^{i\pi(q_m^2\rho + q_e^2\sigma + 2q_e\cdot q_m\upsilon)}}{\Phi(\rho, \sigma, \upsilon)}. \tag{3.10}$$

As was also noted in [21], it is natural to combine the moduli ρ, σ and υ into a matrix Ω as in (2.2). In the above form, the function $\Phi(\rho, \sigma, \upsilon)$ is manifestly $SL(2, \mathbf{Z})$ invariant, which suggests that it can be written as a modular form in Ω. Indeed, a remarkable identity proved by Gritsenko and Nikulin [23] expresses the product representation (3.8) in terms of the product of even genus 2 theta-functions as in formula (2.4). The role of the automorphic form Φ in string theory was first recognized in [24].

State counting

The above single five-brane partition function has a concrete interpretation as a trace of the multi-string quantum states of a target space topology $K3 \times S^1 \times \mathbf{R}$. On such a target space a string carries three additive quantum numbers: a winding number k, a momentum l along the S^1 and a helicity m. Together the three integers (k, l, m) form a vector on the lattice $\Gamma^{2,1}$ with length-squared $m^2 - 4kl$, which is invariant under the symmetry group

$$SO(2, 1, \mathbf{Z}) \cong SL(2, \mathbf{Z}) \tag{3.11}$$

We claim that this $SL(2, \mathbf{Z})$ group should be identified with the electric-magnetic duality group. Level-matching on the string tells us that the conformal dimension h in the $K3$ sigma model must be set equal to $h = kl$. If we look at the elliptic genus formula we see that the number of single string states with given quantum numbers (k, l, m) is $|c(4kl - m^2)|$, and thus duality invariant. Such a string state represents a space-time boson or fermion depending on the sign of $c(4kl - m^2)$. (The sign of $c(n)$ is $+1$ if $n \equiv 0 \pmod 4$ and -1 if $n \equiv -1 \pmod 4$, with the exception of $c(-1) = 2$.)

A state in the multi-string Hilbert space is characterized by a set of occupation numbers $N^I_{k,l,m}$ with $I = 1, \ldots, |c(4kl - m^2)|$. Hence, the degeneracy $d(q_e, q_m)$ counts the number of independent multi-string states $|\{N^I_{k,l,m}\}\rangle$ that satisfy the appropriate level-matching conditions implemented via the integral over the moduli σ, ρ and υ. These take the form

$$\begin{aligned} \tfrac{1}{2}q_m^2 + \sum_{k,l,m,I} kN^I_{k,l,m} &= 1 \\ \tfrac{1}{2}q_e^2 + \sum_{k,l,m,I} lN^I_{k,l,m} &= 1 \\ q_e \cdot q_m + \sum_{k,l,m,I} mN^I_{k,l,m} &= 1 \end{aligned} \tag{3.12}$$

The first two relations are obvious generalisations of the level-matching conditions of the heterotic string. In the case of only electric or magnetic charges they indeed reproduce the usual counting. The third line relates the sum of the helicities of the individual strings to the quantity $q_e \cdot q_m$. A suggestive interpretation of this constraint is that $q_e \cdot q_m$ represents the contribution to the helicity as carried by the external electric-magnetic field of the dyon, when considered as made up from a separate electric and magnetic 'point charge'. According to this interpretation, the third constraint in (3.13) essentially puts the total helicity of the dyonic state equal to zero.

4. COMPARISON WITH D-BRANE COUNTING.

Here we would like to indicate how this representation of the BPS states is related to the more conventional construction in terms of D-branes [25, 26, 7, 9]. As we will argue, both the string representation as well as the level matching relations have a natural interpretation from this point of view.

Strings and D-brane intersections

Let us consider a five-brane wrapped around the $K3$ compactification manifold, so that its world-volume has the space-like topology of $K3 \times S^1$. A pure five-brane only carries NS-NS charge. More general BPS-configurations that also carry R-R charge can be obtained by forming bound states with D-branes. For our purposes the most convenient description of these bound states is given in the context of type II B string theory. In this case we need to include 1-branes, 3-branes and 5-branes. When more of these D-branes are taken to lie within the five-brane world volume, they will in general have intersections [26, 25]. The collection of BPS states that corresponds to a given charge configuration are obtained by quantizing the appropriate degrees of freedom of these intersections [7].

Since $K3$ has only non-trivial homology cycles of even dimension, on the given topology of the five-brane of $K3 \times S^1$, all the type IIB D-branes will be wrapped around a corresponding element of $H_*(K3)$ times the S^1. Hence to a given D-brane configuration we can associate a vector

$$q \in H_*(K3, \mathbf{Z}) \tag{4.1}$$

in the integral homology of $K3$. This vector becomes identified with the charge vector

$$q \in \Gamma^{20,4} \tag{4.2}$$

via the isomorphism of $H_*(K3, \mathbf{Z}) \cong \Gamma^{20,4}$, in which the norm on $\Gamma^{20,4}$ is identified with the intersection form. A pair of 3-branes will typically intersect along a 1-dimensional string wound one or more times around the S^1 direction, and similarly the 1-brane intersects with the 5-brane along a string around the S^1.

These strings formed by the D-brane intersections encode the internal degrees of freedom of the five-brane in a completely similar fashion as the string introduced in section 3. In particular, its transversal oscillations are also described by an appropriate $N = 4$ superconformal field theory with target space $K3$, where the BPS-restriction again only allows for either left- or right-moving string oscillations. The spectrum of these quantized 'intersection-strings' will in particular include the excitations of the low-energy effective field theory on the five-brane world volume. The number of excited string states is again counted by means of the $K3$ eliptic genus.

It is evident from the above description that the total string winding number is given by the intersection pairing of the homology class (4.1) on $K3$ defined by the full D-brane configuration. Hence we see that the D-brane representation gives a clear geometrical interpretation of the matching condition

$$\tfrac{1}{2}q_m^2 + \sum_{k,l,m,I} k N^I_{k,l,m} = 1. \tag{4.3}$$

Here we identified the vector in (4.1) with the magnetic charge q_m.

In addition to the string winding number, the string oscillations will also contribute to the total momentum along the S^1. This total momentum is measured from the perspective of the five-brane world-volume, and is therefore related but not equal to the internal KK momentum. The relation between the two quantities is determined via a level matching condition equating this total string momentum to a zero-mode contribution. As before, the form of the zero-mode contribution is determined by means of the free field theory of the massless five-brane modes, and thus depends quadratically on the fluxes and KK-momenta that gives rise to the electric charge q_e. This gives the second condition

$$\tfrac{1}{2}q_e^2 + \sum_{k,l,m,I} l N^I_{k,l,m} = 1. \tag{4.4}$$

as the constraint of translation invariance on the world-volume along the S^1 direction.

Finally, since the D-brane intersection strings carry a non-zero space-time helicity m, we can also introduce a third level matching condition that equates the sum of the individual string contributions to the total helicity quantum number.

T-duality

We can learn more about the dyonic five-brane configuration by considering the effect of the T-duality transformation that interchanges the electric and magnetic charges. Concretely, let us consider the configuration of a dyonic five-brane wound along the A-cycle of the internal two-torus T^2, and act on it with the simultaneous $R \to 1/R$ transformation on both the A- and B-cycle. This map leaves the five-brane location invariant. However, when applied to the intersection strings within the five-brane, it changes their winding direction to the B-cycle, while in addition it interchanges the winding and momentum quantum numbers. It would appear therefore that the new intersection strings lie perpendicular to the five-brane.

An alternative conclusion, however, is that a dyonic five-brane should rather be thought of a pair of perpendicular five-branes, one around the A-cycle and one around the B-cycle. Both five-branes contain a collection of D-brane intersection strings, which however are T-duals of each other in that the momentum quantum numbers of the A-cycle strings are identified with the winding quantum numbers of the B-cycle strings. In this picture, the total winding number of the intersection strings around, say, the A-cycle is measured by q_m^2, while the total string winding number around the B-cycle is q_e^2.

A generating function

It has been argued that the above multiple D-brane description leads to a two-dimensional sigma model with target space the sum of symmetric products of $K3$ manifolds [7]. The 1/2 BPS states are in one-to-one correspondence with ground states of this model and correspond to harmonic forms. The number of these ground states follows from a direct application of the so-called orbifold formula, and is summarized in terms of the generating function (see [19])

$$\sum_{n} e^{2\pi i n\sigma} \dim H^{*}\left(\frac{(K3)^{n}}{S_{n}}\right) = \prod_{l>0} \frac{1}{(1-e^{2\pi i l\sigma})^{24}} \tag{4.5}$$

Our results now suggest a concrete generalization of this counting formula to the 1/4 BPS states, in which case one has to include the transversal string oscillations.

As was first suggested in [7], the counting of these states is naturally related to the elliptic genus of the above-mentioned sigma model. Based on our degeneracy formula, we conjecture that these elliptic genera have a generating function [*]

$$\sum_{n} e^{2\pi i n\sigma} \chi_{\rho,\upsilon}\left(\frac{(K3)^{n}}{S_{n}}\right) = \prod_{k\geq 0, l>0, m\in \mathbf{Z}} \frac{1}{(1-e^{2\pi i(k\rho+l\sigma+m\upsilon)})^{c(4kl-m^{2})}} \tag{4.6}$$

This conjectured identity suggests the following physical interpretation. The terms on the left-hand side count the oscillations of a single long string on the multiple product of the transversal target space $K3$. The right-hand side of our formula (4.6) on the other hand gives the usual second quantized representation of a multiple string state on $K3$ in terms of a string field theory Fock space. The equality of both sides, if indeed true, indicates that the single long string state on the symmetric product of $K3$ provides an exact first quantized representation of the appropriately symmetrized multiple string state on $K3$. Loosely speaking, we equate the elliptic genus of the 'second-quantized manifold' to the second-quantized elliptic genus of a single copy of the manifold. Based on this intuition, we expect that in the above relation the manifold $K3$ can be replaced by an arbitrary manifold X, if one uses the expansion coefficients $c(n)$ of the elliptic genus of X.

We note further that the above formula satisfies a number of highly non-trivial consistency checks. First, the $n = 1$ term gives indeed the answer (3.6) for the $K3$ elliptic genus. Secondly, for $\upsilon = 0$ one recovers the ground state expression (4.5). Thirdly, the expression on the right-hand side of equation (4.6) has the required automorphic properties. Precisely because of that reason this particular expression has been considered before in the literature [23]. It has the important property that, when expanded in powers of $e^{2\pi i\sigma}$ (the so-called Fourier-Jacobi expansion) the n-th coefficient is a weak Jacobi form of weight zero and index n for the modular group $SL(2,\mathbf{Z})$ that acts on the modulus ρ and υ. (See [27] for the theory of Jacobi forms.) The expansion coefficients are therefore indeed candidates for elliptic genera of Calabi-Yau manifolds of (complex) dimension $2n$, which matches the expansion on the left-hand side. Note that the space of weak Jacobi forms of weight zero and fixed index is finite-dimensional. Given the fact that the Euler characters match, this gives extra support to our conjecture.

---

[*] Here in the product we removed, relative to (3.8), the contribution of the states with $l = 0$. The resulting expression is exactly the contribution of the non-degenerate orbits in the fundamental domain integral [21].

Finally, we note that the asymptotic growth of the right-hand side, as described in section 2, gives via the above equality a prediction for the number of single string states on $(K3)^n/S_n$ at large oscillation level. This prediction can be verified by standard techniques.

5. CONCLUDING REMARKS

Let us finally mention some applications and possible generalizations of our result.

Five-dimensional degeneracies

One of the consequences of our analysis is a concrete refinement of the results of Strominger and Vafa [7] on the counting of microscopic black hole states in five dimensions. The formula (4.6) gives an explicit counting formula of these states and in particular allows one to analyze the asymptotic growth in more directions by separately controling the total string winding, momentum and helicity number. In five dimensions the level matching conditions equate these quantum numbers to respectively q^2, the charge Q_H of [7] and the five-dimensional spin J. Explicitely, the degeneracy of these states is given by

$$d(q, Q_H, J) = \oint d\rho d\sigma d\upsilon \, \frac{e^{i\pi(q^2\rho + Q_H\sigma + 2J\upsilon)}}{\Phi'(\rho, \sigma, \upsilon)} \tag{5.1}$$

with Φ' the denominator on the right-hand side of equation (4.6). The asymptotics of Φ' are similar to those of Φ as analyzed in the Appendix.

Generalizations

It would be interesting to extend our results to more general four-dimensional black hole states, by allowing for the possibility of non-zero angular momentum [20] or states away from extremality.

Spinning extremal black holes are in fact most naturally included in our description, although for this we would need to give up manifest $SL(2, \mathbf{Z})$-duality. The most general spinning dyonic black hole geometry is characterized by *four* independent macroscopic quantities (namely the angular momentum J, the length-squared of the charges q_e^2, q_m^2, and $q_e \cdot q_m$). Our most general states, on the other hand, carry at most three macroscopic quantum numbers. In our presentation we eventually arrived at a duality symmetric expression by equating the total 'internal' helicity to the 'external' helicity $q_e \cdot q_m$. However, we can in principle omit this constraint and simply identify the total internal helicity with the macroscopic external angular momentum. This will give a degeneracy formula consistent with the predicted entropy for spinning black holes [20] in the case that $q_e \cdot q_m = 0$.

Another important generalization is to include near extremal black hole states [28]. Within our framework, an obvious step is to relax the BPS condition on the individual strings, and allow for arbitrary left- and right-moving oscillations. We expect that a naive extension of our formalism in this regime would indeed produce an asymptotic number of states in accordance with the four-dimensional macroscopic entropy proportional to the mass squared. This is in essence a consequence of the fact that the mass-shell relation $L_0 =(\mathrm{mass})^2$ is applied twice in our formalism: once on the string on the world-volume, and once on the five-brane in space-time. By a similar argument we also expect that the energy gap will also behave in accordance with the thermodynamic prediction. We should stress however that the resulting description will very likely be of limited validity, since on various crucial points we have made use of the BPS condition. In particular it is not at all clear that the (effective) string theory on the world-volume can still be treated as an (approximately) free string theory.

Algebraic structure

Our results suggest that there exists an interesting algebraic structure behind the $N = 4$ dyon spectrum, related to a generalized Kac-Moody (GKM) algebra. The particular (super)algebra that underlies our degeneracy formula is a so-called automorphic correction [23] of a hyperbolic Kac-Moody algebra with three simple roots with Cartan matrix

$$\begin{pmatrix} 2 & -2 & -2 \\ -2 & 2 & -2 \\ -2 & -2 & 2 \end{pmatrix} \tag{5.2}$$

(Note that the corresponding GKM has an infinite number of imaginary simple roots, roughly corresponding to the single string BPS states.) The fact that the denominator of this GKM appears (in the denominator) of our partition function, suggests that perhaps the full characters, including the numerator, also play a role in the BPS spectrum. Perhaps it is possible to realize the spectrum generating algebra of the $N = 4$ dyon BPS states in terms of this symmetry algebra (cf. [29]). Generalized Kac-Moody algebras also recently appeared in the $N = 2$ context [22], where it was suggested that the heterotic string vertex operators representing the perturbative BPS states form a GKM.

ACKNOWLEDGEMENTS

We would like to thank S. Bais, R. Borcherds, S. Ferrara, G. v.d. Geer, C. Hofman, E. Kiritsis, C. Kounnas, G. Moore, D. Neumann, L. Susskind, C. Vafa and E. Witten for helpful discussions. This research is partly supported by a Pionier Fellowship of NWO, a Fellowship of the Royal Dutch Academy of Sciences (K.N.A.W.), the Packard Foundation and the A.P. Sloan Foundation.

APPENDIX

The asymptotic behavior of the degeneracy formula (2.3) are related to the zeroes of the automorphic form Φ in the integrand. These zeroes are well understood using either standard facts on genus two Riemann surfaces, the results of Borcherds [10] or the representation in terms of a string one-loop amplitude [22, 21] as in (3.5). From the latter point of view we understand that $\Phi(\rho,\sigma,\upsilon)$ acquires a zero or pole whenever the moduli ρ, σ and υ that parametrize the Narain lattice $\Gamma^{3,2}$ allow chiral vertex operators, *i.e.* elements $p=(p_L,p_R)\in\Gamma^{3,2}$ with $p_R=0$. In terms of the integer lattice vector $p=(k,l,m,a,c)\in\Gamma^{3,2}\cong\mathbf{Z}^5$ we have [21]

$$p_R^2=\frac{1}{2Y}|k\rho+l\sigma+m\upsilon+a(\rho\sigma-\upsilon^2)+c|^2 \tag{A.1}$$

with $Y=\rho_2\sigma_2-\upsilon_2^2$, and

$$p^2=\tfrac{1}{2}m^2-2kl+2ac. \tag{A.2}$$

If we use the vector notation $y=(\rho,\sigma,2\upsilon)$, with $-\frac{1}{2}y^2=\rho\sigma-\upsilon^2$, we see that the zeroes and poles occur at the 'rational quadratic divisors' of [10]

$$-\tfrac{1}{2}ay^2+b\cdot y+c=0 \tag{A.3}$$

where $b=(k,l,m)\in\Gamma^{2,1}$ with norm-squared $b^2=-2kl+\frac{1}{2}m^2$ and $a,c\in\mathbf{Z}$. We can write equation (A.3) also as $p\cdot v=0$, where we have introduced the 5-dimensional null vector $v=(y;-\frac{1}{2}y^2,1)$. Of course $|p\cdot v|^2\sim p_R^2$. In terms of the coefficients $c(n)$, the order of the zero of $\Phi(y)$ at such a divisor is $\sum_{n>0}c(-2n^2p^2)$ with $p^2>0$. In our case the only possibility is $c(-1)=2$, so we necessarily have $p^2=1/2$ and the partition function $1/\Phi(y)$ has a second order pole at this divisor.

In the theory of genus two curves or abelian surfaces, the equation (A.3) is well-known to describe (a component of) the so-called Humbert surface H_Δ with discriminant $\Delta=2p^2$ [30]. In our case we are interested in the surface H_1. This is indeed known to be the zero-locus of the product of all even theta-functions.

The 'tachyon pole' at $\upsilon = 0$ occurs for $b = (0,0,1)$ and $a = c = 0$, which describes the factorization on a product of two elliptic curves. All the other poles are transformations of this one by $Sp(2, \mathbf{Z}) \cong SO(3,2,\mathbf{Z})$. This group acts linear on the vectors v and p, which is another way to see that the divisors are of the form (A.3). The leading contribution in the Fourier coefficient

$$D(q) = \int d^3y \, \frac{e^{2\pi i q \cdot y}}{\Phi(y)} \tag{A.4}$$

for large q from the divisor (A.3) is of the form $D(q) \sim e^{2\pi\mu|q|}$ with $\mu^2 = (b^2 + 2ac)/a^2 = 1/2a^2$. So the dominant term will be given by $a = 1$. This gives indeed the black-hole entropy (2.9). The other coefficients are then constrainted by $4c - 4kl + m^2 = 1$, so in particular m is odd, and k, l can be arbitrary. However, since we have the freedom to shift the variables ρ, σ, υ by integers, we can put $k, l, c = 0$ and $m = 1$. The divisor is then given by $\rho\sigma - \upsilon^2 + \upsilon = 0$.

Let us finally make a few remarks about the geometrical interpretation in terms of a genus two surface. Let A_1, A_2, B_1, B_2 be a basis for the homology group $H_1(\Sigma)$ of a genus two Riemann surface Σ. Now consider the quotient of $\bigwedge^2 H_1$ by the relation

$$A_1 \wedge B_1 + A_2 \wedge B_2 = 0 \tag{A.5}$$

and call the resulting 5-dimensional lattice $L \cong \Gamma^{3,2}$. It naturally carries a signature $(3,2)$ bilinear form, coming from the intersection form on $\bigwedge^2 H_1$. This makes explicit the isomorphism $Sp(2,\mathbf{Z}) \cong SO(3,2,\mathbf{Z})$. As a basis of L we choose

$$B_1 \wedge A_2,\ B_2 \wedge A_1,\ A_1 \wedge B_1 = B_2 \wedge A_2,\ B_1 \wedge B_2,\ A_1 \wedge A_2. \tag{A.6}$$

There is a natural map $L \to \mathbf{C}$ given in terms of the periods of the abelian differentials ω_1, ω_2

$$C \wedge D \to \oint_C \omega_1 \oint_D \omega_2 - \oint_D \omega_1 \oint_C \omega_2 \tag{A.7}$$

Under this map our basis (A.6) gives the 'bi-periods'

$$\rho,\ \sigma,\ \upsilon,\ \rho\sigma - \upsilon^2,\ 1. \tag{A.8}$$

It is clear that symplectic transformations will act linear on these variables. To any basis element of L we can associate a zero-homology cycle in the homotopy group $\pi_1(\Sigma)$ by

$$C \wedge D \to [C, D] = CDC^{-1}D^{-1} \tag{A.9}$$

Note that $[A_1, B_1][A_2, B_2] \sim 1$ so that this map is well-defined. It associates a bi-period to a vanishing cycle. Indeed, in this way the divisor $\upsilon = 0$ describes the usual pinching along the dividing cycle $[A_1, B_1] = [B_2, A_2]$. Other divisors can be similarly interpreted.

E_8 (mathematics)

In mathematics, **E_8** is any of several closely related exceptional simple Lie groups, linear algebraic groups or Lie algebras of dimension 248; the same notation is used for the corresponding root lattice, which has rank 8. The designation E_8 comes from the Cartan–Killing classification of the complex simple Lie algebras, which fall into four infinite series labeled A_n, B_n, C_n, D_n, and five exceptional cases labeled E_6, E_7, E_8, F_4, and G_2. The E_8 algebra is the largest and most complicated of these exceptional cases.

Basic description

The Lie group E_8 has dimension 248. Its rank, which is the dimension of its maximal torus, is eight.

Therefore, the vectors of the root system are in eight-dimensional Euclidean space: they are described explicitly later in this article. The Weyl group of E_8, which is the group of symmetries of the maximal torus which are induced by conjugations in the whole group, has order $2^{14}\,3^5\,5^2\,7 = 696\,729\,600$.

The compact group E_8 is unique among simple compact Lie groups in that its non-trivial representation of smallest dimension is the adjoint representation (of dimension 248) acting on the Lie algebra E_8 itself; it is also the unique one which has the following four properties: trivial center, compact, simply connected, and simply laced (all roots have the same length).

There is a Lie algebra E_k for every integer $k \geq 3$. The largest value of k for which E_k is finite-dimensional is $k=8$, that is, E_k is infinite-dimensional for any $k > 8$.

Real and complex forms

There is a unique complex Lie algebra of type E_8, corresponding to a complex group of complex dimension 248. The complex Lie group E_8 of complex dimension 248 can be considered as a simple real Lie group of real dimension 496. This is simply connected, has maximal compact subgroup the compact form (see below) of E_8, and has an outer automorphism group of order 2 generated by complex conjugation.

As well as the complex Lie group of type E_8, there are three real forms of the Lie algebra, three real forms of the group with trivial center (two of which have non-algebraic double covers, giving two further real forms), all of real dimension 248, as follows:

- The compact form (which is usually the one meant if no other information is given), which is simply connected and has trivial outer automorphism group.
- The split form, EVIII (or $E_{8(8)}$), which has maximal compact subgroup Spin(16)/(**Z**/2**Z**), fundamental group of order 2 (implying that it has a double cover, which is a simply connected Lie real group but is not algebraic, see below) and has trivial outer automorphism group.
- EIX (or $E_{8(-24)}$), which has maximal compact subgroup $E_7 \times SU(2)/(-1,-1)$, fundamental group of order 2 (again implying a double cover, which is not algebraic) and has trivial outer automorphism group.

For a complete list of real forms of simple Lie algebras, see the list of simple Lie groups.

E_8 as an algebraic group

By means of a Chevalley basis for the Lie algebra, one can define E_8 as a linear algebraic group over the integers and, consequently, over any commutative ring and in particular over any field: this defines the so-called split (sometimes also known as “untwisted”) form of E_8. Over an algebraically closed field, this is the only form; however, over other fields, there are often many other forms, or “twists” of E_8, which are classified in the general framework of Galois cohomology (over a perfect field k) by the set $H^1(k,\mathrm{Aut}(E_8))$ which, because the Dynkin diagram of E_8 (see below) has no automorphisms, coincides with $H^1(k,E_8)$.[1]

Over **R**, the real connected component of the identity of these algebraically twisted forms of E_8 coincide with the three real Lie groups mentioned above, but with a subtlety concerning the fundamental group: all forms of E_8 are simply connected in the sense of algebraic geometry, meaning that they admit no non-trivial algebraic coverings; the non-compact and simply connected real Lie group forms of E_8 are therefore not algebraic and admit no faithful finite-dimensional representations.

Over finite fields, the Lang–Steinberg theorem implies that $H^1(k,E_8)=0$, meaning that E_8 has no twisted forms: see below.

The characters of finite dimensional representations of the real and complex Lie algebras and Lie groups are all given by the Weyl character formula. The dimensions of the smallest irreducible representations are (sequence A121732 in the OEIS):

> 1, 248, 3875, 27000, 30380, 147250, 779247, 1763125, 2450240, 4096000, 4881384, 6696000, 26411008, 70680000, 76271625, 79143000, 146325270, 203205000, 281545875, 301694976, 344452500, 820260000, 1094951000, 2172667860, 2275896000, 2642777280, 2903770000, 3929713760, 4076399250, 4825673125, 6899079264, 8634368000 (twice), 12692520960…

The 248-dimensional representation is the adjoint representation. There are two non-isomorphic irreducible representations of dimension 8634368000 (it is not unique; however, the next integer with this property is 175898504162692612600853299200000 (sequence A181746 in the OEIS)). The fundamental representations are those with dimensions 3875, 6696000, 6899079264, 146325270, 2450240, 30380, 248 and 147250 (corresponding to the eight nodes in the Dynkin diagram in the order chosen for the Cartan matrix below, i.e., the nodes are read in the seven-node chain first, with the last node being connected to the third).

The coefficients of the character formulas for infinite dimensional irreducible representations of E_8 depend on some large square matrices consisting of polynomials, the Lusztig–Vogan polynomials, an analogue of Kazhdan–Lusztig polynomials introduced for reductive groups in general by George Lusztig and David Kazhdan (1983). The values at 1 of the Lusztig–Vogan polynomials give the coefficients of the matrices relating the standard representations (whose characters are easy to describe) with the irreducible representations.

These matrices were computed after four years of collaboration by a group of 18 mathematicians and computer scientists, led by Jeffrey Adams, with much of the programming done by Fokko du Cloux. The most difficult case (for exceptional groups) is the split real form of E_8 (see above), where the largest matrix is of size 453060×453060. The Lusztig–Vogan polynomials for all other exceptional simple groups have been known for some time; the calculation for the split form of E_8 is far longer than any other case. The announcement of the result in March 2007 received extraordinary attention from the media (see the external links), to the surprise of the mathematicians working on it.

The representations of the E_8 groups over finite fields are given by Deligne–Lusztig theory.

Constructions

One can construct the (compact form of the) E_8 group as the automorphism group of the corresponding $\mathbf{e}_8$ Lie algebra. This algebra has a 120-dimensional subalgebra **so**(16) generated by J_{ij} as well as 128 new generators Q_a that transform as a Weyl–Majorana spinor of **spin**(16). These statements determine the commutators

$$[J_{ij}, J_{k\ell}] = \delta_{jk} J_{i\ell} - \delta_{j\ell} J_{ik} - \delta_{ik} J_{j\ell} + \delta_{i\ell} J_{jk}$$

as well as

$$[J_{ij}, Q_a] = \frac{1}{4}(\gamma_i\gamma_j - \gamma_j\gamma_i)_{ab} Q_b,$$

while the remaining commutators (not anticommutators!) between the spinor generators are defined as

$$[Q_a, Q_b] = \gamma^{[i}_{ac}\gamma^{j]}_{cb} J_{ij}.$$

It is then possible to check that the Jacobi identity is satisfied.

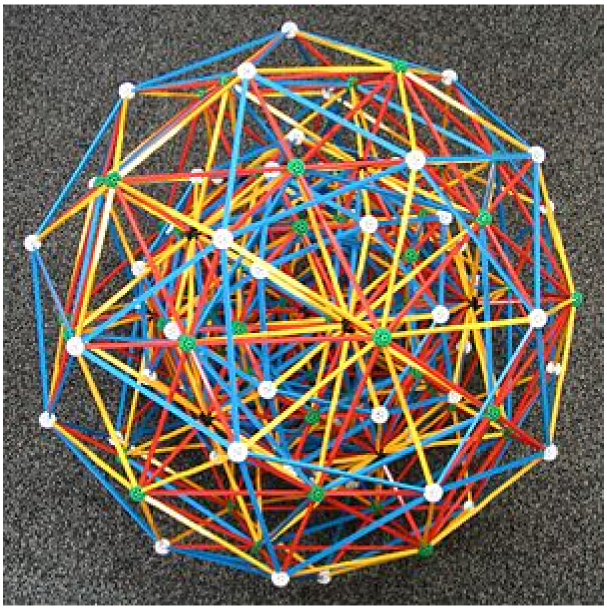
Geometry

The compact real form of E_8 is the isometry group of the 128-dimensional exceptional compact Riemannian symmetric space EVIII (in Cartan's classification). It is known informally as the "octooctonionic projective plane" because it can be built using an algebra that is the tensor product of the octonions with themselves, and is also known as a Rosenfeld projective plane, though it does not obey the usual axioms of a projective plane. This can be seen systematically using a construction known as the *magic square*, due to Hans Freudenthal and Jacques Tits (Landsberg & Manivel 2001).

E_8 root system

A root system of rank *r* is a particular finite configuration of vectors, called *roots*, which span an *r*-dimensional Euclidean space and satisfy certain geometrical properties. In particular, the root system must be invariant under reflection through the hyperplane perpendicular to any root.

The $\mathbf{E_8}$ **root system** is a rank 8 root system containing 240 root vectors spanning $\mathbf{R}^8$. It is irreducible in the sense that it cannot be built from root systems of smaller rank. All the root vectors in E_8 have the same length. It is convenient for a number of purposes to normalize them to have length $\sqrt{2}$. These 240 vectors are the vertices of a semi-regular polytope discovered by Thorold Gosset in 1900, sometimes known as the 4_{21} polytope.



Zome model of the E_8 root system, projected into three-space, and represented by the vertices of the 4_{21} polytope, 
Construction

In the so-called *even coordinate system*, E_8 is given as the set of all vectors in $\mathbf{R}^8$ with length squared equal to 2 such that coordinates are either all integers or all half-integers and the sum of the coordinates is even.

Explicitly, there are 112 roots with integer entries obtained from

$$(\pm 1, \pm 1, 0, 0, 0, 0, 0, 0)$$

by taking an arbitrary combination of signs and an arbitrary permutation of coordinates, and 128 roots with half-integer entries obtained from

$$\left(\pm\tfrac{1}{2}, \pm\tfrac{1}{2}, \pm\tfrac{1}{2}, \pm\tfrac{1}{2}, \pm\tfrac{1}{2}, \pm\tfrac{1}{2}, \pm\tfrac{1}{2}, \pm\tfrac{1}{2}\right)$$

by taking an even number of minus signs (or, equivalently, requiring that the sum of all the eight coordinates be even). There are 240 roots in all.

The 112 roots with integer entries form a D_8 root system. The E_8 root system also contains a copy of A_8 (which has 72 roots) as well as E_6 and E_7 (in fact, the latter two are usually *defined* as subsets of E_8).

In the *odd coordinate system*, E_8 is given by taking the roots in the even coordinate system and changing the sign of any one coordinate. The roots with integer entries are the same while those with half-integer entries have an odd number of minus signs rather than an even number.

Dynkin diagram

The Dynkin diagram for E_8 is given by .

This diagram gives a concise visual summary of the root structure. Each node of this diagram represents a simple root. A line joining two simple roots indicates that they are at an angle of 120° to each other. Two simple roots which are not joined by a line are orthogonal.

Cartan matrix

The Cartan matrix of a rank r root system is an $r \times r$ matrix whose entries are derived from the simple roots. Specifically, the entries of the Cartan matrix are given by

$$A_{ij} = 2\frac{(\alpha_i, \alpha_j)}{(\alpha_i, \alpha_i)}$$

where $(\ ,\ )$ is the Euclidean inner product and α_i are the simple roots. The entries are independent of the choice of simple roots (up to ordering).

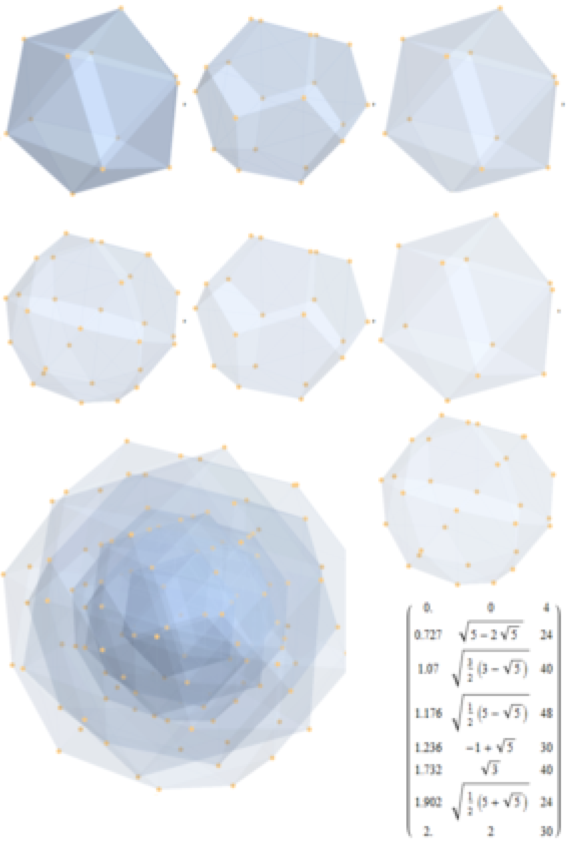
The Cartan matrix for E_8 is given by

$$\begin{bmatrix} 2 & -1 & 0 & 0 & 0 & 0 & 0 & 0 \\ -1 & 2 & -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 2 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & 2 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 2 & -1 & 0 & -1 \\ 0 & 0 & 0 & 0 & -1 & 2 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & -1 & 2 & 0 \\ 0 & 0 & 0 & 0 & -1 & 0 & 0 & 2 \end{bmatrix}.$$

The determinant of this matrix is equal to 1.

Simple roots

A set of simple roots for a root system Φ is a set of roots that form a basis for the Euclidean space spanned by Φ with the special property that each root has components with respect to this basis that are either all nonnegative or all nonpositive.



$$\begin{pmatrix} 0. & 0 & 4 \\ 0.727 & \sqrt{5-2\sqrt{5}} & 24 \\ 1.07 & \sqrt{\frac{1}{2}(3-\sqrt{5})} & 40 \\ 1.176 & \sqrt{\frac{1}{2}(5-\sqrt{5})} & 48 \\ 1.236 & -1+\sqrt{5} & 30 \\ 1.732 & \sqrt{3} & 40 \\ 1.902 & \sqrt{\frac{1}{2}(5+\sqrt{5})} & 24 \\ 2. & 2 & 30 \end{pmatrix}$$

Shown in 3D projection using the basis vectors [u,v,w] giving H3 symmetry:

u = $(1, \varphi, 0, -1, \varphi, 0,0,0)$

v = $(\varphi, 0, 1, \varphi, 0, -1,0,0)$

w = $(0, 1, \varphi, 0, -1, \varphi,0,0)$

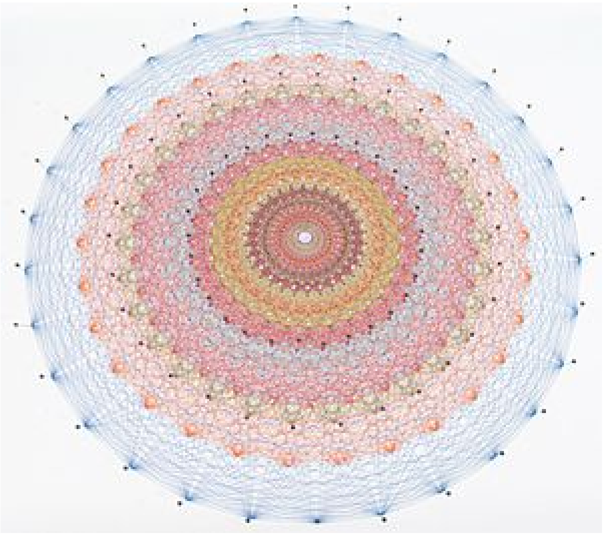
The projected 4_{21} polytope vertices are sorted and tallied by their 3D norm generating the increasingly transparent hulls of each set of tallied norms. These show:

1. 4 points at the origin
2. 2 icosahedrons
3. 2 dodecahedrons
4. 4 icosahedrons
5. 1 icosadodecahedron
6. 2 dodecahedrons
7. 2 icosahedrons
8. 1 icosadodecahedron

for 240 vertices. This is, of course, 2 concentric sets of hulls from the H4 symmetry of the 600-cell scaled by the golden ratio.[2]

Given the E_8 Cartan matrix (above) and a Dynkin diagram node ordering of: 
One choice of simple roots is given by the rows of the following matrix:

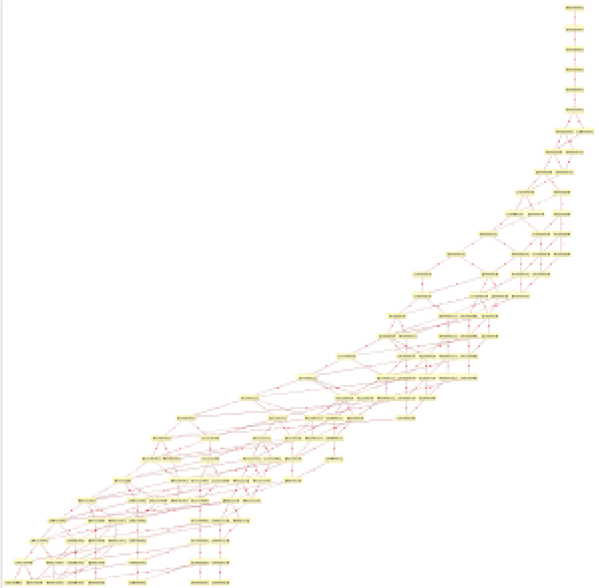
$$\begin{bmatrix} 1 & -1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 \\ -\frac{1}{2} & -\frac{1}{2} & -\frac{1}{2} & -\frac{1}{2} & -\frac{1}{2} & -\frac{1}{2} & -\frac{1}{2} & -\frac{1}{2} \\ 0 & 0 & 0 & 0 & 0 & 1 & -1 & 0 \end{bmatrix}.$$



E8 2d projection with thread made by hand

Weyl group

The Weyl group of E_8 is of order 696729600, and can be described as $O_8^+(2)$: it is of the form 2.*G*.2 (that is, a stem extension by the cyclic group of order 2 of an extension of the cyclic group of order 2 by a group *G*) where *G* is the unique simple group of order 174182400 (which can be described as $PS\Omega_8^+(2)$).[3]



Hasse diagram of E8 root poset with edge labels identifying added simple root position.

E_8 root lattice

The integral span of the E_8 root system forms a lattice in $\mathbf{R}^8$ naturally called the **E_8 root lattice**. This lattice is rather remarkable in that it is the only (nontrivial) even, unimodular lattice with rank less than 16.

Simple subalgebras of E_8

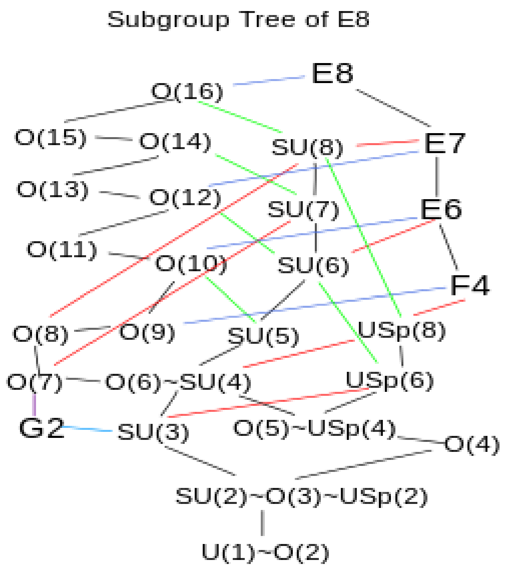
The Lie algebra E8 contains as subalgebras all the exceptional Lie algebras as well as many other important Lie algebras in mathematics and physics. The height of the Lie algebra on the diagram approximately corresponds to the rank of the algebra. A line from an algebra down to a lower algebra indicates that the lower algebra is a subalgebra of the higher algebra.

Chevalley groups of type E_8

Chevalley (1955) showed that the points of the (split) algebraic group E_8 (see above) over a finite field with q elements form a finite Chevalley group, generally written $E_8(q)$, which is simple for any q,[4][5] and constitutes one of the infinite families addressed by the classification of finite simple groups. Its number of elements is given by the formula (sequence A008868 in the OEIS):

$$q^{120}\left(q^{30}-1\right)\left(q^{24}-1\right)\left(q^{20}-1\right)\left(q^{18}-1\right)\left(q^{14}-1\right)\left(q^{12}-1\right)\left(q^{8}-1\right)\left(q^{2}-1\right)$$

The first term in this sequence, the order of $E_8(2)$, namely



An incomplete simple subgroup tree of E_8

337 804 753 143 634 806 261 388 190 614 085 595 079 991 692 242 467 651 576 160 959 909 068 800 000 ≈ 3.38×10^{74}, is already larger than the size of the Monster group. This group $E_8(2)$ is the last one described (but without its character table) in the ATLAS of Finite Groups.[6]

The Schur multiplier of $E_8(q)$ is trivial, and its outer automorphism group is that of field automorphisms (i.e., cyclic of order f if $q=p^f$ where p is prime).

Lusztig (1979) described the unipotent representations of finite groups of type E_8.

Subgroups

The smaller exceptional groups E_7 and E_6 sit inside E_8. In the compact group, both $E_7\times SU(2)/(-1,-1)$ and $E_6\times SU(3)/(\mathbf{Z}/3\mathbf{Z})$ are maximal subgroups of E_8.

The 248-dimensional adjoint representation of E_8 may be considered in terms of its restricted representation to the first of these subgroups. It transforms under $E_7\times SU(2)$ as a sum of tensor product representations, which may be labelled as a pair of dimensions as (3,1) + (1,133) + (2,56) (since there is a quotient in the product, these notations may strictly be taken as indicating the infinitesimal (Lie algebra) representations). Since the adjoint representation can be described by the roots together with the generators in the Cartan subalgebra, we may see that decomposition by looking at these. In this description,

- (3,1) consists of the roots (0,0,0,0,0,0,1,−1), (0,0,0,0,0,0,−1,1) and the Cartan generator corresponding to the last dimension;
- (1,133) consists of all roots with (1,1), (−1,−1), (0,0), $(-\tfrac{1}{2},-\tfrac{1}{2})$ or $(\tfrac{1}{2},\tfrac{1}{2})$ in the last two dimensions, together with the Cartan generators corresponding to the first seven dimensions;
- (2,56) consists of all roots with permutations of (1,0), (−1,0) or $(\tfrac{1}{2},-\tfrac{1}{2})$ in the last two dimensions.

The 248-dimensional adjoint representation of E_8, when similarly restricted, transforms under $E_6\times SU(3)$ as: (8,1) + (1,78) + (3,27) + $(\overline{3},\overline{27})$. We may again see the decomposition by looking at the roots together with the generators in the Cartan subalgebra. In this description,

- (8,1) consists of the roots with permutations of (1,−1,0) in the last three dimensions, together with the Cartan generator corresponding to the last two dimensions;
- (1,78) consists of all roots with (0,0,0), ($-\frac{1}{2}$,$-\frac{1}{2}$,$-\frac{1}{2}$) or ($\frac{1}{2}$,$\frac{1}{2}$,$\frac{1}{2}$) in the last three dimensions, together with the Cartan generators corresponding to the first six dimensions;
- (3,27) consists of all roots with permutations of (1,0,0), (1,1,0) or ($-\frac{1}{2}$,$\frac{1}{2}$,$\frac{1}{2}$) in the last three dimensions.
- ($\overline{3}$,$\overline{27}$) consists of all roots with permutations of (−1,0,0), (−1,−1,0) or ($\frac{1}{2}$,$-\frac{1}{2}$,$-\frac{1}{2}$) in the last three dimensions.

The finite quasisimple groups that can embed in (the compact form of) E_8 were found by Griess & Ryba (1999).

The Dempwolff group is a subgroup of (the compact form of) E_8. It is contained in the Thompson sporadic group, which acts on the underlying vector space of the Lie group E_8 but does not preserve the Lie bracket. The Thompson group fixes a lattice and does preserve the Lie bracket of this lattice mod 3, giving an embedding of the Thompson group into $E_8(\mathbf{F}_3)$.

Applications

The E_8 Lie group has applications in theoretical physics and especially in string theory and supergravity. $E_8 \times E_8$ is the gauge group of one of the two types of heterotic string and is one of two anomaly-free gauge groups that can be coupled to the $N = 1$ supergravity in ten dimensions. E_8 is the U-duality group of supergravity on an eight-torus (in its split form).

One way to incorporate the standard model of particle physics into heterotic string theory is the symmetry breaking of E_8 to its maximal subalgebra $SU(3) \times E_6$.

In 1982, Michael Freedman used the E_8 lattice to construct an example of a topological 4-manifold, the E_8 manifold, which has no smooth structure.

Antony Garrett Lisi's incomplete "An Exceptionally Simple Theory of Everything" attempts to describe all known fundamental interactions in physics as part of the E_8 Lie algebra.[7][8]

R. Coldea, D. A. Tennant, and E. M. Wheeler et al. (2010) reported an experiment where the electron spins of a cobalt-niobium crystal exhibited, under certain conditions, two of the eight peaks related to E_8 that were predicted by Zamolodchikov (1989).[9][10]

History

Wilhelm Killing (1888a, 1888b, 1889, 1890) discovered the complex Lie algebra E_8 during his classification of simple compact Lie algebras, though he did not prove its existence, which was first shown by Élie Cartan. Cartan determined that a complex simple Lie algebra of type E_8 admits three real forms. Each of them gives rise to a simple Lie group of dimension 248, exactly one of which (as for any complex simple Lie algebra) is compact. Chevalley (1955) introduced algebraic groups and Lie algebras of type E_8 over other fields: for example, in the case of finite fields they lead to an infinite family of finite simple groups of Lie type.

Sporadic groups and string theory.

First European Congress of Mathematics, Vol. I (Paris, 1992), 411–421, Progr. Math., 119, Birkhäuser, Basel, 1994.

Richard E. Borcherds, DPMMS, 16 Mill Lane, Cambridge, CB2 1SB, England.

This is an expanded version of my talk at the ECM.

1. Some classical infinite product identities.

I will start by giving some well known product identities. The first is

$$\sum_{n\in\mathbf{Z}}(-1)^n q^{3(n+1/6)^2/2} = q^{1/24}\prod_{n>0}(1-q^n).$$

This identity was found by Euler while investigating the partition function; the right hand side is essentially the inverse of the generating function $\prod(1-q^n)^{-1}=\sum p(n)q^n$ of the partition function, and the left hand side is a theta function. A similar identity due to Gauss is

$$\sum_{n\in\mathbf{Z}} q^{n^2} = (1+q)^2(1-q^2)(1+q^3)^2(1-q^4)\dots$$

Both of these are special cases of Jacobi's triple product identity

$$\sum_{n\in\mathbf{Z}}(-1)^n q^{n^2}z^n = \prod_{n>0}(1-q^{2n})(1-q^{2n-1}z)(1-q^{2n-1}z^{-1})$$

if we choose z to be some fixed power of q. Finally Weyl's denominator formula for finite dimensional Lie algebras is

$$e^\rho\sum_{w\in W}\det(w)e^{-w(\rho)} = \prod_{\alpha>0}(1-e^\alpha)$$

where W is the Weyl group, ρ is the Weyl vector, and the product is over all positive roots α. This is a special case of Weyl's character formula which says that the character of a finite dimensional representation is equal to a sum similar to the left hand side divided by the product on the right hand side; for the 1-dimensional representation the character is 1 so the sum is equal to the product.

The Weyl character formula looks rather like the other product formulas. This similarity was explained by Macdonald and Kac as follows. Macdonald observed that the Weyl denominator formula was just a statement about finite root systems, and generalized this to affine root systems, producing a collection of identities called the Macdonald identities. The Macdonald identity for the simplest affine root system is just the Jacobi triple product identity. Kac observed that the Macdonald identities were just the denominator formulas for the Kac-Moody algebras that he and Moody had discovered a few years before, and went on to prove a character formula for representations of these algebras generalizing the Weyl character formula. The Weyl-Kac denominator formula [12] for Kac-Moody algebras is

$$e^\rho\sum_{w\in W}\det(w)e^{-w(\rho)} = \prod_{\alpha>0}(1-e^\alpha)^{\mathrm{mult}(\alpha)}$$

where $\mathrm{mult}(\alpha)$ is the multiplicity of the root α, which is just the dimension of the vector space corresponding to the root α. For finite dimensional Lie algebras the multiplicity of a root is always 1 which is why this expression does not appear in the Weyl denominator formula. For affine Lie algebras such as $SL_n(\mathbf{R}[z,z^{-1}])$ this formula is just a Macdonald identity; for example the Jacobi triple product identity is just the Weyl-Kac denominator formula for $SL_2(\mathbf{R}[z,z^{-1}])$.

I will now briefly describe a proof of the Weyl-Kac character formula using Lie algebra cohomology due to Bott, Kostant, Garland and Lepowsky [10, 14]. Perhaps the best way to motivate Lie algebra cohomology is by analogy with the de Rham cohomology of a compact Riemannian manifold M. The de Rham cohomology of M is defined to be the cohomology groups of the sequence

$$\Lambda^0 \longrightarrow \Lambda^1 \longrightarrow \Lambda^2 \longrightarrow \dots$$

where Λ^n is the vector space of smooth n-forms over M and the arrows are given by the exterior derivative d. The Riemannian manifold on M defines inner products on all the spaces Λ^n which we can use to define the adjoint d^* of d. The Laplace operator is defined as $\Omega = dd^* + d^*d$, and the main theorem of Hodge theory says that the n'th cohomology group H^n is isomorphic to the kernel of Ω on Λ^n. If we have a complex like the one above, the Euler-Poincaré principle states that the alternating sum $\Lambda^* = \Lambda^0 - \Lambda^1 + \Lambda^2 - \ldots$ is equal to the alternating sum $H^* = H^0 - H^1 + H^2 - \ldots$. Strictly speaking, this does not make sense unless the groups Λ^n are all finite dimensional (which they are not) and almost all 0. I will deal with this problem by ignoring it.

Lie algebra cohomology is very similar except that we replace the space of n forms on a manifold by the n'th exterior power of the dual of some Lie algebra, and replace the Riemannian metric on M by an invariant (or contravariant) bilinear form on the Lie algebra. Then, at least for the Lie algebras I will be talking about, the analogues of Hodge theory and the Euler-Poincaré principle are both true.

The Weyl-Kac character formula now turns out to be the Euler-Poincaré principle applied to the cohomology of a suitable Lie algebra. Any Kac-Moody algebra can be written as a (vector space) sum of subalgebras $E \oplus H \oplus F$ where H is the Cartan subalgebra, and E and F are the subalgebras associated to the positive and negative roots. For example, for $SL_n(\mathbf{R})$ the algebras E, F, and H are the upper triangular, lower triangular, and diagonal matrices. The Weyl-Kac denominator formula for the Kac Moody algebra is the Euler-Poincaré principle applied to the cohomology of the subalgebra E, and the cohomology groups can be worked out using Hodge theory. To see this, we use the facts that $\Lambda^*(A \oplus B) = \Lambda^*(A) \otimes \Lambda^*(B)$ for any vector spaces A and B, and $\Lambda^*(A) = 1 - A$ if A is 1-dimensional, so if a vector space is a sum of 1-dimensional spaces A_α, then $\Lambda^*(A)$ is just the product of the factors $(1 - A_\alpha)$. This is where the product in the Weyl-Kac denominator formula comes from. It is more difficult to see why the cohomology gives a sum over the Weyl group; I will just state that the dimension of the n'th cohomology group is the number of elements of the Weyl group of length n. This makes it plausible that the alternating sum over the Weyl group has something to do with the alternating sum of the cohomology groups.

The Weyl-Kac denominator formula is true for non affine Kac-Moody algebras, but unfortunately there are no known examples, other than the finite dimensional and affine algebras, for which the root multiplicities are known explicitly, so this does not really give any new identities. (It is of course always possible to calculate the root multiplicities by using the Weyl-Kac formula or something equivalent to it, but there is no simpler description of them.) However there is a class of Lie algebras, called generalized Kac-Moody algebras [2], which are similar to Kac-Moody algebras, and we can find some examples of these for which the root multiplicities are known. For a finite dimensional Lie algebra all roots have positive norm. For a Kac-Moody algebra, roots can have zero or negative norm, but all simple roots have positive norm, while generalized Kac-Moody algebras can have simple roots of negative norm. Generalized Kac-Moody algebras can also be characterized as Lie algebras with an almost positive definite contravariant bilinear form. More precisely, a Lie algebra G is a generalized Kac-Moody algebra if it satisfies the following conditions:

1. G is graded as $G = \oplus_{n \in \mathbf{Z}} G_n$ such that G_n is finite dimensional for $n \neq 0$.
2. G has an invariant bilinear form compatible with this grading.
3. G has an involution ω preserving $(,)$ and mapping G_n to G_{-n} which acts as -1 on G_0.
4. If we define the contravariant bilinear form $(,)_0$ on G by $(g,h)_0 = (g, \omega(h))$, then $(,)_0$ is positive definite on G_n for $n \neq 0$.

(If we strengthen condition 4 slightly by saying that $(,)_0$ should be positive definite on the whole of G, then the algebras we get are essentially sums of finite dimensional and affine Kac-Moody algebras.)

Many examples of generalized Kac-Moody algebras can be constructed using string theory.

2. String theory.

I will describe how to quantize a string moving in spacetime. The space of states of a quantized string is sometimes a generalized Kac-Moody algebra. See [15] for a more detailed account of the things in this section.

A classical closed string moving in spacetime can be represented by a map from $\mathbf{S}^1 \times \mathbf{R}^1$ to $\mathbf{R}^{n,1}$, where $\mathbf{S}^1$ is the string, $\mathbf{R}^1$ is time on the string, and $\mathbf{R}^{n,1}$ is $n+1$-dimensional spacetime. The classical equations of motion for the string say that the action must be stationary, where the action is some function defined on the space of all maps from $\mathbf{S}^1 \times \mathbf{R}^1$ to $\mathbf{R}^{n,1}$. The original action is the Nambu-Goto action, which is equal to the area of the image of $\mathbf{S}^1 \times \mathbf{R}^1$. (It does not matter that this area is usually infinite, because we are only interested in the change in the area under small local perturbations, and this is well defined. Also it is easier to use a slightly different action called the Polyakov action, but this produces the same solutions to the classical equations of motion.)

Phase space is defined to be the space of all solutions to the classical equations of motion, possibly quotiented out by the action of some group. (It is often defined to be the cotangent space to "configuration space", because this is more or less the same thing, because an element of this cotangent space is roughly the same as giving the position and momentum of everything, and this often determines a unique solution to the classical equations of motion.) The phase space of some classical system can often be made into a symplectic manifold in a canonical way, so that it has a nondegenerate closed 2-form on it. On any symplectic manifold the vector fields preserving the 2-form are called the Hamiltonian vector fields, and can be thought of as the Lie algebra of the group of automorphisms of the symplectic manifold. This Lie algebra has a canonical central extension equal to the Lie algebra of all smooth functions on the manifold under the Poisson bracket (which takes the functions f and g to $\langle df, dg\rangle$). In other words we have the following exact sequence of Lie algebras (at least if the symplectic manifold is compact and simply connected):

$$0 \longrightarrow \mathbf{R} \longrightarrow \Lambda^0 \xrightarrow{d} \Lambda^1_{\text{closed}} \longrightarrow 0,$$

where Λ^0 is the Lie algebra of smooth functions under Poisson bracket, and $\Lambda^1_{\text{closed}}$ is the Lie algebra of closed 1-forms, which are identified with the Hamiltonian vector fields if we use the 2-form to identify 1-forms with vector fields.

The quantization of the string is roughly a representation of some Lie subalgebra of the Lie algebra of functions on phase space. Which subalgebra and which representation we take are up to the person doing the quantization. (This is a gross simplification of what is usually meant by quantization.)

The result of quantizing a (parameterized chiral) string is sometimes a vertex algebra V [1]. Vertex algebras (with some minor extra structure, such as a grading or a bilinear form or an action of the Virasoro algebra) are also called vertex operator algebras [8], meromorphic conformal field theories, W-algebras, and chiral algebras.

To construct the space of states of an unparameterized string, we would like to take the subspace of the vertex algebra V fixed by the diffeomorphism group of the circle $\mathbf{S}^1$, which is $H^0(Diff(\mathbf{S}^1), V)$. This does not work because $Diff(\mathbf{S}^1)$ does not quite act on V; instead we only get a projective action of it on V, so the space of fixed vectors is 0. We can get around this problem by defining the space of physical states of an unparameterized string to be the semi-infinite cohomology group $H^{\infty+1/2}(Vir, V)$ [9]. Here Vir is the Virasoro algebra, spanned by elements L_n, $n \in Z$, and c with the relations

$$\begin{aligned}[L_m, L_n] &= (m-n)L_{m+n} + \delta_m^{-n}(m^3 - m)c/12\\ [L_m, c] &= 0\end{aligned}$$

and is a central extension of the Lie algebra of polynomial vector fields on the circle.

This cohomology group $H^{\infty+1/2}(Vir, V)$ is the generalized Kac-Moody algebra we were trying to construct. It turns out to be nonzero only if spacetime is 26-dimensional; the mysterious number 26 appears because it is minus the value of c when Vir acts on the space of semi-infinite forms over Vir.

3. The monster Lie algebra.

We can apply the denominator formula $H^*(E) = \Lambda^*(E)$ of section 1 to some of the generalized Kac-Moody algebras constructed using string theory in section 2. For one of these algebras, called the monster Lie algebra, this leads to a proof of Conway and Norton's moonshine conjectures for the monster simple group.

The monster Lie algebra [4] is the simplest example of a Lie algebra of physical states of a chiral string on some orbifold. In this case the orbifold is a quotient of the 26-dimensional torus $\mathbf{R}^{25,1}/II_{25,1}$ by an involution, where $II_{25,1}$ is the unique 26-dimensional even unimodular Lorentzian lattice. This algebra can be described in terms of the graded representation $V = \oplus V_n$ of the monster constructed by Frenkel, Lepowsky and Meurman [8], with the property that $\dim(V_n) = c(n-1)$, the coefficient of q^n in the elliptic modular function $j(q) - 744 = \sum c(n)q^n = q^{-1} + 196884q + \ldots$. It follows from the Goddard-Thorn no-ghost theorem [11] that the monster Lie algebra is a $\mathbf{Z}^2$-graded Lie algebra $\oplus_{m,n\in\mathbf{Z}}M_{m,n}$, whose piece $M_{m,n}$ of degree $(m,n)\in\mathbf{Z}^2$ is isomorphic as a module over the monster to V_{mn} if $(m,n)\neq(0,0)$ and to $\mathbf{R}^2$ if $(m,n)=(0,0)$. For small degrees it looks like

$$\begin{array}{ccccccccc}
 & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \\
\cdots & 0 & 0 & 0 & 0 & V_3 & V_6 & V_9 & \cdots \\
\cdots & 0 & 0 & 0 & 0 & V_2 & V_4 & V_6 & \cdots \\
\cdots & 0 & 0 & V_{-1} & 0 & V_1 & V_2 & V_3 & \cdots \\
\cdots & 0 & 0 & 0 & \mathbf{R}^2 & 0 & 0 & 0 & \cdots. \\
\cdots & V_3 & V_2 & V_1 & 0 & V_{-1} & 0 & 0 & \cdots \\
\cdots & V_6 & V_4 & V_2 & 0 & 0 & 0 & 0 & \cdots \\
\cdots & V_9 & V_6 & V_3 & 0 & 0 & 0 & 0 & \cdots \\
 & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots &
\end{array}$$

In the decomposition of this algebra as $E\oplus H\oplus F$, the Cartan subalgebra H is the 2-dimensional algebra of degree 0, E is the sum of everything lying to the right of H (in the diagram above), and F is the sum of everything to the left of H. The real roots correspond to the two 1-dimensional spaces V_{-1}, and the simple roots are the ones in the column to the right of H.

To work out the denominator formula $H^*(E)=\Lambda^*(E)$ for E explicitly, we need to know how the Laplace operator Ω acts on $\Lambda^n(E)$. This is easy to describe: it just multiplies any element of degree $(m,n)\in\mathbf{Z}^2$ by $(m-1)n$, so that $H^n(E)$ is just the subspace of elements of $\Lambda^n(E)$ of degree $(1,n)$ or $(m,0)$. This implies that $H^0(E)=\mathbf{R}$, $H^1(E)=\sum_n V_n pq^n$, $H^2(E)=\sum_{m>0}V_m p^{m+1}$, and $H^n=0$ for $n>2$, where we use powers of p and q to keep track of the $\mathbf{Z}^2$ grading.

If we substitute these values into the formula $H^*(E)=\Lambda^*(E)$ and take dimensions of both sides, we obtain the product formula for the j function

$$p^{-1}\prod_{m>0,n\in\mathbf{Z}}(1-p^m q^n)^{c(mn)}=j(p)-j(q)$$

which is the denominator formula of the monster Lie algebra, in the same way that the Macdonald identities are the denominator formulas of the affine Lie algebras.

The monster group acts on the monster Lie algebra by diagram automorphisms. (It is not the full group of diagram automorphisms; its has the special property that $M_{a,b}=M_{c,d}$ as representations of the monster whenever $ab=cd$, $(a,b)\neq(0,0)\neq(c,d)$.) By taking traces of various elements of the monster on the formula $H^*(E)=\Lambda^*(E)$ we obtain the following product formulas involving the coefficients of the Thompson series $T_g(q)=\sum_{n\in\mathbf{Z}}Tr(g|V_n)q^n$:

$$\begin{aligned}&\sum_{m\in\mathbf{Z}}Tr(g|V_m)p^m-\sum_{n\in\mathbf{Z}}Tr(g|V_n)q^n\\ =&p^{-1}\exp(-\sum_{i>0}\sum_{m>0,n\in\mathbf{Z}}Tr(g^i|V_{mn})p^{mi}q^{ni}/i).\end{aligned}$$

For $g=1$ this is just the product formula for the elliptic modular function. These formulas can be rewritten as recursion formulas for the coefficients $Tr(g|V_n)$, and the same recursion formulas for certain modular functions were conjectured by Norton [16] and proved by Koike [13]. This can be used [4] to prove Conway and Norton's moonshine conjectures [5] that the Thompson series $T_g(q)$ are all modular functions (more precisely, normalized Hauptmoduls of genus 0 groups). Norton's generalizations of these conjectures in [17] are still not proved.

4. Modular forms on $O_{n+2,2}(\mathbf{R})$.

The denominator formulas of the examples of many generalized Kac-Moody algebras are modular forms on $O_{n+2,2}(\mathbf{R})$, which is the group of rotations of $\mathbf{R}^{n+2,2}$, and is also the group of conformal transformations of the conformal completion of $\mathbf{R}^{n+1,1}$.

For $n=-1$, $O_{n+2,2}(\mathbf{R})$ is locally isomorphic to $SL_2(\mathbf{R})$ so modular forms on this group are essentially the same as ordinary modular forms. One example is the theta function $\sum q^{n^2}$, which can be written as an infinite product by Gauss's identity.

For $n=0$, $O_{n+2,2}(\mathbf{R})$ is locally isomorphic to $SL_2(\mathbf{R})\times SL_2(\mathbf{R})$. Modular forms on this group are usually Hilbert modular forms, but the examples we give are not, because the discrete subgroup we use is of the form $\Gamma_1\times\Gamma_2$, where each Γ_1 is a subgroup of $SL_2(\mathbf{R})$. (Informally, we could think of them as "degenerate Hilbert modular forms" for the "degenerate real quadratic number field" $Q(\sqrt{1})$.) An example of one of these modular functions is $j(p)-j(q)$, which can be written as an infinite product using the denominator formula of the monster Lie algebra.

For $n=1$, $O_{n+2,2}(\mathbf{R})$ is locally isomorphic to $Sp_4(\mathbf{R})$, so modular forms on this group are essentially Siegel modular forms of genus (or degree) 2. An example of such a form is the Siegel theta function $\sum_{i,j\in\mathbf{Z}} p^{i^2}q^{j^2}r^{ij}$. We will show how to write this as an infinite product in the next section.

I know of modular forms on $O_{n,2}(\mathbf{R})$ which can be written as interesting infinite products for $n=1$, 2, 3, 4, 6, 8, 10, 14, 18, and 26. It is curious that these seem to be exactly the integers for which there is a lacunary modular form of weight $n/2$ which is a product of eta functions (for example $\eta(q)^{26}$); see Serre [18] and Dyson [6]. (The number $n=18$ does not appear in Serre's paper, but the form $\eta(q)^9\eta(q^2)^9$ of weight 18/2 seems to be lacunary.)

5. A superalgebra of rank 3.

I will give a fairly typical example of one of the generalized Kac-Moody superalgebras of higher rank that are (sometimes only conjecturally) the spaces of physical states of some sort of string on some sort of orbifold. Gauss's product identity for the theta function can be written as

$$\sum_{n\in\mathbf{Z}}(-1)^n q^{n^2}=\prod_{n>0}\frac{1-q^n}{1+q^n}.$$

I write it like this to bring out the analogy with the product formula for Siegel's theta function of degree 2, which is

$$\sum_{m,n\in\mathbf{Z}}(-1)^{m+n}p^{m^2}q^{n^2}r^{mn}=\prod_{a+b+c>0}\left(\frac{1-p^aq^cr^b}{1+p^aq^cr^b}\right)^{f(ac-b^2)}$$

where $f(n)$ is defined by $\sum f(n)q^n=1/(\sum_n(-1)^nq^n)=1+2q+4q^2+8q^3+14q^4+\dots$. (The product does not converge for all values of p, q, and r for which the sum is defined.) This is the denominator formula for a generalized Kac-Moody superalgebra of rank 3. This superalgebra is graded by $\mathbf{Z}^3$, and the subspace of degree (a,b,c) had dimension 3 if $(a,b,c)=(0,0,0)$, and $f(ac-b^2)|f(ac-b^2)$ otherwise. (The symbol $m|n$ for the dimension of a superspace means that it is the sum of an ordinary part of dimension m and a super part of dimension n.) This product formula can be proved using the theory of Jacobi forms [7].

The product is a product over all positive semidefinite binary quadratic forms $ax^2+2bxy+cy^2$, and the identity above is equivalent to the following curious fact about such forms. Let $\mathbf{Z}^n$ be a lattice spanned by n pairwise orthogonal vectors of norm 1, and let $r_{a,b,c}(n)$ be the number of representations of the quadratic form $ax^2+2bxy+cy^2$ in the lattice $\mathbf{Z}^n$ which are not contained in any sublattice of the form $\mathbf{Z}^{n-1}$. Then $\sum_{n>0}(-1)^n r_{a,b,c}(n)/n$ depends only on the discriminant and the highest common factor of the coefficients of the form $ax^2+2bxy+cy^2$. This result is unusual because it is usually only possible to say something about the average number of representations of forms of fixed discriminant.

The Mellin transform of Siegel's theta function of degree 2 is essentially a real analytic Eisenstein series (see Zagier [18] for example). Unfortunately it seems to be very difficult to use the product formula for Siegel's theta function to say anything about real analytic Eisenstein series. For that matter, it seems to be just as difficult to use Gauss's product formula for the theta function to say anything about its Mellin transform, the Riemann zeta function.

6. A Lie algebra of rank 26.

I will finish by describing the largest interesting generalized Kac-Moody algebra that I know of [3]. It is the space of physical states of a string moving on a 26-dimensional torus, and is very closely related to the monster Lie algebra, which is the space of states of a string moving on a $\mathbf{Z}_2$ orbifold of the same torus.

The denominator formula for this Lie algebra is

$$e^\rho \prod_{r\in\Pi^+}(1-e^r)^{p_{24}(1-r^2/2)} = \sum_{w\in W}\det(w)w(e^\rho\prod_{n>0}(1-e^{n\rho})^{24}).$$

Here both sides are elements of a completion of the group ring of $II_{1,1}$. The vector ρ is the Weyl vector of this lattice which has inner product -1 with all simple roots of the Weyl group W, and $p_{24}(n)$ is the number of partitions of n into parts of 24 colours.

The Lie algebra itself is graded by $II_{1,1}$, and the piece of degree $r \in II_{1,1}$ has dimension 26 if $r = 0$, and $p_{24}(1-r^2/2)$ otherwise. The algebra is acted on by a group $\Lambda.Aut(\Lambda)$ where Λ is the Leech lattice and $Aut(\Lambda)$ is the double cover of Conway's largest simple group. We can write down a twisted denominator identity similar to the one above for every conjugacy class of this group, by taking traces in the formula $H^*(E) = \Lambda^*(E)$.

The function

$$f(v) = \sum_{w\in W}\det(w)e^{(2\pi i w(\rho),v)}\prod_{n>0}(1-e^{(2\pi i n w(\rho),v)})^{24}.$$

is an automorphic form of the group $O_{26,2}(\mathbf{R})$ with respect to the discrete subgroup $II_{26,2}$. This follows from the functional equation

$$f(2v/(v,v)) = -((v,v)/2)^{12}f(v).$$

I will give a brief sketch of the proof of this functional equation. If we just consider purely imaginary values of v, then f is a solution of the wave equation, and this implies that $((v,v)/2)^{26/2-1}f(2v/(v,v))$ is also a solution by the transformation of the wave operator under the conformal transformation $v \to 2v/(v,v)$. On the other hand, it is easy to show that $f(v)$ vanishes whenever v is imaginary and has norm 2, because the series for $\log(f(v))$ has positive terms and therefore has a singularity on the edge of its region of convergence; this singularity is at all points of the surface C, so f must vanish there because it it regular and $\log(f)$ is not. The fact that f vanishes on this surface easily implies that $f(v)$ and $-((v,v)/2)^{12}f(2v/(v,v))$ both have the same partial derivatives of order at most 1 on this surface. These two functions both satisfy the wave equation and have the same partial derivatives of order at most 1 on a non-characteristic surface, so by the Cauchy-Kovalevsky theorem they must be equal.

The function $f(v)$ also satisfies the trivial functional equations $f(v) = f(v+\lambda)$ for $\lambda \in II_{25,1}$, and $f(w(v)) = \det(w)f(v)$ for w an automorphism of $II_{25,1}$ of spinor norm 1. Together these transformations generate a group isomorphic to the subgroup of index 2 of $Aut(II_{26,2})$ of elements of spinor norm 1. This means that f is essentially a modular form on the group $O_{26,2}(\mathbf{R})$ with respect to the discrete subgroup $Aut(II_{26,2})$. There are many other examples of Lie algebras or superalgebras (for example, two superalgebras of superstrings on a 10 dimensional torus) whose denominator functions are modular forms on $O_{n+2,2}(\mathbf{R})$ for some n. I do not know whether there are an infinite number of such examples.

"Introduction to Stringy Moonshine "

June, 2018

Tohru Eguchi, University of Tokyo

Monstrous Moonshine

Several years ago we found some curious phenomenon in string theory [1], i.e. appearance of exotic discrete symmetries in the theory. This is now called as moonshine phenomenon and is now under intensive study. Today I would like to give you a brief introduction to moonshine phenomena which may possibly play an interesting role in string theory in the future.

Before going to the moonshine phenomenon in string theory let me briefly recall the story of monstrous moonshine which is well-known. Modular J function has a q-series expansion

$$J(q) = \frac{1}{q} + 744 + 196884q + 21493760q^2 + 864299970q^3 \\ +20245856256q^4 + 333202640600q^5 + \cdots .$$

$$q = e^{2\pi i\tau},\ \ Im(\tau) > 0,\ \ J(\tau) = J(\frac{a\tau + b}{c\tau + d}),\ \ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in SL(2, Z)$$

It turns out q-expansion coefficients of J-function are decomposed into a sum of dimensions of irreducible representations of the monster group M as

$$196884 = 1 + 196883,\ \ 21493760 = 1 + 196883 + 21296876,$$
$$864299970 = 2 \times 1 + 2 \times 196883 + 21296876 + 842609326,$$
$$20245856256 = 1 \times 1 + 3 \times 196883 + 2 \times 21296876 \\ +842609326 + 19360062527, \cdots .$$

Dimensions of irreducible representations of monster are in fact given by

$$\{1,\ 196883,\ 21296876,\ 842609326,\\ 18538750076,\ 19360062527\cdots\}$$

Monster group is the largest sporadic discrete group, of order $\approx\ 10^{53}$ and the strange relationship between modular form and the largest discrete group was first noted by McKay.

To be precise we may write as

$$J_1(\tau) = J(q) - 744 = \sum_{n=-1} c(n)q^n, \qquad c(0) = 0$$

$$= \sum_{n=-1} Tr_{V(n)}\, 1 \times q^n, \qquad dim V(n) = c(n)$$

McKay-Thompson series is given by

$$J_g(\tau) = \sum_{n=-1} Tr_{V(n)}\, g \times q^n, \quad g \in M$$

where $Tr_{V(n)}\, g$ denotes the character of a group element g in the representation $V(n)$. This depends on the conjugacy class g of M. If McKay-Thompson series is known for all conjugacy classes, decomposition of $V(n)$ into irreducible representations become uniquely determined. Series J_g are modular forms with respect to subgroups of $SL(2, Z)$ and possess similar properties like the modular J-function such as the genus=0 (Hauptmodul) property.

Phenomenon of monstrous moonshine has been understood mathematically in early 1990's using the technology of vertex operator algebra. However, we still do not have a 'simple' physical explanation of this phenomenon.

Elliptic genus

We now consider string theory compactified on K_3 surface. K_3 surface is a complex 2-dimensional hyperKähler manifold and is ubiquitous in string theory. It possesses $SU(2)$ holonomy and a holomorphic 2-form. Thus the string theory on K_3 has an N=4 superconformal symmetry and contains the level $k = 1$ affine $SU(2)$ symmetry and the central charge $c = 6$.

Now instead of modular J-function we consider the elliptic genus of K_3 surface. Elliptic genus describes the topological invariants of the target manifold and counts the number of BPS states in the theory. Using worldsheet variables it is written as

$$Z_{elliptic}(z;\tau) = Tr_{\mathcal{H}_L\times\mathcal{H}_R}(-1)^{F_L+F_R}e^{4\pi izJ^3_{L,0}}q^{L_0-\frac{c}{24}}\bar{q}^{\bar{L}_0-\frac{c}{24}}$$

Here L_0 denotes the zero mode of the Visasoro operators and F_L and F_R are left and right moving fermion numbers. In ellitpic genus the right moving sector is frozen to the supersymmetric ground states (BPS states) while in the left moving sector all the states in the Hilbert space $\mathcal{H}_L$ contribute.

N=4, level k theory contains a SUSY algebra

$$\{\bar{G}^i_0, \bar{G}^{*\,j}_0\} = 2\delta^{ij}\bar{L}_0 - \frac{k}{2}\delta^{ij},\ (i,j=1,2) \Longrightarrow \bar{L}_0 \geq \frac{k}{4}$$

$$\text{BPS states possess} \qquad L_0 = \frac{k}{4}$$

In general it is difficult to compute elliptic genus, however, we were able to evaluate it by making use of Gepner models. Elliptic genus of K3 surface is given by [2]:

$$Z_{K3}(z;\tau) = 8\left[\left(\frac{\theta_2(z;\tau)}{\theta_2(0;\tau)}\right)^2 + \left(\frac{\theta_3(z;\tau)}{\theta_3(0;\tau)}\right)^2 + \left(\frac{\theta_4(z;\tau)}{\theta_4(0;\tau)}\right)^2\right]$$

Here $\theta_i(\tau, z)$ are Jacobi theta functions.

$$Z_{K3}(z=0) = 24, \qquad Z_{K3}(z=\frac{1}{2}) = 16 + O(q),$$
$$Z_{K3}(z=\frac{1+\tau}{2}) = 2q^{-\frac{1}{2}} + O(q^{\frac{1}{2}})$$

It is known that the elliptic genus of a complex D-dimensional manifold is a Jacobi form of weight=0 and index=D/2. When D=2, space of Jacobi form is one-dimensional and given by the above formula.

Jacobi form (weight k and index m) is defined by

$$\varphi(\tau, z + a\tau + b) = e^{-2\pi i m(a^2\tau + 2az)}\varphi(\tau, z),$$
$$\varphi(\frac{a\tau+b}{c\tau+d}, \frac{z}{c\tau+d}) = (c\tau+d)^k e^{\frac{2\pi i m c z^2}{c\tau+d}}\varphi(\tau, z)$$

We would like to study the decomposition of the elliptic genus in terms of irreducible representations of N=4 SCA. In N=4 SCA, hightest-weight states $|h, \ell\rangle$ are parametrized by

$$L_0|h,\ell\rangle = h|h,\ell\rangle, \qquad J_0^3|h,\ell\rangle = \ell|h,\ell\rangle$$

and the theory possesses two different type of representations, i.e. BPS and non-BPS representations. In the case of $k = 1$ there are representations (in Ramond sector)

$$\text{BPS rep.} \qquad h = \frac{1}{4}; \qquad \ell = 0, \ \frac{1}{2}$$

$$\text{non-BPS rep.} \qquad h > \frac{1}{4}; \qquad \ell = \frac{1}{2}$$

Character of a representation is given by

$$Tr_{\mathcal{R}}(-1)^F q^{L_0} e^{4\pi i z J_0^3}$$

Its index is given by the value at $z = 0$, $Tr_{\mathcal{R}}(-1)^F q^{L_0}$. BPS representations have a non-vanishing index

$$\text{index (BPS, } \ell = 0) = 1$$

$$\text{index (BPS, } \ell = \frac{1}{2}) = -2$$

Character function of $\ell = 0$ BPS representation has the form [3]

$$ch^{\tilde{R}}_{h=\frac{1}{4},\ell=0}(z;\tau) = \frac{\theta_1(z;\tau)^2}{\eta(\tau)^3}\mu(z;\tau)$$

where

$$\mu(z;\tau) = \frac{-ie^{\pi i z}}{\theta_1(z;\tau)}\sum_n (-1)^n \frac{q^{\frac{1}{2}n(n+1)}e^{2\pi i n z}}{1 - q^n e^{2\pi i z}}$$

On the other hand the character of non-BPS representations are given by

$$ch^{\tilde{R}}_{h>\frac{1}{4},\ell=\frac{1}{2}} = q^{h-\frac{3}{8}}\ \frac{\theta_1(z;\tau)^2}{\eta(\tau)^3}$$

These have vanishing indices

$$\text{index (non-BPS rep)} = 0$$

At the unitarity bound non-BPS representation splits into a sum of two BPS representations

$$\lim_{h\to\frac{1}{4}} q^{h-\frac{3}{8}}\ \frac{\theta_1^2}{\eta^3} = ch^{\tilde{R}}_{h=\frac{1}{4},\ell=\frac{1}{2}} + 2ch^{\tilde{R}}_{h=\frac{1}{4},\ell=0}$$

Function $\mu(z;\tau)$ is a typical example of the so-called Mock theta functions (Lerch sum or Appell function). Mock theta functions look like theta functions but they have anomalous modular transformation laws and are difficult to handle. Recently there were developments in understanding the nature of Mock theta functions due to Zwegers [4]. He has introduced a method of regularization which is similar to those used in physics and improved the modular property of mock theta functions so that they transform as analytic Jacobi forms.

It is possible to derive the following idenities

$$\begin{aligned} ch^{\tilde{R}}_{h=\frac{1}{4},\ell=0}(z;\tau) &= \left(\frac{\theta_2(z;\tau)}{\theta_2(0;\tau)}\right)^2 + \mu_2(\tau)\frac{\theta_1(z;\tau)^2}{\eta(\tau)^3} \\ &= \left(\frac{\theta_3(z;\tau)}{\theta_3(0;\tau)}\right)^2 + \mu_3(\tau)\frac{\theta_1(z;\tau)^2}{\eta(\tau)^3} \\ &= \left(\frac{\theta_4(z;\tau)}{\theta_4(0;\tau)}\right)^2 + \mu_4(\tau)\frac{\theta_1(z;\tau)^2}{\eta(\tau)^3} \end{aligned}$$

where

$$\mu_2(\tau)=\mu(z=\frac{1}{2};\tau),\ \mu_3(\tau)=\mu(z=\frac{1+\tau}{2};\tau),\ \mu_4(\tau)=\mu(z=\frac{\tau}{2};\tau)$$

$$\mu(z;\tau) = \frac{-ie^{\pi iz}}{\theta_1(z;\tau)}\sum_n (-1)^n \frac{q^{\frac{1}{2}n(n+1)}e^{2\pi inz}}{1-q^n e^{2\pi iz}}$$

Then we can rewrite the ellitpic genus as

$$Z_{K3}=24ch^{\tilde{R}}_{h=\frac{1}{4},\ell=0}(z;\tau)-8\sum_{i=2}^{4}\mu_i(\tau)\frac{\theta_1(z;\tau)^2}{\eta(\tau)^3}$$

Using q-expansion of functions μ_i we find

$$8\left(\mu_2(\tau)+\mu_3(\tau)+\mu_4(\tau)\right)=-2\sum_{n=0}A(n)q^{n-\frac{1}{8}}$$

$$Z_{K3}=24ch^{\tilde{R}}_{h=\frac{1}{4},\ell=0}(z,\tau)+2\sum_{n\geq 0}A(n)ch^{\tilde{R}}_{h=\frac{1}{4}+n,\ell=\frac{1}{2}}(z,\tau)$$

At smaller values of n, Fourier coefficients $A(n)$ may be obtained by direct inspection. We find, $A(0)=-1$

n	1	2	3	4	5	6	7	8	$\cdots$
$A(n)$	45	231	770	2277	5796	13915	30843	65550	$\ldots$

Surprize: the dimensions of irreducible reps. of Mathieu group M_{24} appear

$$\text{dimensions}:\{\ 45\quad 231\quad 770\quad 990\quad 1771\quad 2024\quad 2277\quad 3312\quad 3520\quad 5313\quad 5544\quad 5796\quad 10395\quad \cdots\}$$

$$A(6)=13915=3520+10395,$$
$$A(7)=30843=10395+5796+5544+5313+2024+1771$$

Mathieu moonshine [1]

M_{24} is a subgroup of S_{24} (permutation group of 24 objects) and its order is given by $\approx 10^9$. M_{24} is known for its many interesting arithmetic properties and in particular intimately tied to Golay code of error corrections.

Mathieu group appeared before in the work of Mukai on K_3 surface.

Mukai[5] considered K3 surfaces with finite automorphism group. Then these groups are sugbgroups of M_{23}.

♣ Twisted Elliptic Genus

Dimension of a representation equals the trace of the identity representation: we may identify as

$$A(n) = Tr_{V_n}\ 1$$
$$V_1 = 45 + 45^*,\ V_2 = 231 + 231^*,\ V_3 = 770 + 770^*, \cdots$$

We may consider the trace of other group elements in M_{24}

$$A_g(n) = Tr_{V_n}\ g, \qquad\qquad g \in M_{24}$$

$Tr\ g$ depends only on the conjugacy class of g. There exists 26 conjugacy classes $\{g\}$ in M_{24} and also 26 irreducible representations $\{R\}$. We have the character table given by

$$\chi_R{}^g = Tr_R\ g$$

Character table of the Mathieu group M_{24} Here we have used $e_p^{\pm} = \frac{1}{2}\left(\pm\sqrt{-p} - 1\right)$.

(Some conjugacy classes are suppressed due to lack of space).

There are two types of conjugacy classes in M_{24}, type I and type II.
Conjugacy class of type I fixes at least one element out of 24 and thus they arise from the conjugacy classes of M_{23}.
On the other hand conjugacy class of type II does not have a fixed point and is intrinsically M_{24}.
For each conjugacy class we want to construct a twisted genus (analogue of McKay-Thompson series in monstrous moonshine)

$$A_g = \sum_{n=1}^{\infty} Tr_{V_n}\; g \times q^n$$

For instance,

$$A_{2A} = -6q + 14q^2 - 28q^3 + 42q^4 - 56q^5 + 86q^6 + \cdots$$

and has the right modular property ($Z_{2A} \in \Gamma_0(2)$).

Twisted genus is decomposed into massless and massive parts

$$Z_g(\tau,z)=\chi_g\, ch^{\tilde{R}}_{h=\frac{1}{4},\ell=0}+\sum_{n\geq 0}A_g(n)ch^{\tilde{R}}_{\frac{1}{4}+n,\ell=\frac{1}{2}}(z,\tau)$$

Here χ_g is the Euler number assigned to the class g

g	1A	2A	3A	5A	4B	7A	8A	6A	11A	15A	14A	23A	others
χ_g	24	8	6	4	4	3	2	2	2	1	1	1	0

χ_g vanishes for type II classes. We note that χ_g can be written as $\chi_g=\chi_1^g+\chi_{23}^g$ which is equal to the number of fixed points of the permutation rep. of g.

conjugacy class	cycle shape
1A	1^{24}
2A	$1^8\cdot 2^8$
3A	$1^6\cdot 3^6$
5A	$1^4\cdot 5^4$
4B	$1^4\cdot 2^2\cdot 4^4$
7A	$1^3\cdot 7^3$
7B	$1^3\cdot 7^3$
8A	$1^2\cdot 2^1\cdot 4^1\cdot 8^2$
6A	$1^2\cdot 2^2\cdot 3^2\cdot 6^2$
11A	$1^2\cdot 11^2$
15A	$1^1\cdot 3^1\cdot 5^1\cdot 15^1$
15B	$1^1\cdot 3^1\cdot 5^1\cdot 15^1$
14A	$1^1\cdot 2^1\cdot 7^1\cdot 14^1$
14B	$1^1\cdot 2^1\cdot 7^1\cdot 14^1$
23A	$1^1\cdot 23^1$
23B	$1^1\cdot 23^1$
12B	12^2
6B	6^4
4C	4^6
3B	3^8
2B	2^{12}
10A	$2^2\cdot 10^2$
21A	$3^1\cdot 21^1$
21B	$3^1\cdot 21^1$
4A	$2^4\cdot 4^4$
12A	$2^1\cdot 4^1\cdot 6^1\cdot 12^1$

Twisted genera for all conjugacy classes of M_{24} have been obtained by our efforts [6, 7]. They reproduce correct lower-order expansion coefficients and are invariant under the Hecke subgroup $\Gamma_0(N)$

$$\Gamma_0(N) = \{\begin{pmatrix} a & b \\ c & d \end{pmatrix}, \ ad - bc = 1, \ c \equiv 0, \ mod\, N\}$$

N denotes the order of the element g.

From the study of K3 surface with $Z_p(p = 2, 3, \cdots)$ symmetry, for instance, twisted genera of classes $pA(p = 2, 3, \cdots)$ are known [8, 9]

$$Z_{pA}(z;\tau) = \frac{2}{p+1}\phi_{0,1}(z;\tau) + \frac{2p}{p+1}\phi_2^{(p)}(\tau)\phi_{-2,1}(z;\tau)$$

where

$$\phi_{0,1}(z;\tau) = \frac{1}{2}Z_{K3}(z;\tau), \qquad \phi_{-2,1}(z;\tau) = -\frac{\theta_1(z;\tau)^2}{\eta(\tau)^6}$$

are the basis of Jacobi forms with index=1 and

$$\begin{aligned}\phi_2^{(p)}(\tau) &= \frac{24}{p-1}q\partial_q \log\left(\frac{\eta(p\tau)}{\eta(\tau)}\right), \\ &= \frac{24}{p-1}\sum_{k=1}\sigma_1(k)(q^k - pq^{pk})\end{aligned}$$

is an element of $\Gamma_0(p)$.

In the case of type II twisted genera are modular forms of $\Gamma_0(N)$ (with a multiplier system) . They are given in terms of quotients of eta functions.

♣ Proof of Mathieu moonshine

Orthogonality relation of characters:

$$\sum_g n_g\, \chi_{R'}^g\, \bar{\chi}_R^g = |G|\delta_{RR'}$$

n_g is the number of elements in the conjugacy class g and $|G|$ denotes the order of the group. Let $c_R(n)$ be he multiplicity of representation R in the decompostion of K3 elliptic genus at level n. We then have

$$\sum_R c_R(n)\chi_R^g = A_g(n)$$

Then using the orthogonality relation we find

$$\sum_g \frac{1}{|G|} n_g \bar{\chi}_R^g A_g(n) = c_R(n)$$

We have checked that the multiplicities $c_R(n)$ are all positive integers upto $n = 1000$ and this gives a very strong evidence for Mathieu moonshine conjecture.

Recently Gannon has proved by mathematical induction that the multiplicities are all positive integers.

Unfortunately the proof so far did not provide much insight into the nature of Mathieu moonshine. The situation is a bit like the case of Monstrous moonshine. 24 of M_{24} will certainly be the Euler number of K_3 and M_{24} permutes homology classes. There are, however, various indications that string theory on K_3 can not have such a high symmetry as M_{24}. Instead of the total Hilbert space the BRS subsector of the theory may possibly possess an enhanced symmetry. It will be interesting to look into the algebraic structures of BPS states to explain Mathieu moonshine.

More Moonshine Phenomena

Recently there have been intense interests in exploring new types of moonshine phenomena other than Mathieu moonshine. Already several types of new moonshine phenomena have been discovered.

- Umbral moonshine [11, 12]
- free fermions on 24 dim. lattice
- moonshine of Spin(7) manifolds
-

. . .

Umbral moonshine was first discovered by generalizing the Mathieu moonshine for the case of Jacobi forms with higher index such as

$$Z(k=2)=a\left[\left(\frac{\theta_2(z)\theta_3(z)}{\theta_2(0)\theta_3(0)}\right)^2+\left(\frac{\theta_2(z)\theta_4(z)}{\theta_2(0)\theta_4(0)}\right)^2+\left(\frac{\theta_3(z)\theta_4(z)}{\theta_3(0)\theta_4(0)}\right)^2\right]$$
$$+b\left[\left(\frac{\theta_2(z)}{\theta_2(0)}\right)^4+\left(\frac{\theta_3(z)}{\theta_3(0)}\right)^4+\left(\frac{\theta_4(z)}{\theta_4(0)}\right)^4\right]$$

When we take a special value $a=4, b=0$, for instance, one finds a moonshine phenomenon with the symmetry group M_{12} acting on this theory.

There is a mysterious relation between Umbral moonshine and Niemeier lattice (self-dual lattices in 24 dimensions). Niemeier lattice is given by a combination of A-D-E type root lattice with appropriate weight vectors so that the lattice becomes self-dual. If one divides the automorphisim group of Niemeier lattice by the automorphism group of A-D-E lattice one obtains discrete groups

$$G_1 = M_{24},\ G_2 = M_{12},\ G_3 = 2.2^3 L_3(2),\ G_4 = 2.S_6,\ G_6 = 2.A_4$$

which agrees exactly with the symmetry groups of Umbral moonshine. At the moment there is no explanation of this coincidence.

Moonshine symmetries recently discovered in string theory are still very mysterious and we may encounter many more surprises in the near future.

Abstract

In a remarkable variety of contexts appears the modular data associated to finite groups. And yet, compared to the well-understood affine algebra modular data, the general properties of this finite group modular data has been poorly explored. In this paper we undergo such a study. We identify some senses in which the finite group data is similar to, and different from, the affine data. We also consider the data arising from a cohomological twist, and write down, explicitly in terms of quantities associated directly with the finite group, the modular S and T matrices for a *general* twist, for what appears to be the first time in print.

1 Mathematical and Physical Origin

Throughout this paper, let G denote any finite group (good references to finite group and character theory are provided by [1, 2, 3]).

Physically, the modular data we will describe in the next section arise in several ways. It is a (2+1)-dimensional Chern-Simons theory with finite gauge group G [4, 5]. As Witten showed, 3-dimensional topological field theory corresponds to 2-dimensional conformal field theory (CFT), and the corresponding CFTs here are orbifolds by symmetry group G of a holomorphic CFT [6, 4, 7, 8] (e.g. the E_8 level 1 WZW orbifolded by any finite subgroup of the compact simply-connected Lie group $E_8(\mathbb{R})$). This CFT incarnation is important to us, as it provides some motivation for specific investigations we will perform. Nevertheless, both of these incarnations are probably of direct value only as toy models.

Note that more generally, to each G we will obtain a finite-dimensional representation of the mapping class group $\Gamma_{g,n}$ for the genus g surfaces with n punctures [9]. In this paper though we will consider only the modular group $\mathrm{SL}_2(\mathbb{Z})$, corresponding to $\Gamma_{1,0}$, and in particular the matrices S and T.

It is clear that many different CFTs can realise the same modular data – e.g. all 71 of the $c = 24$ holomorphic theories have $S = T = (1)$. So any given G will correspond to several different CFTs. Likewise, all we can say about the central charge c associated to G is that it will be a positive multiple of 8.

Associated with the RCFT we expect to have some sort of quantum-group which captures the modular data and representation theory of the chiral algebra (so e.g. the fusion coefficients are tensor product coefficients of irreducible modules). This was done for arbitrary finite G in [7], and is the quantum-double of the group algebra $\mathbb{C}[G]$ (see also [10, 11, 12]).

There should also be a vertex operator algebra (VOA) interpretation to this data, assigning a VOA to each finite group. One way to do this is to start with the VOA associated with any even self-dual Euclidean lattice Λ for which $G \leq \mathrm{Aut}\,\Lambda$. Orbifolding it by G should yield our data (with the value $c = \dim \Lambda$). For example, any finite subgroup of $\mathrm{SU}_2(\mathbb{C})$ or $\mathrm{SU}_3(\mathbb{C})$ works with the $\Lambda = E_8$ root lattice. By Cayley's Theorem, such a lattice Λ can always be found for a given group G: e.g. embed G in some $\mathfrak{S}_n$ and take Λ to be the orthogonal direct sum of n copies of E_8. In [13, 10], this VOA interpretation is addressed.

Although these holomorphic orbifolds are perhaps too artificial to be of direct interest, it can be expected that they provide a good hint of the behaviour of more general orbifolds. Indeed this is the case – e.g. they can be seen in the theory of permutation orbifolds [14].

Perhaps the most physical incarnation of this modular data is in (2+1)-dimensional quantum field theories where a continuous gauge group has been spontaneously broken to a finite group [15]. Non-abelian anyons (i.e. particles whose statistics are governed by the braid group rather than the symmetric group) arise as topological excitations. The effective field theory describing the long-distance physics is governed by the quantum-group of [7]. Adding a Chern-Simons term corresponds to the cohomological twist to be discussed shortly.

Actually, this modular data arose originally in mathematics, in an important but technical way in Lusztig's determination of the irreducible characters of the finite groups of Lie type [16, 17]. In describing some of these, the so-called 'unipotent' characters, he was led to consider this modular data for the groups $G \in \{\mathbb{Z}_2 \times \cdots \times \mathbb{Z}_2\, , \mathfrak{S}_3\, , \mathfrak{S}_4\, , \mathfrak{S}_5\, \}$. For example, $\mathfrak{S}_5$ arises in groups of type E_8. Our primary fields Φ parametrise the unipotent characters associated to a given 2-sided cell in the Weyl group. [16] interprets the fusion algebra as the Grothendieck ring for G-equivariant vector bundles. This Lusztig interpretation is significant as it indicates the richness of the purely group theoretic side of the data we explore below.

An intriguing application to quantum computing[‡] has been suggested by Kitaev [18]. One of the main challenges of actually implementing an effective quantum computer is decoherence: interaction with the environment makes quantum superpositions very unstable. The standard approaches to this involve quantum error correction, but Kitaev's proposal is to incorporate into the hardware the non-abelian anyons of [15]. The resulting computer would operate quite robustly amidst localised disturbances.

From many of these approaches, we also expect to have characters $\mathrm{ch}_a(\tau)$ which realise this modular data as in (2.1) and (2.2) below. These appear to be given in [8], at least when G is a subgroup of $E_8(\mathbb{C})$ (see Theorem 4.3 there).

In summary, what we get is a set of modular data (i.e. matrices S and T) for any choice of finite group G. Now, much information about a group can be recovered easily from its character table: e.g. whether it is abelian, simple, solvable, nilpotent, ... (see e.g. Ch.22 of [1]). For instance, G is simple iff for all irreducible $\chi \not\equiv 1$, $\chi(a) = \chi(e)$ only for $a = e$. Thus it can be expected that our modular data, which probably includes the character table, should tell us a lot about the group, i.e. be sensitive to a lot of the group-theoretic properties of G.

It does not appear to be known yet whether the modular data associated to distinct G will always be distinct. A tempting guess would be that this modular data is a function of the group algebra, but that it succeeds in distinguishing groups which have different character tables. An easy result along these lines is: Given any groups G and H with equal matrix S, if G is abelian then $G \cong H$. (The character table of an abelian group also uniquely determines it.) The non-abelian order-8 groups $\mathfrak{D}_4$ and $\mathfrak{Q}_4$ have identical character tables, but their matrices S and T are both different. More generally, we will see below that the matrices S for the groups with at most 50 primary fields are all distinct.

There are two ways to generalise this data. One is by a 'twisting' by some element of a cohomology group [4] (see also [6]). We will look at this twisting in Section 5. This twisting is rather interesting, because completely analogously one can speak of the twisting of modular data associated to Lie groups: the cohomology group there is $\mathbb{Z}$, and 'twisting' by cohomology class $[k]$ gives WZW at level k for that Lie group ! So the untwisted finite group modular data is 'level 0' in this sense. On the other hand, the WZW models at level 0 are trivial. Another difference with WZW is that the cohomology group here is finite, so there are only finitely many different possible 'levels' to this finite group data.

The twisting was incorporated in the quantum-group picture in [7]. How to obtain topological (e.g. oriented knot) invariants from this twisted data was explained in [20]. It turns out that these knot invariants are functions of the "knot group" (i.e. the fundamental group of the complement of the knot). Though non-isotopic knots can have the same knot group, this does not imply that these finite group topological invariants are uninteresting. For instance [21], these invariants can distinguish a knot from its inverse (i.e. the knot with opposite orientation), unlike the more familiar topological invariants coming from affine algebras (or quantum groups $U_q(\mathfrak{g})$).

This twisting is reminiscent, though independent, of *discrete torsion* [19]. The twist changes the modular data, while discrete torsion changes the modular invariant partition function but leaves unchanged the modular data. We use discrete torsion in §4.1.

[‡] We thank Sander Bais for informing us of this.

A second way to generalise this data is suggested by the subfactor interpretation of RCFT. There is a von Neumann subfactor and from this a fusion ring, associated to any group-subgroup pair $G \leq H$ [22]. Our data comes from the diagonal embedding of G in $G \times G$. The fusion ring for generic pairs $G \leq H$ is non-commutative (so e.g. Verlinde's formula will not work), but it is commutative for much more than just $G \leq G \times G$ and so we can expect here a significant generalisation of this finite group data corresponding in some way to physics. To our knowledge, such a physical interpretation has not been developed.

The finite group modular data behaves very differently from the affine modular data. Yet finite group theory is certainly richer than nontwisted affine Lie theory, so its modular data should be explored. It should be interesting both from the group theory and RCFT sides. In particular, it should be interesting to RCFT for the same reasons as the affine data: Affine modular data is regarded as physically interesting primarily because it serves as a toy model, and because of the GKO coset construction; similarly, the finite group modular data is equally a toy model, and is involved in the orbifold construction.

As always, there are unexpected surprises. One of the differences we have found between the finite group data and the affine data is the large number of modular invariants for the former – in contrast the affine modular invariants are surprisingly rare and generally are associated with Dynkin diagram symmetries. There is one family of exceptions to this rule: the orthogonal algebras at level 2 have a rich collection of modular invariants [33]. This was rather mysterious. But what we find is that the only overlap between the affine data and nonabelian finite group data occurs with the orthogonal algebras at level 2 ! This clearly provides a partial resolution of that mystery.

Our main intention with this paper is to make the mathematical physics community more familiar with this modular data, by developing and illustrating some of the basic ideas and constructions. As a large and relatively unexplored class of RCFTs, studying it can correct some of the prejudices we have developed with our rather artificial preoccupation with the affine data. Finally, this material suggests the thought: "There's some kind of analogy relating affine algebras and finite groups" – after all, both are directly associated to topological groups – and we try to work out some of its aspects. See the Table below. Of course there are differences as well as similarities, and identifying these will help us develop a better understanding of generic modular data.

List of Notation

G	a group with finitely many elements
$\mathbb{N}$	the nonnegative integers
ch_a	RCFT characters, see e.g. (2.1), (2.8)
ξ_m	the m-th root of unity $\exp[2\pi\mathrm{i}/m]$
$\mathbb{Z}_n$	the cyclic group (the integers modulo n)
$\mathfrak{S}_n$	the symmetric group of order $n!$
$\mathfrak{A}_n$	the alternating group of order $n!/2$

$\mathfrak{D}_n$	the (binary) dihedral group (3.3) of order $2n$
$\mathfrak{Q}_{2n}$	the (generalised) quaternion group (3.4) of order $4n$
e	the identity element in the group
$\|G\|$	the order (cardinality) of G
K_a	the conjugacy class of a, i.e. $\{gag^{-1} \mid g \in G\}$
R	a set of representatives for each conjugacy class K_a
$\chi, \psi, \ldots$	irreducible characters
$\mathrm{Irr}(G)$	the set of all irreducible characters of G
$G(a,b)$	see below (2.12)
$\deg(\chi)$	dimension of corresponding representation
$C_G(a)$	the centraliser of a in G, i.e. $\{g \in G \mid ga = ag\}$
Φ	set of "primary fields" (a, χ) where $\chi \in \mathrm{Irr}(C_G(a))$
$e(G)$	the exponent of G (smallest n such that $g^n = e$ for all $g \in G$)
$Z(G)$	the centre of G
G'	the commutator subgroup $\langle ghg^{-1}h^{-1} \rangle$
$k(G)$	the class number of G, i.e. the number of conjugacy classes
$H \leq G$	H is a subgroup of G
$H \lhd G$	H is a normal subgroup of G
χ_H^G	the induced character of $\chi \in \mathrm{Irr}(H)$, where $H \leq G$
$M(G)$	the Schur multiplier $H^2(G, U(1))$
β	a $U(1)$-valued 2-cocycle
$r(G, \beta)$	the number of inequivalent projective β-representations of G
β-$\mathrm{Irr}(G)$	the set of all irreducible projective β-characters of G
$\tilde{\chi}, \tilde{\psi}, \ldots$	irreducible projective characters
α	a 3-cocycle in $H^3(G, U(1))$
CT	a 3-cocycle α such that all 2-cocycles β_a are coboundaries (see §5.2)
S^α, T^α	the modular data twisted by a 3-cocycle α
$\mathbb{F}_q$	the finite field with q elements

The affine algebra versus finite group analogy

primary fields in Φ	r-tuples $\lambda \in P_+(X_{r,k})$	pairs (g, χ)
level	a number $k \in \mathbb{N}$	a twist $\alpha \in H^3(G, U(1))$
simple currents	extended Dynkin diagram symmetry (except $\hat{E}_{8,2}$)	$Z(G) \times G/G'$ (untwisted case)
conjugation	unextended Dynkin symmetry	involutive Galois permutations
conformal embedding	$X_{r,k} \subset Y_{s,1}$	perhaps $H \lhd G$
central charge	$c = \frac{k \dim X_r}{k + h^\vee}$	$c \in 8\mathbb{Z}$
Chern-Simons theory	gauge group is Lie gp	gauge group is finite group
CFT	WZW model	holomorphic orbifold
quantum-group	$U_q(X_r)$, $q^N = 1$	quantum double $D^\alpha(G)$
VOA	Frenkel-Zhu	Dong-Mason
rank-level duality	$\widehat{\mathrm{su}}(n)_k \leftrightarrow \widehat{\mathrm{su}}(k)_n, \ldots$	electric/magnetic duality(??)

2 Untwisted modular data

2.1 Modular data for any RCFT

In this paper we explore what we call the modular data of G, from the perspective of RCFT. This subsection is intended as a quick review of the basic RCFT data (see e.g. [23] for a more comprehensive treatment), and we end it with a brief description of the modular data associated with affine algebras.

Let Φ denote the (finite) set of primary fields in the RCFT. One of these primaries, the "vacuum" '0', is privileged. By the *modular data* we mean the modular matrices S and T, whose entries S_{ab} and T_{ab} are parametrised by $a, b \in \Phi$. These matrices are unitary, T is diagonal, S is symmetric, and together they define a representation of $\mathrm{SL}_2(\mathbb{Z})$ realised by the modular action on the RCFT characters $\mathrm{ch}_a(\tau)$:

$$\mathrm{ch}_a(-1/\tau) = \sum_{b\in\Phi} S_{ab}\,\mathrm{ch}_b(\tau), \tag{2.1}$$

$$\mathrm{ch}_a(\tau+1) = \sum_{b\in\Phi} T_{ab}\,\mathrm{ch}_b(\tau), \tag{2.2}$$

so $(ST)^3 = S^2 =: C$ commutes with S and T and is a permutation matrix called *charge conjugation.* Note that $S^* = SC$ and $C0 = 0$. These ch_a are assumed to be linearly independent and in general will depend on other variables than τ, but it is conventional to write only τ.

All RCFTs in this paper are *unitary.* This implies that the entries $S_{a0} = S_{0a}$ will all be strictly positive. The ratio $\frac{S_{a0}}{S_{00}}$ is called the *quantum dimension* of a. The *fusion coefficients* $N_{ab}^c \in \mathbb{N}$ of the theory can be obtained from S using *Verlinde's formula*

$$N_{ab}^c = \sum_{d\in\Phi} \frac{S_{ad}\,S_{bd}\,S^*_{cd}}{S_{0d}}. \tag{2.3}$$

A *simple current* [24] can be defined as any $j \in \Phi$ with quantum-dimension 1: i.e. $S_{j0} = S_{00}$. To any simple current j is associated a "charge" $Q_j : \Phi \to \mathbb{Q}$, an integer R_j, and a permutation J of Φ, such that $J0 = j$,

$$S_{Ja,b} = \exp[2\pi\mathrm{i}\, Q_j(b)]\, S_{ab}, \tag{2.4}$$

$$T_{Ja,Ja}T^*_{aa} = \exp[2\pi\mathrm{i}\,(R_j\,\tfrac{n-1}{2n} - Q_j(a))], \tag{2.5}$$

$$N_{j,b}^c = \delta_{c,Jb}, \tag{2.6}$$

where n in (2.5) is the order of J. Note that $nQ_j \in \mathbb{Z}$. For instance $j = 0$ is a simple current, corresponding to the identity permutation. Simple currents define an abelian group given by composition of the corresponding permutations.

The matrix S also obeys another important symmetry, called *Galois* [25]. In particular, the entries S_{ab} will lie in some cyclotomic field $\mathbb{Q}(\xi_m)$, where ξ_m throughout this paper denotes the mth root of unity $\exp[2\pi\mathrm{i}/m]$. This means that each S_{ab} can be written as a polynomial in ξ_m with rational coefficients. The Galois group $\mathrm{Gal}(\mathbb{Q}(\xi_m)/\mathbb{Q})$ consists of all automorphisms of the field $\mathbb{Q}(\xi_m)$, and is isomorphic to the multiplicative group $\mathbb{Z}_m^\times$ of integers coprime to m. In particular, to any $\ell \in \mathbb{Z}_m^\times$ we get an automorphism $\sigma_\ell \in \mathrm{Gal}(\mathbb{Q}(\xi_m)/\mathbb{Q})$ sending ξ_m to ξ_m^ℓ. Applying it to entries of S, we get

$$\sigma(S_{ab}) = \epsilon_\sigma(a)\, S_{\sigma(a),b} = \epsilon_\sigma(b)\, S_{a,\sigma(b)}, \tag{2.7}$$

where each $\epsilon_\sigma(a)$ is a sign ± 1, and where $a \mapsto \sigma(a)$ is a permutation of Φ. The simplest example of this Galois action is charge conjugation C: σ_{-1} is complex conjugation; the corresponding $\epsilon_{\sigma_{-1}}$ is identically $+1$, while the permutation $a \mapsto \sigma_{-1}a$ is given by C.

The Galois and simple current permutations respect each other: $\sigma_\ell(Ja) = J^\ell(\sigma_\ell(a))$. Also, $\epsilon_\sigma(Ja) = \epsilon_\sigma(a)$ and $Q_j(\sigma_\ell(a)) \equiv \ell\, Q_j(a) \pmod 1$.

The one-loop partition function $\mathcal{Z}(\tau)$ of the RCFT is a modular invariant sesquilinear combination of RCFT characters:

$$\mathcal{Z}(\tau) = \sum_{a,b\in\Phi} M_{ab}\,\mathrm{ch}_a(\tau)\,\mathrm{ch}_b(\tau)^*. \tag{2.8}$$

Modular invariance means that the coefficient matrix M commutes with S and T. In addition, $M_{00} = 1$, and each coefficient is a non-negative integer: $M_{ab} \in \mathbb{N}$. Any such $\mathcal{Z}$ or M is called a *physical invariant* or *modular invariant* (such an M may or may not be realised as a partition function for an RCFT). $M = I$ is always a physical invariant. For a given choice of modular data, there will only be finitely many physical invariants.

A special family of physical invariants are the *automorphism invariants*, where M is a permutation matrix. An example is $M = C$. The product MM' of any automorphism invariant M with any physical invariant M' will also be a physical invariant.

One of the uses of both simple currents and this Galois action is that they can be used to construct physical invariants. The simplest construction (originally due to [26] but since generalised considerably, see [27] and references therein) starts with any simple current j, with order n say. Then

$$M(j)_{ab} = \sum_{i=1}^{n} \delta_{J^i a,b}\,\delta^1(Q_j(a) + \frac{i}{2n}R_j), \tag{2.9}$$

where $\delta^1(x) = 1$ if $x \in \mathbb{Z}$ and $= 0$ otherwise. For instance the choice $j = 0$ yields the identity matrix $M(0) = I$. $M(j)$ will be a physical invariant iff $T_{jj}T_{00}^*$ is an nth root of 1. $M(j)$ will be an automorphism invariant iff $T_{jj}T_{00}^*$ is a *primitive* nth root of 1.

Given any order-two Galois automorphism σ with the properties that $\sigma(0) = 0$ and $T_{\sigma a,\sigma a} = T_{a,a}$, then $M(\sigma)_{ab} := \delta_{b,\sigma a}$ defines an automorphism invariant (this construction was originally due to [28] but was since generalised). Again, C is an example.

The most familiar example of modular data comes from the affine nontwisted algebras. The literature on affine modular data is very extensive (indeed this affine ↔ finite group imbalance is a primary motivation for this paper) and it certainly is not our intention to review it here. See [29, 23] for a deeper treatment.

Choose any finite-dimensional simple Lie algebra X_r, and any *level* $k \in \mathbb{N}$. $X_r^{(1)} = \hat{X}_r$ denotes the infinite-dimensional nontwisted affine Kac-Moody algebra [29]. Its integrable highest-weight modules at level k are parametrised by $(r+1)$-tuples $\lambda = (\lambda_0, \lambda_1, \ldots, \lambda_r)$, where each $\lambda_i \in \mathbb{N}$, and $\sum_{i=0}^{r} a_i^\vee \lambda_i = k$. The positive constants $a_i^\vee$ are called colabels – e.g. for $A_r^{(1)}$ or $C_r^{(1)}$ all $a_i^\vee = 1$. The (finite) collection of these highest-weights is denoted P_+^k and is the set of primary fields Φ. The "vacuum" 0 is $(k, 0, 0, \ldots, 0)$. The matrices S and T are given in Theorem 13.8 of [29]: S is related to the corresponding Lie group characters at elements of finite order, while T is related to the eigenvalues of the quadratic Casimir. A useful parameter is the dual Coxeter number $h^\vee := \sum_{i=0}^r a_i^\vee$, and a useful $(r+1)$-tuple is the Weyl vector $\rho := (1,1,1,\ldots,1)$. The affine fusion coefficients are given combinatorially by what is usually called the Kac-Walton formula [29, 30], though it has other co-discoverers.

The simplest example is the choice $X_r = A_1$ (i.e. $\mathrm{sl}_2(\mathbb{C})$) for which $h^\vee = 2$. For any level $k \in \mathbb{N}$, one has $P_+^k = \{(k,0),(k-1,1),\ldots,(0,k)\}$. The modular data is then

$$\begin{aligned} S_{\lambda\mu} = & \sqrt{\tfrac{2}{k+2}}\,\sin(\pi\tfrac{(\lambda_1+1)(\mu_1+1)}{k+2}), && (2.10)\\ T_{\lambda\mu} = & \exp[\pi \mathrm{i}\tfrac{(\lambda_1+1)^2}{2(k+2)} - \tfrac{\pi\mathrm{i}}{4}]\,\delta_{\lambda,\mu}. && (2.11)\end{aligned}$$

The charge conjugation of affine modular data corresponds to an order-one or -two symmetry of the unextended Dynkin diagram. For $A_1^{(1)}$ it is trivial, but for the other $A_r^{(1)}$ it is non-trivial. The simple currents were classified in [31], and with one exception ($E_8^{(1)}$ level 2) correspond to symmetries of the extended Dynkin diagram. $A_1^{(1)}$ has one non-trivial such symmetry, corresponding to the interchange of the nodes labeled '0' and '1'. This yields a permutation J of P_+^k given by $J(\lambda_0,\lambda_1) = (\lambda_1,\lambda_0)$, and corresponding to primary field $j = J0 = (0,k)$. Note that $Q_j(\lambda) = (-1)^{\lambda_1}$ and $R_j = k$. Thus $M(j)$ is a physical invariant whenever k is even. It is an automorphism invariant whenever $k \equiv 2 \pmod 4$.

The Galois action can be understood geometrically in terms of the affine Weyl group [25]. In general $\sigma(0) \neq 0$ and the signs ϵ_σ are both positive and negative. The S entries lie in the cyclotomic field $\mathbb{Q}(\xi_{f\,(k+h^\vee)})$, where f is a number depending only on the choice of algebra – e.g. $f = 4$ for A_1, and $f = 3,4,1,4,3$ for $X_r = E_6, E_7, E_8, F_4, G_2$, respectively (we will use this in the proof of Theorem 1 below). Also, $h^\vee = 12, 18, 30, 9, 4$ for those algebras.

A surprising feature is that almost all of the affine physical invariants can be understood in terms of the symmetries of the extended Dynkin diagram. For example, the classification for $A_1^{(1)}$ was done in [32]: apart from $M = M(0) = I$ (for all k) and $M = M(j)$ (for all even k), there are only 3 other physical invariants (at $k = 10, 16, 28$). The physical invariant classification for general affine algebras is still open; see [33] and references therein for a list of the algebras and levels for which it has been completed.

2.2 Finite group modular data

After this brief review of modular data in general RCFTs, and of affine modular data as specific examples, we turn to the modular data associated with a finite group G.

Fix a set R of representatives of each conjugacy class of G. So the identity e of G is in R, and more generally the centre $Z(G)$ of G is a subset of R.

For any $a \in G$, let K_a be the conjugacy class containing a. By $C_G(a)$ we mean the *centraliser* of a in G, i.e. the set of all elements in G which commute with a. $C_G(a)$ is a subgroup of G, and in fact $|G| = |K_a| \cdot |C_G(a)|$.

The primary fields of the G modular data are labelled by pairs (a,χ), where $a \in R$, and where χ is an irreducible character of $C_G(a)$. We will write $\Phi = \Phi(G)$ for the set of all these pairs. In this set, the vacuum '0' corresponds to $(e,1)$, with 1 the character of the trivial representation of $G = C_G(e)$. It will be convenient at times to identify (a,χ) with each $(g^{-1}ag, \chi^g)$, where $\chi^g(h) = \chi(ghg^{-1})$ is an irreducible character of $C_G(g^{-1}ag)$.

We set

$$S_{(a,\chi),(b,\chi')} = \frac{1}{|C_G(a)|\,|C_G(b)|}\sum_{g\in G(a,b)} \chi(gbg^{-1})^*\,\chi'(g^{-1}ag)^* \tag{2.12}$$

$$= \frac{1}{|G|}\sum_{g\in K_a,h\in K_b\cap C_G(g)} \chi(xhx^{-1})^*\,\chi'(ygy^{-1})^*, \tag{2.13}$$

$$T_{(a,\chi),(a',\chi')} = \delta_{a,a'}\delta_{\chi,\chi'}\frac{\chi(a)}{\chi(e)}, \tag{2.14}$$

where $G(a,b)=\{g\in G\,|\,agbg^{-1}=gbg^{-1}a\}$, and where x,y are any solutions to $g=x^{-1}ax$ and $h=y^{-1}by$. The equivalence of (2.12) and (2.13), and the fact that (2.13) does not depend on the choice of x,y, are easy arguments.

Note that the strange set $G(a,b)$ is precisely the set of all g for which $g^{-1}ag\in C_G(b)$ and $gbg^{-1}\in C_G(a)$. If there are no such g, then $G(a,b)$ is empty and the sum (and the matrix entry) would be equal to 0. A special case of this is Proposition 1(a) below.

S is symmetric and unitary, and gives rise (via Verlinde's formula) to non-negative integer fusion coefficients. The fusion coefficient $N_{(a,\chi_1),(b,\chi_2)}^{(c,\chi_3)}$ in fact has algebraic interpretations. For example, let ρ_i be representations corresponding to characters χ_i. Write $T(a)$ for a set of representatives of the left cosets of $C_G(a)$. Define the space

$$X=\bigoplus(\rho_1x)\otimes(\rho_2y), \tag{2.15}$$

where the sum is over all $x\in T(a)$, $y\in T(b)$ for which $(x^{-1}ax)\,(y^{-1}by)=c$, and where we interpret 'ρ_1x', 'ρ_2y' as belonging to the induced representations $(\rho_1)C_G(a)^G$, $(\rho_2)^G_{C_G(b)}$, respectively (we'll say more on induced representations below). X carries a representation of $C_G(c)$, using the usual coproduct. The fusion coefficient equals the multiplicity of ρ_3 in X [10]. (There are other interpretations of these fusion coefficients – see e.g. [16, 6, 7].)

Since a is in the centre of $C_G(a)$, $\chi(a)/\chi(e)$ in (2.14) will be an nth root of 1, where n is the order of a. Because $T_{00}=1$, the given normalisation of T corresponds to the central charge c being a multiple of 24; we are free to multiply (2.14) by any third root of 1, permitting c to be other multiples of 8.

In order to more fully exploit the formula (2.12), it is important to understand the notion of *induced character* (or representation) (see e.g. [3]). Given a representation $\rho:H\to W$ of a subgroup H of G, of character χ, we call a representation $\rho':G\to V$ of G an induced representation if V equals the direct sum of vector spaces W_a, for each coset $aH\in G/H$, where W_a is defined by $\rho'(aH)W=W_a$. An induced representation always exists and is unique up to isomorphism, and is denoted ρ_H^G. In terms of characters, we get the important formula (somewhat reminiscent of (2.12)):

$$\chi_H^G(g)=\frac{1}{|H|}\sum_{\substack{a\in G\\ a^{-1}ga\in H}}\chi(a^{-1}ga). \tag{2.16}$$

Suppose that $\chi'\in\mathrm{Irr}(C_G(b))$ is the restriction to $C_G(b)$ of some character $\overline{\chi}'$ defined on the group $G(a|b):=\langle G(a,b),C_G(b)\rangle$ (this happens fairly often in practice – see e.g. Ch.27 of

[1] for a relevant discussion). Then provided $G(a,b)\neq\emptyset$, (2.12) collapses to

$$S_{(a,\chi),(b,\chi')}=\frac{1}{|C_G(b)|}\,\overline{\chi}'(a)^*\,\chi^G_{C_G(a)}(b)^*. \tag{2.17}$$

Equation (2.17) for instance applies whenever χ' is identically 1. Another important instance of (2.17) is when z lies in the centre $Z(G)$, since then $C_G(z)=G$ and we get

$$S_{(a,\chi),(z,\chi')}=\frac{\chi(z)^*}{|C_G(a)|}\,\chi'(a)^*. \tag{2.18}$$

For instance, the quantum dimension of $(a,\chi)\in\Phi$ is

$$\frac{S_{(a,\chi),(e,1)}}{S_{(e,1),(e,1)}}=|K_a|\deg(\chi), \tag{2.19}$$

which amazingly enough is always a positive *integer* ! In fact from (2.16), (2.19) has a simple group-theoretic interpretation: it is the degree of the induced character $\chi^G_{C_G(a)}$. This integrality is very unusual, and shows that generically this finite group modular data is qualitatively different from affine data.

Equation (2.17) says we can expect many 0's in S. Any character $\chi\in\mathrm{Irr}(H)$ with degree $\chi(e)>1$ will have a zero – in fact $\chi(h)$ will be zero for at least $|Z(H)|\,(\chi(e)^2-1)$ group elements (see e.g. Ch. 23 of [1]). Hence the (z,χ) row will have 0's iff χ is not of degree 1. Dually, for any $b\in H$ there will be at least $k(H)-|C_H(b)|$ different $\chi'\in\mathrm{Irr}(H)$ with $\chi'(b)=0$, where $k(H)$ is the class number of H, so for instance the $(a,1)$ row will have 0's whenever e.g. there are elements in $C_G(a)$ whose centraliser in $C_G(a)$ is small. This seems to also be different from the affine case, where 0's are quite rare and fairly generically tend to be due to simple current fixed points.

Equation (2.18) also says

$$\frac{S_{(e,\chi),(a,\chi')}}{S_{(e,1),(a,\chi')}}=\chi(a)^*. \tag{2.20}$$

As long as we could identify by looking at S and T the primaries of the form $(e,\star)$, then the matrix S will contain the character table of G, and we would know that groups with different character tables would necessarily have different matrices S and T.

From (2.19), we see that the simple currents are precisely the pairs (z,φ), where z lies in the centre $Z(G)$ of G, and φ is a degree-1 character of G. Thus the group of simple currents is isomorphic to the direct product $Z(G)\times G/G'$, where G' is the commutator subgroup of G. The simple current $j=(z,\varphi)$ corresponds to permutation $J_{(z,\varphi)}(a,\chi)=(za,\varphi\chi)\in\Phi$, and charge $e^{2\pi\mathrm{i}Q}=\varphi(a)^*\chi(z)^*/\chi(1)$, which is always a root of unity as it should be. We get that $M(z,\varphi)$ (in the notation of the previous subsection) is always a physical invariant; it is an automorphism invariant iff z and φ have the same order.

Generic groups have many simple currents. A group for which $G=G'$ is called *perfect*; a group will have no non-trivial simple currents iff it is perfect and has trivial centre. For example this happens whenever G is non-cyclic simple. All perfect groups with small orders have been classified [34], and using this we can list all groups G with order $|G|<688128$ which have no non-trivial simple currents. The orders under 2000 of these groups are (see also Prop. 1(g)): 60, 168, 360, 504, 660, 960 (twice), 1092, 1344 (twice), and 1920.

When (and only when) G is abelian, all primaries will be simple currents, and hence the modular data will be rather trivial and uninteresting. This can also happen with the affine algebras: namely, the simply-laced algebras $A_r^{(1)}, D_r^{(1)}, E_6^{(1)}, E_7^{(1)}, E_8^{(1)}$ at level 1.

Charge conjugation takes (a,χ) to (a^{-1},χ^*), where the complex conjugate χ^* is the character of the contragredient representation. Now a^{-1} may not lie in our set R of conjugacy class representatives: recall that by (a^{-1},χ^*) we really mean $(g^{-1}a^{-1}g,\chi^{g\,*})\in\Phi$ where $g^{-1}a^{-1}g\in R$. This is not so trivial as it may seem: if a and a^{-1} are conjugate, (a,χ) and (a^{-1},χ^*) may be identified even though χ is complex-valued. An example is $\mathfrak{S}_3$, $a=(123)$, given below. Note though from (2.20) that the field $\mathbb{Q}(S)$ contains the field generated over $\mathbb{Q}$ by all character values $\chi(a)$, $\chi\in\mathrm{Irr}(G)$, $a\in G$, so if some characters of G are complex, the C won't be trivial.

The Galois symmetry is also straightforward. The character values of any group lie in the cyclotomic field $\mathbb{Q}(\xi_e)$ where $e=e(G)$ is the exponent of the group (the least common multiple of the orders of all group elements) – see Thm.8.7 of [3]. Hence the entries of S and T lie in the cyclotomic field $\mathbb{Q}(\xi_e)$, so the relevant Galois group is the multiplicative group $\mathbb{Z}_e^\times$. The Galois automorphism σ_ℓ takes (a,χ) to $(a^\ell,\sigma_\ell\circ\chi)$: $\sigma_\ell\circ\chi$ is the function obtained by applying σ_ℓ to each complex number $\chi(a)$; it is an irreducible character (of degree equal to that of χ) iff χ is [3]. Note another curiousity here: the Galois parities ϵ_ℓ are all identically equal to 1 ! This is very different from the generic affine situation. Note also that every Galois permutation fixes the vacuum $(e,1)$ (since every quantum dimension is rational), so large numbers of automorphism invariants will arise generically: whenever $\ell^2\equiv 1 \pmod{e(G)}$, the permutation σ_ℓ on Φ will define an automorphism invariant. We will return to this in §4.1.

Let us collect a few of the observations we have made here.

Proposition 1. (a) Choose any $(a,\chi),(a',\chi')\in\Phi$. If the order of a does not divide the exponent of $C_G(a')$, or if the order of a' does not divide the exponent of $C_G(a)$, then $S_{(a,\chi),(a',\chi')}=0$.

(b) The order of T *equals* (and not merely divides) the exponent of G.

(c) If $S(G)=S(H)$, then $|G|=|H|$.

(d) If $a^{-1}\notin K_a$, then the charge conjugate $C(a,\chi)\neq(a,\chi)$ for all $\chi\in\mathrm{Irr}(C_G(a))$. If $\chi\in\mathrm{Irr}(G)$ is not real-valued, then $C(z,\chi)\neq(z,\chi)$ for all $z\in Z(G)$.

(e) The quantum dimensions $S_{(a,\chi),(e,1)}/S_{(e,1),(e,1)}$ are always integers.

(f) The Galois parities $\epsilon_\sigma(a,\chi)$ are always $+1$, and the vacuum $(e,1)$ is fixed by all σ.

(g) The groups $G\neq\{e\}$ with at most 75 primaries, which have no non-trivial simple currents, are the simple groups $G=\mathfrak{A}_5,\mathrm{PSL}_2(\mathbb{F}_7),\mathfrak{A}_6,\mathrm{SL}_2(\mathbb{F}_8),\mathrm{PSL}_2(\mathbb{F}_{11})$, and $\mathfrak{A}_7$, with $(|G|,|\Phi|)=(60,22),(168,35),(360,44),(504,74),(660,58)$, and (2520,74).

(h) For any group $G\neq\{e\}$, there will be at least 5 physical invariants. If $G/Z(G)$ is nonabelian, then there will be at least $a+(b+c)^2$ physical invariants, where $a=|Z(G)|\,|G/G'|$, b equals the number of subgroups of $Z(G)$, and c equals the number of subgroups of G/G'.

The proof for (b) is the following. Choose any group H, and any $a \in Z(H)$ with prime-power order p^m. Then any irreducible representation of H will send a to the multiple of the identity matrix by some p^mth root of 1, i.e. $\chi(a)/\chi(e)$ will be a p^mth root of 1 for all $\chi \in \mathrm{Irr}(H)$. Now, that root of 1 must be primitive for some χ, as otherwise $a^{p^{m-1}}$ and e would have identical character values. Applying that fact to $H = C_G(a)$ gives us the desired order of T.

The proof of (c) is the comparison of $S_{(e,1),(e,1)}$ for G and H.

A constructive proof of (h) is given in §4.2. Incidentally, this bound can probably be significantly improved. $G = \mathbb{Z}_2$, with 6 physical invariants, is probably the lowest number. By comparison, affine algebras have relatively few physical invariants: e.g. both $B_\ell^{(1)}$ and $C_\ell^{(1)}$ at generic levels are expected to have only 2. ■

We have already remarked on several occasions above, that the finite group modular data are very different from affine modular data. At this stage (we will have more to say when we come to general twisted finite group modular data), this statement can be substantiated by noting that the two sets have a very small intersection.

Theorem 1. Let S and T be the Kac-Peterson matrices corresponding to an affine algebra $X_r^{(1)}$ at some level $k \geq 1$ (where X_r is simple). Let G be a finite group with $S(G) = S$ and $T(G) = \varphi T$ for some third root φ of 1. Then either

(i) $(X_r, k) = (E_8, 1)$ and $G = \{e\}$, or

(ii) $(X_r, k) = (D_{8n}, 1)$, and $G = \mathbb{Z}_2$.

Sketch of proof Write $n = k + h^\vee$. Recall that there is a Galois automorphism for any ℓ coprime to fn, where f for the exceptional algebras was given in §2.1. A consequence of the affine Weyl interpretation of the affine Galois permutation σ_ℓ of P_+^k is that the vectors $\sigma_\ell(\lambda + \rho)$ and $\ell\,(\lambda + \rho)$ have the same norm mod $2n$.

A nice way to handle the exceptional algebras is to check that $\ell\rho$ and ρ have the same norm (mod $2n$) for any ℓ coming from Galois (since all Galois automorphisms here will fix the vacuum 0). For instance, for E_7 we get $\rho^2 = 399/2$, so we see that $2n$ must divide $(\ell^2 - 1)\,399/2$. Now, the "Definition of 24" says that $\ell^2 - 1$ here can be replaced with 24: more precisely, the gcd of all numbers $\ell^2 - 1$, for ℓ coprime to fn, will equal $\gcd(24, (fn)^\infty)$. Hence, n must divide $2 \cdot 3^2 \cdot 7 \cdot 19$.

Now, $n > h^\vee = 18$. Also, if n is too big (i.e. if there is an ℓ coprime to fn such that $(h^\vee - 1)\ell < n$), then $\sigma_\ell(0)$ will equal $(m, \ell - 1, \ell - 1, \ldots, \ell - 1)$, where $m = n - 1 - \ell\,(h^\vee - 1)$, violating the result that 0 is fixed by all Galois automorphisms. For E_7, this is the condition that no ℓ, $1 < \ell < \frac{n}{17}$, can be coprime to $2n$.

We can now write down the possibilities for n: they are $19, 21, 38, 42, 57, 63$. Subtracting 18 gives the possible levels. $n = 19$ fails, since it would have to correspond to an abelian group with order $\frac{1}{S_{00}} = \sqrt{2}$. The remaining 5 possibilities all have non-integral quantum dimensions.

The other exceptional algebras are all done similarly. The only surviving n for G_2 are $n = 7, 8, 14$; for F_4 are $n = 12, 13, 18, 36, 39$; for E_6 are $n = 18, 24, 26, 36, 52$; and for E_8 are $n = 40, 48, 60, 62, 80, 120$. In all these cases, a weight with non-integral quantum dimension is easily found.

The best way to handle the classical algebras is to compute the quantum dimension of any weight in the Galois orbit of 0, and show it must be larger than 1, for some σ_ℓ. For now consider $k>1$ for A_r and C_r, and $k>2$ for B_r and D_r. Up to a sign, the quantum dimension of $\sigma_\ell(0)$ for the algebras A_r, B_r, C_r, D_r is, respectively,

$$\prod_{a=1}^{r}\frac{\sin(\pi\ell a/n)^{r+1-a}}{\sin(\pi a/n)^{r+1-a}}, \tag{2.21}$$

$$\prod_{a=0}^{r-1}\frac{\sin(\pi\ell\,(a+1/2)/n)}{\sin(\pi\,(a+1/2)/n)}\prod_{b=1}^{2r-2}\frac{\sin(\pi\ell b/n)^{[\frac{2r-b}{2}]}}{\sin(\pi b/n)^{[\frac{2r-b}{2}]}}, \tag{2.22}$$

$$\prod_{a=1}^{r-1}\frac{\sin(\pi\ell a/n)^{r-a}\,\sin(\pi\ell\,(a-1/2)/n)^{r-a}}{\sin(\pi a/n)^{r-a}\,\sin(\pi\,(a-1/2)/n)^{r-a}}\prod_{b=r}^{2r-1}\frac{\sin(\pi\ell b/2n)}{\sin(\pi b/2n)}, \tag{2.23}$$

$$\prod_{a=1}^{r-1}\frac{\sin(\pi\ell a/n)^{[\frac{2r-a+1}{2}]}}{\sin(\pi a/n)^{[\frac{2r-a+1}{2}]}}\prod_{b=r}^{2r-3}\frac{\sin(\pi\ell b/n)^{[\frac{2r-b-1}{2}]}}{\sin(\pi b/n)^{[\frac{2r-b-1}{2}]}}, \tag{2.24}$$

where $[x]$ here denotes the greatest integer not more than x. The absolute value of each of these is quickly seen to be greater than 1 unless $\ell\equiv\pm1 \pmod n$ (for A_r or D_r) or $\ell\equiv\pm1 \pmod{2n}$ (for B_r and C_r). This exhausts the possible ℓ coprime to fn only if the Euler totient $\varphi(n)\leq 2$ (for A_r and D_r) or $\varphi(2n)\leq 2$ (for B_r and C_r). By definition $\varphi(m)$ is the number of h, $1\leq h\leq m$, coprime to m; it is less than 3 only for $m=1,2,3,4,6$. So only A_1 level 2, A_2 level 3, A_1 level 4, and A_3 level 2 survive, but their central charges aren't multiples of 8.

The series A_r, D_{odd} and D_{even} at $k=1$ possess only simple currents (so would have to correspond to an abelian group G), and have the fusion groups $\mathbb{Z}_{r+1}, \mathbb{Z}_4, \mathbb{Z}_2\times\mathbb{Z}_2$ respectively. Abelian G has fusion group $G\times G$, so that leaves only D_{even} and $G=\mathbb{Z}_2$. D_n level 1 has $c=n$, concluding the argument. B_r level 1 has only 2 primaries so is covered e.g. by Theorem 2 below. The modular data of C_r level 1 is identical with that of A_1 level r.

Level 2 for D_r can be handled by requiring $|G|=\frac{1}{S_{00}}=2\sqrt{2r}$ and the quantum dimension $\frac{S_{\Lambda_r,0}}{S_{00}}=\sqrt{r}$ to both be integers (see [33] for the necessary S entries). For B_r at level 2, first read off from [33] that $|G|=\frac{1}{S_{00}}=2\sqrt{2r+1}$, so $2r+1=s^2$ for some odd integer s. Now, $T_{\Lambda_1,\Lambda_1}=\mathrm{i}\,\exp[-\pi\mathrm{i}\,\frac{1}{2s^2}]$ is a primitive s^2-root of 1, but $T(G)$ will have order dividing $|G|=2s$, and so those matrices cannot be equal. ■

For which groups will the number of primaries be low? Consider the formula

$$|\Phi(G)|=\sum_{a\in R}k(C_G(a)), \tag{2.25}$$

where $k(H)$ is the class number of H, i.e. the number of conjugacy classes in, or irreducible representations of, H. Note that the smaller $k(G)$ is, the fewer summands there will be in (2.25), the larger each conjugacy class $|K_a|$ will tend to be, so the smaller the centralisers $|C_G(a)|=\frac{|G|}{|K_a|}$ will tend to be, and the smaller the $k(C_G(a))$ in (2.25) will tend to be. Thus, we should expect $|\Phi|$ to grow with $k(G)$. The groups with class number less than 13 are classified [35]. This allows all G with at most 77 primaries to be listed. We make this argument precise in the proof of Thm. 2 below.

When G is abelian, it has $|G|^2$ primaries – this is the extreme case. The number of primaries for the even dihedral groups $\mathfrak{D}_{2n}$, and the quaternion group $\mathfrak{Q}_{2n}$, are both $2n^2+14$, which grows like $|G|^2/8$. The odd dihedral groups $\mathfrak{D}_m$, m odd, have $\frac{m^2+7}{2}$ primaries (see below). By comparison (using the data given in Ch.20 of [3]), $\mathrm{SL}_2(\mathbb{F}_q)$ has q^2+8q+9 primaries for q any power of an odd prime, and q^2+q+2 primaries for q any power of 2 – in either case, that number grows like $|G|^{2/3}$. Our computations so far suggest the following rule of thumb: the more abelian the group is, the messier it behaves (i.e. the more its primaries, the more its physical invariants, etc), while the closer the group is to being non-abelian simple, the better behaved it will be.

From this point of view, an interesting measure of how complicated a group is relative to its size, is the ratio

$$\mathcal{N}(G) := \frac{\log|\Phi(G)|}{\log|G|}. \tag{2.26}$$

It ranges from 0 to 2, with 2 achieved iff G is abelian. How low can $\mathcal{N}(G)$ be ? Some small values are $\mathcal{N}(\mathfrak{A}_5) \approx .75$, $\mathcal{N}(\mathfrak{A}_7) \approx .55$ and $\mathcal{N}(M_{11}) \approx .49$. Sporadic simple groups like the Monster should have $\mathcal{N}$ very small.

Theorem 2. There are precisely 33 groups G with at most 50 primaries:

- the abelian groups $G = \mathbb{Z}_1, \mathbb{Z}_2, \mathbb{Z}_3, \mathbb{Z}_4, \mathbb{Z}_2\times\mathbb{Z}_2, \mathbb{Z}_5, \mathbb{Z}_6, \mathbb{Z}_7$, with precisely $|G|^2$ primaries;
- the symmetric and alternating groups $\mathfrak{S}_3, \mathfrak{A}_4, \mathfrak{S}_4, \mathfrak{A}_5, \mathfrak{S}_5, \mathfrak{A}_6$ with $(|G|, |\Phi|) = (6,8)$, (12,14),(24,21),(60,22),(120,39),(360,44);
- the (semi)dihedral and quaternion groups $\mathfrak{D}_5, \mathfrak{D}_4, \mathfrak{Q}_4, \mathfrak{D}_7, \mathfrak{D}_9, \mathfrak{D}_8, \mathfrak{Q}_8, S\mathfrak{D}_8$ with $(|G|, |\Phi|) = (10,16), (8,22), (8,22), (14,28), (18,43), (16,46), (16,46), (16,46)$;
- the Frobenius groups $\mathbb{Z}_5 \times_f \mathbb{Z}_4$, $\mathbb{Z}_7 \times_f \mathbb{Z}_3$, $\mathbb{Z}_3^2 \times_f \mathbb{Z}_2$, $\mathbb{Z}_3^2 \times_f \mathbb{Z}_4$, $\mathbb{Z}_3^2 \times_f \mathfrak{Q}_4$, $\mathbb{Z}_7 \times_f \mathbb{Z}_6$, $\mathbb{Z}_{11} \times_f \mathbb{Z}_5$ with $(|G|, |\Phi|) = (20,22), (21,32), (18,44), (36,36), (72,32), (42,44), (55,49)$;
- the remaining groups $\mathbb{Z}_2 \times \mathfrak{S}_3$, DC_3, $\mathrm{PSL}_2(\mathbb{F}_7)$, and $\mathrm{SL}_2(\mathbb{F}_3)$, with $(|G|, |\Phi|) = (12,44)$, (12,32), (168,35), (24,42).

The semidihedral group $S\mathfrak{D}_{4m}$ is defined by the presentation

$$S\mathfrak{D}_{4n} = \langle r, s \mid r^{4n} = s^2 = e,\, srsr = r^{2n}\rangle. \tag{2.27}$$

and has order $8m$. The other groups are defined in [35]. An interesting consequence of Theorem 2, as mentioned earlier, is that all groups with $|\Phi(G)| \leq 50$ are uniquely determined by their matrix S.

A useful quantity for proving Thm. 2 is $h(n)$, the minimum possible class number $k(H)$ for H with order n and non-trivial centre. Knowing $h(n)$ gives a lower bound for $|\Phi(G)|$ once we know the orders $|C_G(a)|$ of its centralisers. [35] can be used for the smaller n, basic results on the classification of finite groups, as well as the congruence $k(H) \equiv |H| \pmod{16}$ when $|H|$ is odd, give us other n. What we find is e.g. $h(n) = n$ for all $n \leq 27$, except for $n = 8, 12, 16, 18, 20, 24$ (with $h(n) = 5, 6, 7, 9, 8, 7$, resp). Also useful is the largest value $\ell(k)$ of $|H|$, for H with non-trivial centres and class number $k(H) \leq k$. For instance for $k = 1, 2, \ldots, 8$ we get $\ell = 1, 2, 3, 4, 8, 12, 24, 48$.

Consider the smallest $|\Phi|$ can be if $k(G) \geq 13$. Note that at most one $a \in R$ can have a centraliser $C_G(a)$ with class number 2 — otherwise if there were two then together exactly $|G|/\ell(2) + |G|/\ell(2) > |G| - 1$ elements would be in the (disjoint) conjugacy classes $K_a \cup K_b \subset G - e$. More generally, at most $\ell(k) - 1$ a's could have $k(C_G(a)) \leq k$. Thus (2.25) will be bounded below by $13 + 2 + 3 + 4 + 4 \cdot 5 + 4 \cdot 6 + 7 = 73$. Tightening the argument (e.g. $\frac{1}{2} + \frac{1}{3} + \frac{1}{4}$ is too big) gives $|\Phi| \geq 78$. Thus using the tables of [35] we would be able to find all groups with at most 77 primaries. Similarly, to do $|\Phi| \leq 50$ it is enough to consider $k(G) \leq 9$. In [35] are also given the orders of the centralisers $C_G(a)$. It is now straightforward to get the Theorem. ∎

3 Examples

In this section we give a number of explicit examples of untwisted modular data. We also identify their physical invariants in some cases, leading to a perplexing situation we will discuss more fully next section.

Incidentally, a simple construction is direct product: the modular data for the direct product $G \times H$ is easily obtained from that of G and H. For example, $\Phi(G \times H) = \Phi(G) \times \Phi(H)$, $S(G \times H)$ is the Kronecker matrix product $S(G) \otimes S(H)$, etc. Of course, semi-direct product in general will be much more difficult to work out.

3.1 Abelian groups

Abelian G (untwisted) is trivial to work out, but also very uninteresting. Write G in the following canonical way: $G \cong \mathbb{Z}_{d_1} \times \mathbb{Z}_{d_2} \times \cdots \times \mathbb{Z}_{d_s}$ where $d_1|d_2|\cdots|d_s$. For convenience, define a bilinear form on $\mathbb{Z}^s$ by $\langle m, n\rangle = \sum_i \frac{m_i n_i}{d_i}$. We can identify Φ here with the $2s$-tuple $(m, n) \in \mathbb{Z}^s \times \mathbb{Z}^s$, where $0 \leq m_i \leq d_i - 1$ and $0 \leq n_i \leq d_i - 1$: in particular, m corresponds to the group element $(m_1, m_2, \ldots, m_s) \in \mathbb{Z}_{d_1} \times \cdots \times \mathbb{Z}_{d_s}$, and n corresponds to the character φ_n of G defined by $\varphi_n(m) = \exp[2\pi \mathrm{i}\langle m, n\rangle]$. The matrices S and T are given by

$$S_{(m,n),(m',n')} = \frac{1}{|G|}\exp[-2\pi\mathrm{i}(\langle m', n\rangle + \langle m, n'\rangle)], \qquad T_{(m,n),(m,n)} = \exp[2\pi\mathrm{i}\langle m, n\rangle]. \tag{3.1}$$

All $(m, n) \in \Phi$ are simple currents, with composition given by pairwise addition. Charge conjugation takes (m, n) to $(-m, -n)$, and more generally the ℓth Galois automorphism (for $\ell \in \mathbb{Z}_{d_s}^{\times}$) sends (m, n) to $(\ell m, \ell n)$.

G will have many physical invariants, but they can all be most elegantly interpreted using lattices as was explained in [36] (the standard reference for lattice theory is [37]). In particular let Λ be the $4s$-dimensional integral indefinite lattice, given by the orthogonal direct sum $\Lambda = \sqrt{d_1}II_{2,2} \oplus \sqrt{d_2}II_{2,2} \oplus \cdots \oplus \sqrt{d_s}II_{2,2}$, where $II_{2,2} = II_{1,1} \oplus II_{1,1}$ is the unique 4-dimensional even self-dual indefinite lattice. Then there is a natural one-to-one bijection between the physical invariants of G and the even self-dual 'gluings' of Λ, i.e. the even self-dual $4s$-dimensional lattices containing Λ. For instance, for $G = \mathbb{Z}_p$ (p prime), one finds that there are precisely 6 (if $p = 2$) or 8 (if $p > 2$) physical invariants. Two of these are

$$(\sum_{i=0}^{p-1} \mathrm{ch}_{i0})\,(\sum_{j=0}^{p-1} \mathrm{ch}^*_{0j}) \qquad \text{and} \qquad \sum_{i,j=0}^{p-1} \mathrm{ch}_{ij}\, \mathrm{ch}^*_{-j,-i}\,, \tag{3.2}$$

using obvious notation.

The non-abelian groups are much more interesting, and we turn to them in the next subsection. The number of non-abelian groups of order $n \leq 50$ are 1 (for $n = 6, 10, 14, 21, 22, 26, 34, 38, 39, 46$), 2 ($n = 8, 27, 28, 44$), 3 ($n = 12, 18, 20, 30, 50$), 5 (for $n = 42$), 9 (for $n = 16$), 10 (for $n = 36$), 11 (for $n = 40$), 12 (for $n = 24$), 44 (for $n = 32$), 47 (for $n = 48$), and 0 otherwise.

3.2 Some infinite series

It is not hard to work out S and T for the infinite series $\mathfrak{D}_n$ (dihedral) and $\mathfrak{Q}_{2n}$ (quaternion):

$$\mathfrak{D}_n = \langle r, s \mid r^n = s^2 = e,\, rsrs = e\rangle, \tag{3.3}$$

$$\mathfrak{Q}_{2n} = \langle r, s \mid r^{2n} = e,\, s^2 = r^n,\, rsrs^{-1} = e\rangle, \tag{3.4}$$

The character tables of $\mathfrak{D}_{4n}$ and $\mathfrak{Q}_{4n}$ are identical.

Consider first the even dihedral groups $\mathfrak{D}_{2n}$, of order $4n$. $\mathfrak{D}_{2n}$ has $n + 3$ conjugacy classes, with representatives $R = \{e,\, r^n,\, r^k\ (1 \leq k \leq n-1),\, s,\, sr\}$. It has an equal number of irreducible representations; 4 are one-dimensional and $n - 1$ are two-dimensional. The characters and centralisers of the various classes are indicated in the following table.

	e	r^n	r^k	s	sr
ψ_0	1	1	1	1	1
ψ_1	1	1	1	-1	-1
ψ_2	1	$(-1)^n$	$(-1)^k$	1	-1
ψ_3	1	$(-1)^n$	$(-1)^k$	-1	1
χ_i	2	$2(-1)^i$	$2\cos\frac{\pi i k}{n}$	0	0
$C_G(g)$	$\mathfrak{D}_{2n}$	$\mathfrak{D}_{2n}$	$\mathbb{Z}_{2n}$	$\mathbb{Z}_2 \times \mathbb{Z}_2$	$\mathbb{Z}_2 \times \mathbb{Z}_2$

It follows that the number of primaries is equal to $|\Phi| = 2n^2 + 14$. Denote by ψ_i $(0 \leq i < 2n)$ the characters of $\langle r\rangle \cong \mathbb{Z}_{2n}$, given by $\psi_i(r^k) = \xi_{2n}^{ik}$. Likewise, denote by ϕ_{ab} and φ_{ab} $(0 \leq a, b \leq 1)$ the characters of $\langle s, r^n\rangle \cong \mathbb{Z}_2 \times \mathbb{Z}_2$ and $\langle rs, r^n\rangle \cong \mathbb{Z}_2 \times \mathbb{Z}_2$, respectively, where $\phi_{ab}(s^k r^{n\ell}) = \varphi_{ab}((rs)^k r^{n\ell}) = (-1)^{ak+b\ell}$.

The values of the diagonal entries of T follow directly from (2.14). Eq. (2.18) easily computes any S entry involving e or r^n. The remaining non-zero S entries are

$$S_{(r^k,\psi_i),(r^\ell,\psi_j)} = \frac{1}{n}\cos(\pi\frac{\ell i + kj}{n}), \tag{3.5}$$

$$S_{(s,\phi_{ab}),(s,\phi_{cd})} = S_{(rs,\varphi_{ab}),(rs,\varphi_{cd})} = \frac{1}{4}\cdot\begin{cases} (-1)^{a+c} + (-1)^{a+b+c+d} & \text{if } n \text{ even,} \\ (-1)^{a+c} & \text{if } n \text{ odd,} \end{cases} \tag{3.6}$$

and in addition for n odd $S_{(s,\phi_{ab}),(sr,\varphi_{cd})} = \frac{1}{4}(-1)^{a+b+c+d}$.

The odd dihedral groups $\mathfrak{D}_{2n+1}$ can be worked out in the same way. $\mathfrak{D}_{2n+1}$ has $n+2$ conjugacy classes, with representatives $R = \{e,\, r^k\ (1 \le k \le n),\, s\}$. It has two one-dimensional representations, and n two-dimensional representations. The characters and centralisers of the various classes are reproduced in the following table.

	e	r^k	s
ψ_0	1	1	1
ψ_1	1	1	-1
χ_i	2	$2\cos\frac{2\pi ik}{2n+1}$	0
$C_G(g)$	$\mathfrak{D}_{2n+1}$	$\mathbb{Z}_{2n+1}$	$\mathbb{Z}_2$

One finds that the number of primary fields is $|\Phi| = 2n^2 + 2n + 4$. Write ψ_i for the characters of $\langle r\rangle \cong \mathbb{Z}_{2n+1}$ as before, and φ_i for the obvious two characters of $\langle s\rangle \cong \mathbb{Z}_2$. The calculation of S and T proceeds like for the even dihedral groups:

$$S_{(r^k,\psi_i),(r^\ell,\psi_j)} = \frac{2}{2n+1}\cos(2\pi\frac{kj+\ell i}{2n+1}), \tag{3.7}$$

$$S_{(s,\varphi_i),(s,\varphi_j)} = \frac{1}{2}(-1)^{i+j}. \tag{3.8}$$

The semidihedral groups $S\mathfrak{D}_{4m}$ (2.27) have the same matrix T as $\mathfrak{D}_{4m}$, but their matrix S is always complex.

Next turn to the quaternions $\mathfrak{Q}_{2n}$. It has $n+3$ conjugacy classes, with representatives $R = \{e,\, r^n,\, r^k\ (1 \le k \le n-1),\, s,\, sr\}$. It has 4 one-dimensional and $n-1$ two-dimensional representations. The characters and centralisers of the various classes are indicated in the following table (put $\iota = 1$ for n even, and $\iota = \mathrm{i}$ for n odd).

	e	r^n	r^k	s	sr
ψ_0	1	1	1	1	1
ψ_1	1	1	1	-1	-1
ψ_2	1	$(-1)^n$	$(-1)^k$	ι	$-\iota$
ψ_3	1	$(-1)^n$	$(-1)^k$	$-\iota$	ι
χ_i	2	$2(-1)^i$	$2\cos\frac{\pi ik}{n}$	0	0
$C_G(g)$	$\mathfrak{Q}_{2n}$	$\mathfrak{Q}_{2n}$	$\mathbb{Z}_{2n}$	$\mathbb{Z}_4$	$\mathbb{Z}_4$

The number of primaries is equal to $|\Phi| = 2n^2 + 14$. Denote by ψ_i the $2n$ characters of $\langle r\rangle \cong \mathbb{Z}_{2n}$, and by ϕ_a and φ_a the 4 characters of $\langle s\rangle \cong \mathbb{Z}_4$ and $\langle rs\rangle \cong \mathbb{Z}_4$, respectively. The nonzero S entries not involving e or r^n are

$$S_{(r^k,\psi_i),(r^\ell,\psi_j)} = \frac{1}{n}\cos(\pi\frac{\ell i + kj}{n}), \tag{3.9}$$

$$S_{(s,\phi_a),(s,\phi_b)} = S_{(rs,\varphi_a),(rs,\varphi_b)} = \frac{1}{4}\cdot\begin{cases} \mathrm{i}^{a-b} & \text{if } n \text{ odd,} \\ 2\cos(\pi\frac{a+b}{2}) & \text{if } n \text{ even,}\end{cases} \tag{3.10}$$

and in addition for n odd $S_{(s,\phi_a),(sr,\varphi_b)} = \frac{1}{4}\mathrm{i}^{a+b}$.

For our final example in this subsection, we will consider the series of non-abelian simple groups, $\mathrm{SL}_2(\mathbb{F}_q)$ for $q = 2^n$. Note that $\mathrm{SL}_2(\mathbb{F}_2) \cong \mathfrak{S}_3$ and $\mathrm{SL}_2(\mathbb{F}_4) \cong \mathfrak{A}_5$.

The order of $\mathrm{SL}_2(\mathbb{F}_q)$ is $q(q^2-1)$. There are $q+1$ conjugacy classes whose representatives can be chosen in

$$R = \left\{e,\, \iota = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix},\, \alpha^a = \begin{pmatrix} s^a & 0 \\ 0 & s^{-a} \end{pmatrix},\, \beta^b \;:\; 1 \le a \le \tfrac{q-2}{2} \text{ and } 1 \le b \le \tfrac{q}{2}\right\}, \tag{3.11}$$

where s is any generator of the cyclic multiplicative group $\mathbb{F}_q^*$, and where β is an element of order $q+1$ (its exact form is not important). The characters (the labels i and j run from 1 to $\frac{q}{2}-1$ and $\frac{q}{2}$ respectively) and centralisers are given below, from which one finds the number of primaries equals $|\Phi| = q^2+q+2$, as mentioned before.

	e	ι	α^a	β^b
ψ_0	1	1	1	1
ψ_1	q	0	1	-1
χ_i	$q+1$	1	$2\cos\frac{2\pi ia}{q-1}$	0
θ_j	$q-1$	-1	0	$-2\cos\frac{2\pi jb}{q+1}$
$C_G(g)$	$\mathrm{SL}_2(\mathbb{F}_q)$	$\mathbb{Z}_2^n$	$\mathbb{Z}_{q-1}$	$\mathbb{Z}_{q+1}$

Because $2, q-1, q+1$ are pairwise coprime, Proposition 1(a) says that the only potentially nonvanishing $S_{(a,\chi),(b,\phi)}$ entries have $a = e$ or $b = e$, or $a = b = \iota$, or a, b are both powers of α, or a, b are both powers of β. The relevant sets $G(g,h)$ here are $G(\iota,\iota) = \cup_{a=0}^{q-2}\left(\begin{smallmatrix} 1 & 0 \\ * & 1 \end{smallmatrix}\right)\alpha^a$, $G(\alpha^a,\alpha^b) = \langle a\rangle \cup \langle a\rangle\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, and $G(\beta^a,\beta^b) = \langle\beta\rangle \cup \langle\beta\rangle\gamma$ where $\gamma^{-1}\beta\gamma = \beta^{-1}$.

Explicitly writing down its matrix S would require the evaluation of some interesting character sums, something we have not yet done.

3.3 The physical invariants for $\mathfrak{S}_3$

The non-abelian group of smallest order is $\mathfrak{S}_3$. Its character table is

	e	(123)	(12)
ψ_0	1	1	1
ψ_1	1	1	-1
ψ_2	2	-1	0
$C_G(g)$	$\mathfrak{S}_3$	$\mathbb{Z}_3$	$\mathbb{Z}_2$

The modular data for $\mathfrak{S}_3$ will have 8 primary fields: (e, ψ_i) for $i = 0, 1, 2$; $((123), \varphi_k)$, $k = 0, 1, 2$, for the 3 characters $a \mapsto \xi_3^{ak}$ of $\mathbb{Z}_3$; and $((12), \varphi'_k)$, $k = 0, 1$, for the 2 characters $b \mapsto (-1)^{bk}$ of $\mathbb{Z}_2$. For convenience label these primaries $0, 1, \ldots, 7$.

Since $\mathfrak{S}_3 \cong \mathfrak{D}_3$, we can read $S(\mathfrak{S}_3)$ and $T(\mathfrak{S}_3)$ off from the previous subsection:

$$S = \frac{1}{6}\begin{pmatrix} 1 & 1 & 2 & 2 & 2 & 2 & 3 & 3 \\ 1 & 1 & 2 & 2 & 2 & 2 & -3 & -3 \\ 2 & 2 & 4 & -2 & -2 & -2 & 0 & 0 \\ 2 & 2 & -2 & 4 & -2 & -2 & 0 & 0 \\ 2 & 2 & -2 & -2 & -2 & 4 & 0 & 0 \\ 2 & 2 & -2 & -2 & 4 & -2 & 0 & 0 \\ 3 & -3 & 0 & 0 & 0 & 0 & 3 & -3 \\ 3 & -3 & 0 & 0 & 0 & 0 & -3 & 3 \end{pmatrix}, \tag{3.12}$$

$$T = \mathrm{diag}(1, 1, 1, 1, \xi_3, \xi_3^2, 1, -1). \tag{3.13}$$

There is one non-trivial simple current (e, ψ_1) (namely primary #1), identifiable by the 1 in the corresponding entry of the 0th row of S. Since all entries of S are rational, the charge conjugation and the other Galois permutations σ_ℓ are trivial. Incidentally, groups G for which $S(G)$ is rational are rare; that property requires that the exponent of G divides 24 (e.g. the exponent of $\mathfrak{S}_3$ is 6). To see that, apply Prop.1(b) to the equation $(T_{a,a})^{\ell^2} = T_{\sigma_\ell a, \sigma_\ell a}$.

There are precisely 32 physical invariants for $\mathfrak{S}_3$. Write ch_i for the CFT character corresponding to the ith primary. The automorphism invariants are $M = I$, and the one (call it M') which interchanges $2 \leftrightarrow 3$ and fixes everything else. Extending by the simple current gives us 3 invariants:

$$|\mathrm{ch}_0 + \mathrm{ch}_1|^2 + 2|\mathrm{ch}_2|^2 + 2|\mathrm{ch}_3|^2 + 2|\mathrm{ch}_4|^2 + 2|\mathrm{ch}_5|^2 + k(\mathrm{ch}_2\mathrm{ch}_3^* + \mathrm{ch}_3\mathrm{ch}_2^* - |\mathrm{ch}_2|^2 - |\mathrm{ch}_3|^2), \tag{3.14}$$

for $k = 0, 1, 2$. Write $s_1 := \mathrm{ch}_0 + \mathrm{ch}_1 + \mathrm{ch}_2 + \mathrm{ch}_3$, $s_2 := \mathrm{ch}_0 + \mathrm{ch}_1 + 2\mathrm{ch}_2$, $s_3 := \mathrm{ch}_0 + \mathrm{ch}_1 + 2\mathrm{ch}_3$, $s_4 := \mathrm{ch}_0 + \mathrm{ch}_2 + \mathrm{ch}_6$, and $s_5 := \mathrm{ch}_0 + \mathrm{ch}_3 + \mathrm{ch}_6$; then $s_i s_j^*$ is a physical invariant. The final ones are

$$|\mathrm{ch}_0 + \mathrm{ch}_1 + \mathrm{ch}_2 + \mathrm{ch}_3|^2 + k(\mathrm{ch}_2\mathrm{ch}_3^* + \mathrm{ch}_3\mathrm{ch}_2^* - |\mathrm{ch}_2|^2 - |\mathrm{ch}_3|^2), \tag{3.15}$$

for $k = \pm 1$.

In the next section we manage to identify general constructions yielding most of these physical invariants. Two however remain unexplained: the automorphism invariant M', and the modular invariance of the sum s_1.

Note that in the basis defined by ($\xi = \xi_3 = \exp[2\pi \mathrm{i}/3]$)

$$\begin{aligned}(e_0, \ldots, e_7) \;=\; (&\mathrm{ch}_0 - \mathrm{ch}_1\,,\, \mathrm{ch}_0 + \mathrm{ch}_1 + 2\mathrm{ch}_2\,,\, \mathrm{ch}_0 + \mathrm{ch}_1 - \mathrm{ch}_2\,,\, \mathrm{ch}_3 + \mathrm{ch}_4 + \mathrm{ch}_5\,,\\ &\mathrm{ch}_3 + \xi\mathrm{ch}_4 + \xi^2\mathrm{ch}_5\,,\, \mathrm{ch}_3 + \xi^2\mathrm{ch}_4 + \xi\mathrm{ch}_5\,,\, \mathrm{ch}_6 + \mathrm{ch}_7\,,\, \mathrm{ch}_6 - \mathrm{ch}_7), \end{aligned} \tag{3.16}$$

the matrices S and T become permutation matrices (both non diagonal), corresponding respectively to the permutations (06)(23)(45) and (345)(67) of $\mathfrak{S}_8$ (written in terms of cycles). From this, it is not difficult to compute the dimension (over $\mathbb{C}$) of the commutant of S and T, which turns out to be 11. Hence the 32 physical invariants are not linearly independent (e.g. $s_2 + s_3 = 2s_1$ and $2s_4 - 2s_5 = s_2 - s_3$).

Incidentally, it is a consequence of [6] that for any G, such a basis can always be found in which S and T are permutation matrices. In particular, the characters $\mathrm{ch}_{(a,\chi)}$, for $(a,\chi) \in \Phi$, can be thought of as a function on $G \times G$ taking any pair (xax^{-1}, xbx^{-1}) to $\chi(b)$ when a and b commute, and sending all other pairs in $G \times G$ to 0. They span a space called $C^0(G_{comm})$ in [12]. Now choose any commuting pair $(a,b) \in G \times G$, and define the function $f_{(a,b)}$ to be identically 1 on the set (xax^{-1}, xbx^{-1}) and 0 elsewhere. Then these functions form another basis for $C^0(G_{comm})$. For this choice of basis, our representation of $\mathrm{SL}_2(\mathbb{Z})$ becomes manifestly a permutation representation: $\begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}_2(\mathbb{Z})$ acts on the right by sending $f_{(g,h)}$ to $f_{(g^a h^c, g^b h^d)}$. For instance, we recover T by noting that

$$\mathrm{ch}_{(a,\chi)}(a, ab) = \chi(ab) = \frac{\chi(a)}{\chi(e)}\,\chi(b) = T_{(a,\chi),(a,\chi)}\mathrm{ch}_{(a,\chi)}\ . \tag{3.17}$$

(See equation (5.12) of [12] for the corresponding matrix S calculation.) It is a very special property of the (untwisted) finite group modular data that this $\mathrm{SL}_2(\mathbb{Z})$ representation is actually a permutation representation. For general modular data, usually the matrix T won't even be conjugate to a permutation matrix. Two examples are the simplest affine data, i.e. $A_1^{(1)}$ at level 1, and the simplest twisted group data, $G = \mathbb{Z}_2$ with twist α_1 (see §6.1), whose matrices T are respectively

$$\mathrm{diag}\,(\exp[-\pi\mathrm{i}/12], \exp[5\pi\mathrm{i}/12]) \qquad \text{and} \qquad \mathrm{diag}\,(1, 1, \mathrm{i}, -\mathrm{i})\ . \tag{3.18}$$

The first cannot be similar to a permutation matrix because it does not have 1 as an eigenvalue, while the second cannot because an order 4 permutation matrix has -1 as an eigenvalue.

Incidentally, the analogue of this permutation representation for the twisted finite group data is known [11], and will be discussed in §5.3.

A total of 32 physical invariants for such a small number of primaries is completely unprecedented from the more familiar WZW situation. The orthogonal algebras at level 2 are the worst behaved affine cases, but e.g. $D_{16}^{(1)}$ at level 2 has 23 primaries but only 22 physical invariants. But $\mathfrak{S}_3$, being a dihedral group, is nearly abelian so should be especially bad in this respect.

It seems that the twisted data is better behaved in this respect than the untwisted. For example, we find, combining the discussion of §6.3 with the results of [33], that the twisted modular data for $\mathfrak{S}_3$ has only 9 physical invariants.

4 Making sense of all the physical invariants

We learned in the previous section that there is a surprising number of physical invariants associated to finite group modular data. In this section we try to tame the zoo!

The conventional wisdom in RCFT is that all physical invariants are constructed in two ways: as extensions of chiral algebras, and as automorphisms of those chiral algebras (called automorphism invariants in the unextended case). In the affine case, the physical invariants are almost always 'obvious' in hindsight, as symmetries of the appropriate Dynkin diagram (e.g. simple currents and charge conjugation) are directly responsible for almost all WZW physical invariants. It would be nice to find the analogous statement for the finite group modular data.

A rich supply of physical invariants always comes from simple currents [26, 27]. As these are well-understood, we won't say any more than we did in §2.

4.1 Automorphism invariants

The outer automorphism group $\mathrm{Out}(G)$ provides a systematic way of constructing automorphism invariants. Choose any $\pi \in \mathrm{Out}(G)$. Then π induces an invertible homomorphism $C_G(a) \to C_G(\pi a)$ between centralisers. Define χ^π by the formula $\chi^\pi(g) = \chi(\pi^{-1}g)$ — if $\chi \in \mathrm{Irr}(C_G(a))$ then $\chi^\pi \in \mathrm{Irr}(C_G(\pi a))$. Consider the permutation of Φ defined by $(a, \chi) \mapsto (\pi a, \chi^\pi)$. Then it commutes with S and T and hence defines an automorphism invariant.

Many (but not all) outer automorphisms can be interpreted in the following way: Any time a given group G is a normal subgroup of another group $\widehat{G}$, then any element $\hat{g} \in \widehat{G}$ defines an automorphism of G by conjugation: $g \mapsto \hat{g}g\hat{g}^{-1}$.

Examples of these groups are $\mathrm{Out}(\mathbb{Z}_n) \cong \mathbb{Z}_n^\times$; $\mathrm{Out}(\mathfrak{D}_{2k+1}) \cong \mathbb{Z}_{2k+1}^\times/\{\pm 1\}$; for $n \geq 3$, $\mathrm{Out}(\mathfrak{S}_n) = \{1\}$ and $\mathrm{Out}(\mathfrak{A}_n) \cong \mathbb{Z}_2$, except $\mathrm{Out}(\mathfrak{S}_6) \cong \mathbb{Z}_2$ and $\mathrm{Out}(\mathfrak{A}_6) \cong \mathbb{Z}_2 \times \mathbb{Z}_2$.

Another systematic source are the Galois automorphism invariants — there is one of these for every $\sigma_\ell \in \mathrm{Gal}(\mathbb{Q}(S)/\mathbb{Q})$ with $\ell^2 \equiv 1$ modulo the exponent $e(G)$ of G, and the permutation is simply given by the Galois permutation, which we may write $\sigma_\ell(a, \chi) = (a^\ell, \sigma_\ell \chi)$. If there are s distinct primes which divide $e(G)$, then there will be precisely

$$\begin{cases} 2^{s-1} & \text{if } e(G) \equiv 2 \pmod 4 \\ 2^{s+1} & \text{if } e(G) \equiv 0 \pmod 8 \\ 2^s & \text{otherwise} \end{cases} \tag{4.1}$$

such ℓ, and hence that number of Galois automorphism invariants (though these won't necessarily be distinct, if $\mathbb{Q}(S)$ is smaller than $\mathbb{Q}(\xi_{e(G)})$).

A final source of automorphism invariants is *discrete torsion* [19]. This involves the language of cohomology — see §5.1 for the appropriate definitions. Take any 2-cocycle $\beta \in Z^2(G, U(1))$ for G. This β is entirely independent of the 2-cocycles β_a we discuss in §5.2. For each conjugacy class representative $a \in R$, define $e_a(b) := \beta(a, b)\beta(b, a)^{-1}$. This will be a 1-dimensional representation of $C_G(a)$. Define the permutation of primary fields $(a, \chi) \in \Phi$ sending (a, χ) to $(a, e_a\chi)$. It is easy to check that this commutes with S and T and thus defines an automorphism invariant.

When is this permutation trivial ? Iff each $e_a(b) = 1$, for all $b \in C_G(a)$. In other words, iff each $a \in G$ is β-regular (see §5.1 for the definition). One thing this means is that cohomologous β give the same discrete torsion. So the possibilities for discrete torsion are given by the classes in the finite abelian group $H^2(G, U(1)) = M(G)$, known as the Schur multiplier of G. Each class in $M(G)$ will usually but not always give rise to a different automorphism invariant. Incidentally, this construction applies to untwisted, CT twisted, or non-CT twisted, modular data (see next section for the twisted modular data).

So discrete torsion will always give $|M(G)|$ automorphism invariants, although these are not necessarily all distinct. They are all distinct for $\mathbb{Z}_n^2$, $\mathbb{Z}_n^3$, and $\mathfrak{D}_{even}$.

4.2 Chiral extensions

Making sense of the large number of physical invariants also requires finding the "generic" chiral extensions. Many will come from simple currents. It is tempting to suspect that another rich source could be from certain normal subgroups $N \triangleleft G$.

In particular, Clifford theory (which is concerned with the theory of induced and restricted characters) can be used to explicitly relate the modular data of a group G to that of its normal subgroups H. The formulas we have obtained however are complicated enough that at this point we have been unable to determine explicit relations between the physical invariants of G and H. Nevertheless, the situation is sufficiently analogous to that of conformal embeddings [43] in affine algebras that we expect this to likewise be a rich source of chiral extensions. Incidentally, there are also relations between the modular data of G and G/N.

Nevertheless we have found some interesting generic chiral extensions. Choose any central elements $z, z' \in Z(G)$ and any degree-1 characters $\varphi, \psi \in \mathrm{Irr}(G)$. Define the combinations

$$s_{z,z'} := \sum\nolimits_{\chi \in \mathrm{Irr}(G)} \chi(z') \, \mathrm{ch}_{(z,\chi)} \tag{4.2}$$

$$s'_{\varphi,\psi} := \sum\nolimits_{g \in R} \psi(g) \, \mathrm{ch}_{(g,\varphi)} \tag{4.3}$$

Then it is easy to verify, using (2.17), Frobenius reciprocity, and the orthogonality relations for characters, that $s_{z,z'}(-1/\tau) = s_{z',z^{-1}}(\tau)$ and $s'_{\varphi,\psi}(-1/\tau) = s'_{\psi,\varphi^*}(\tau)$, while $s_{z,z'}(\tau+1) = s_{z,zz'}(\tau)$ and $s'_{\varphi,\psi}(\tau+1) = s'_{\varphi,\varphi\psi}(\tau)$. To see this, consider the coefficient of $\mathrm{ch}_{(a,\chi)}(\tau)$ in $s'_{\varphi,\psi}(-1/\tau)$: it will be

$$\sum_{g \in R} \psi(g) \, \frac{1}{|G|} \, \varphi(a)^* \chi^G_{C_G(a)}(g)^* \tag{4.4}$$

which is $\varphi(a)^*$ times the coefficient of ψ in $\chi^G_{C_G(a)}$, i.e. $\varphi(a)^*$ times the coefficient of χ in $\psi|_{C_G(a)}$, i.e. $\varphi(a)^* \delta_{\psi,\chi}$.

Choose any subgroups $A \leq Z(G)$, $B \leq G/G'$, and define the sums

$$s(A) = \frac{1}{|A|} \sum_{z,z' \in A} s_{z,z'} = \sum_{z \in A} \sum_{\chi : \ker(\chi) \geq A} \chi(e) \, \mathrm{ch}_{z,\chi} \tag{4.5}$$

$$s'(B) = \frac{1}{|B|} \sum_{\varphi,\psi \in B} s'_{\varphi,\psi} = \sum_{\psi \in B} \sum_{g \in \ker(B) \cap R} \mathrm{ch}_{g,\psi} \tag{4.6}$$

By $\ker(\chi)$ we mean all $g \in G$ for which $\chi(g) = \chi(e)$, and by $\ker(B)$ we mean the intersection of all $\ker(\psi)$, where $\psi \in B$ is identified with a degree-1 character of G. Note that the sums $s(A), s'(B)$ are all invariant under S and T. Thus *for any* G, A, A', B, B' we get the remarkable physical invariants

$$s(A)^*\,s(A'),\quad s(A)^* s'(B),\quad s'(B)^* s(A),\quad s'(B)^*\,s'(B'). \tag{4.7}$$

In the case of $\mathfrak{S}_3$ which we worked out in §3.3, $s(e) = s_2$, $s'(\psi_0) = s_5$, and $s'(\psi_0, \psi_1) = s_3$. This alone accounts for 9 of the 32 physical invariants for $\mathfrak{S}_3$.

Incidentally, taking A and B to be the trivial groups completes the proof of Proposition 1(h): the fifth physical invariant of course is the diagonal sum. For the second claim there, there is a natural degree-preserving bijection (see §3.5 of [3]) between the $\chi \in \mathrm{Irr}(G)$ with $\ker(\chi) \geq Z(G)$, and $\mathrm{Irr}(G/Z(G))$, so if $G/Z(G)$ is nonabelian there will always be degree > 1 characters appearing in each $s(A)$ and so they will be different from any $s'(B)$.

5 Twisting, Group Cohomology, and Projective Representations

As advertised in the introduction, one way to generalize the group data described in Section 2 is by introducing some "twisting". This twisting has a cohomological origin, as in the theory of affine algebras [29], where the infinitely many possible twists are labelled by the level k, an integer. In constrast, the twisting of the finite group modular data offers but a finite number of possibilities.

The twisting of this modular data was first described in the most generality by [4, 7, 20] (see also [6]), although to our knowledge explicit expressions for the modular matrices S and T in the most general case have not appeared until now (though the most general fusions appear in (6.44) of [4]). We will recall here their construction, as concretely as possible, and then we will compute explicit examples, making contact with known structures (most notably affine algebras).

5.1 Cohomological preliminaries

As a twisting of the finite group modular data is effected by elements of cohomology groups $H^i(G, U(1)) \cong H^i(G, \mathbb{C}^\times) \cong H^{i+1}(G, \mathbb{Z})$, we will first review the relevant properties and give some examples. For our purposes it is not very important to know how these are defined. We refer the reader to standard textbooks (like [38]) for a more complete treatment. For projective representations, see [2].

For all $i > 0$, $H^i(G, U(1))$ is a finite abelian group, which we will usually write additively, obeying $|G|H^i(G, U(1)) = 0$ (i.e. all elements have order dividing the order of G). For any G, $H^0(G, U(1)) = 0$, while $H^1(G, U(1)) = G/G'$ is the group of one-dimensional representations of G (G' is the commutator subgroup). The next group $M(G) := H^2(G, U(1))$, called the Schur multiplier (or multiplicator), classifies the (projectively) inequivalent projective representations, and for that reason, it will play a central role in the whole construction. The only other group we will be interested in is $H^3(G, U(1))$.

The following results can be useful: the square of the exponent of $M(G)$ divides $|G|$; if G is a p-group (i.e. its order is a power of a prime), then $H^3(G, U(1)) \neq 0$; if e is the exponent of G and e_i is the exponent of $H^i(G, U(1))$, then ee_2, e_1e_2 and e_2e_3 all divide $|G|$.

Computing cohomology groups, even $M(G)$, is usually difficult. They are known however for several familiar groups. For a cyclic group, one has $M(\mathbb{Z}_n) = 0$ and $H^3(\mathbb{Z}_n, U(1)) = \mathbb{Z}_n$. For products of identical cyclic groups,

$$M(\mathbb{Z}_n^k) = \mathbb{Z}_n^{k(k-1)/2}, \quad H^3(\mathbb{Z}_n^k, U(1)) = \mathbb{Z}_n^{k(k^2+5)/6}. \tag{5.1}$$

More generally, the Schur multiplier for any abelian group is as follows: write $G = \mathbb{Z}_{d_1} \times \mathbb{Z}_{d_2} \times \cdots \times \mathbb{Z}_{d_s}$ where $d_1|d_2|\cdots|d_s$, then

$$M(G) = \prod_{j=1}^{s} \mathbb{Z}_{d_j}^{j-1}. \tag{5.2}$$

Other known groups are (see e.g. Ch.6 of [3])

$$\begin{aligned}
&M(\mathfrak{S}_3) = 0, \quad H^3(\mathfrak{S}_3, U(1)) = \mathbb{Z}_6, \quad M(\mathfrak{S}_n) = \mathbb{Z}_2 \quad \text{for } n \geq 4, && (5.3)\\
&M(\mathfrak{A}_n) = \mathbb{Z}_2 \quad \text{for } n \geq 4,\ n \neq 6, 7, \quad M(\mathfrak{A}_n) = \mathbb{Z}_6 \quad \text{for } n = 6, 7, && (5.4)\\
&M(\mathfrak{D}_n) = 0, \quad H^3(\mathfrak{D}_n, U(1)) = \mathbb{Z}_{2n} \qquad \text{for } n \text{ odd}, && (5.5)\\
&M(\mathfrak{D}_n) = \mathbb{Z}_2, \quad H^3(\mathfrak{D}_n, U(1)) = \mathbb{Z}_n \times \mathbb{Z}_2 \times \mathbb{Z}_2 \qquad \text{for } n \text{ even}, && (5.6)\\
&M(\mathfrak{Q}_n) = 0, \quad H^3(\mathfrak{Q}_4, U(1)) = \mathbb{Z}_8, && (5.7)\\
&M(\mathrm{SL}_n(\mathbb{F}_q)) = 0, && (5.8)\\
&M(\mathrm{PSL}_n(\mathbb{F}_q)) = \mathbb{Z}_{\gcd(q-1,n)}, && (5.9)
\end{aligned}$$

where in (5.8) and (5.9), $(n, q) \notin \{(2, 4), (2, 5), (2, 7), (2, 9), (3, 2), (3, 3), (3, 4), (4, 2)\}$.

For odd prime p, there are precisely two different non-abelian groups of order p^3: one of these (a split extension of cyclic groups, the $p \neq 2$ analogue of $\mathfrak{D}_4$) has $M = 0$ and $H^3 = \mathbb{Z}_p \times \mathbb{Z}_p$; the other has $M = \mathbb{Z}_p \times \mathbb{Z}_p$ and $H^3 = \mathbb{Z}_p \times \mathbb{Z}_p \times \mathbb{Z}_p \times \mathbb{Z}_p$. (All groups of order p^2 are abelian.)

This gives some taste of what $M(G)$ and $H^3(G)$ look like for nice groups. The Schur multiplier is known for all simple groups. For instance it is trivial for the Monster.

As mentioned before, the Schur multiplier plays a central role in the theory of projective representations. Indeed a normalised 2-cocycle $\beta \in Z^2(G, U(1))$ is a map $G \times G \to U(1)$ satisfying $\beta(x, 1) = \beta(1, x) = 1$ and the cocycle condition $\beta(x, y)\,\beta(xy, z) = \beta(y, z)\,\beta(x, yz)$ for all $x, y, z \in G$. For any such β, one may consider the projective β-representations, i.e. the maps $\tilde{\rho} : G \to \mathrm{GL}(V)$ obeying $\tilde{\rho}(x)\tilde{\rho}(y) = \beta(x, y)\tilde{\rho}(xy)$. The cocycle condition corresponds to associativity. If β is identically 1, $\tilde{\rho}$ will be an ordinary representation and will be called *linear*.

If β, β' are cohomologous (i.e. $\beta^{-1}\beta'$ is a 2-coboundary – a *2-coboundary* is any $\beta \in Z^2$ of the form $\beta = \gamma(x)\gamma(y)\gamma(xy)^{-1}$), then any β'-representation will be projectively equivalent to some β-representation, and there will be the same number of k-dimensional β-representations as k-dimensional β'-representations, for each $k = 1, 2, \ldots$. Moreover, a β-representation can be one-dimensional only if β is a coboundary.

A natural question is to classify the projective representations belonging to a given cocycle. So let $r(G, \beta)$ denote the number of linearly inequivalent irreducible β-representations of G. We know that $r(G, \beta)$ is a cohomology class invariant. In order to compute this number, one introduces the notion of a β-regular group element: $g \in G$ is β-regular if $\beta(g, h) = \beta(h, g)$

for all h in $C_G(g)$. One may check that g is β-regular if and only if all its conjugates are, so that a whole conjugacy class is β-regular or not. Then

$$r(G,\beta) = \text{number of } \beta\text{−regular conjugacy classes of } G. \tag{5.10}$$

As an immediate consequence, one has the inequality $r(G,\beta) \leq k(G) = r(G,1)$ for any 2-cocycle β, with equality if (but not only if) β is a coboundary.

The projective characters $\tilde{\chi} \in \beta\text{-Irr}(G)$ (defined as usual by the trace of the representation) share many properties with the usual characters, except that they are in general not class functions. Schur's lemma still holds, from which orthogonality and completeness relations follow: for any $\tilde{\chi}, \tilde{\chi}' \in \beta\text{-Irr}(G)$ and any β-regular $a \in G$,

$$\frac{1}{|G|}\sum_{g\in G} \tilde{\chi}(g)^*\, \tilde{\chi}'(g) = \delta_{\tilde{\chi},\tilde{\chi}'}, \tag{5.11}$$

$$\frac{|K_a|}{|G|}\sum_{\tilde{\chi}\ \beta-\mathrm{Irr}} \tilde{\chi}(a)^*\, \tilde{\chi}(b) = \delta_{b\in K_a}\,. \tag{5.12}$$

The dimensions of the irreducible projective representations divide the order of the group, and their squares sum up to $|G|$. All β-characters vanish at non-regular classes.

Examples of projective representation data include the following. Writing $H^2(\mathbb{Z}_n^2, U(1)) = \langle\beta_1\rangle \cong \mathbb{Z}_n$ and $H^2(\mathbb{Z}_n^3, U(1)) = \langle\beta_1,\beta_2,\beta_3\rangle \cong \mathbb{Z}_n^3$, one finds

$$r(\mathbb{Z}_n^2, \beta_1^x) = [\mathrm{GCD}(x,n)]^2, \qquad r(\mathbb{Z}_n^3, \beta_1^x\,\beta_2^y\,\beta_3^z) = n\cdot[\mathrm{GCD}(x,y,z,n)]^2. \tag{5.13}$$

for any $1 \leq x,y,z \leq n$. For the dihedral groups, one has

$$r(\mathfrak{D}_{2n+1},\beta) = n+2, \qquad r(\mathfrak{D}_{2n},\beta) = \begin{cases} n+3 & \text{if } \beta \text{ is coboundary,} \\ n & \text{otherwise.}\end{cases} \tag{5.14}$$

These numbers are known also for $\mathfrak{S}_n$ and $\mathfrak{A}_n$.

5.2 General construction

The possible twistings are parametrised by the finitely many elements $\alpha \in H^3(G,U(1))$. The 3-cocycle condition is $\alpha(g,h,k)\,\alpha(g,hk,\ell)\,\alpha(h,k,\ell) = \alpha(gh,k,\ell)\,\alpha(g,h,k\ell)$. Different 3-cocycles give rise to different modular data, with in general different numbers of primary fields (never more than in the untwisted case), and with matrices S^α and T^α.

The construction starts from a normalised[§] element α of $H^3(G,U(1))$. We can and will assume for convenience that the values of α are always roots of 1 – in fact if α has cohomological order n, then we can require α to take the values of nth roots of 1 (proof: Write $\alpha^n = \delta\beta$; choose any $\gamma = \beta^{-1/n}$, then $\alpha\gamma$ is cohomologous to α and has the desired property.) Because $|G|\,H^3(G,U(1)) = 0$, n will necessarily divide $|G|$.

For all $a,g,h \in G$, we define auxiliary quantities

$$\beta_a(h,g) = \alpha(a,h,g)\,\alpha(h,h^{-1}ah,g)^{-1}\,\alpha(h,g,(hg)^{-1}ahg). \tag{5.15}$$

[§] That is, it satisfies $\alpha(e,h,g) = \alpha(h,e,g) = \alpha(h,g,e) = 1$. This implies that all 2-cocycles are accordingly normalised, $\beta_e(h,g) = \beta_h(e,g) = \beta_h(g,e) = 1$ for all h,g.

It follows from this definition that the β_a's are normalised twisted cocycles on G, namely they satisfy

$$\beta_a(x,y)\,\beta_a(xy,z) = \beta_a(x,yz)\,\beta_{x^{-1}ax}(y,z), \qquad \forall x,y,z \in G. \tag{5.16}$$

Furthermore, the restriction of each β_a to $C_G(a)$ clearly is a normalised 2-cocycle. As such they define projective representations of $C_G(a)$.

The primary fields Φ^α in the model twisted by a given 3-cocycle α will consist of all pairs $(a,\tilde{\chi})$ where $a \in R$ (as before) and $\tilde{\chi} \in \beta_a$-$\mathrm{Irr}(C_G(a))$. As a consequence of the inequality $r(H,\beta) \le k(H)$, we find

$$|\Phi^\alpha| = \sum_{a \in R} r(C_G(a), \beta_a) \le |\Phi|. \tag{5.17}$$

A simplification seems to occur when the 3-cocycle α is such that each 2-cocycle β_a is a coboundary on $C_G(a)$, which is the case considered in [6]. We call the resulting twisting "CT" (cohomologically trivial). Note that when $M(C_G(a)) = 0$ for all a, any twist α will automatically be CT. By no means though are CT twistings restricted to the groups whose centralisers have trivial Schur multipliers — see §6.2 for a class of examples. A CT-twisted theory has the same number of primaries as the untwisted one considered in the previous sections (but different modular matrices).

For CT twistings, [6, 4] proposed explicit formulae for the modular matrices that resemble the untwisted case except with additional phases. Each β_a being a coboundary on $C_G(a)$ by hypothesis, (5.16) can be used to show[¶] that one can find 1-cochains $\epsilon_a : C_G(a) \to U(1)$ for which $\epsilon_a(e) = 1$ and both

$$\beta_a(h,g) = (\delta\epsilon_a)(h,g) = \epsilon_a(h)\,\epsilon_a(g)\,\epsilon_a(hg)^{-1}, \tag{5.18}$$

$$\epsilon_{x^{-1}ax}(x^{-1}hx) = \frac{\beta_a(x, x^{-1}hx)}{\beta_a(h,x)}\epsilon_a(h), \tag{5.19}$$

for all $g,h \in C_G(a)$ and $x \in G$. Now, if $\tilde{\rho}$ is a β_a-representation with character $\tilde{\chi}$, then clearly $\rho(g) = \epsilon_a^{-1}(g)\tilde{\rho}(g)$ is a linear representation with character $\chi = \epsilon_a^{-1}\tilde{\chi}$. The modular matrices then become [6]

$$S^\alpha_{(a,\chi),(a',\chi')} = \frac{1}{|C_G(a)| \cdot |C_G(a')|} \sum_{g \in G(a,a')} \chi^*(ga'g^{-1})\,\chi'^*(g^{-1}ag)\,\sigma^*(a|ga'g^{-1}), \tag{5.20}$$

$$T^\alpha_{(a,\chi),(a',\chi')} = \delta_{a,a'}\delta_{\chi,\chi'}\frac{\chi(a)}{\chi(e)}\,\epsilon_a(a), \tag{5.21}$$

where the function $\sigma(\cdot|\cdot)$ is

$$\sigma(h|g) = \epsilon_h(g)\,\epsilon_g(h). \tag{5.22}$$

(Since $g \in C_G(h)$ if and only if $h \in C_G(g)$, this definition makes sense.) It is easy to see that (5.20),(5.21) are (essentially, i.e. up to a relabelling of the characters χ) independent of the choice of 1-cochains ϵ_a in (5.18),(5.19). These equations permit CT twists to be analysed as thoroughly as the untwisted data.

The interpretation involving 3-cocycles was developed in [4]. Though they give the fusion coefficients for arbitrary α, neither they nor to our knowledge anyone else has given S^α and

---

[¶] We thank Peter Bántay for correspondence on this point.

T^α for nonCT α, *explicitly* in terms of quantities directly associated with G (the closest is [11], which gives S^α in terms of $D^\alpha(G)$ characters). The formulae in the most general case can be obtained by going back to first principles.

The quantum double $D^\alpha(G)$ is a finite dimensional quasi-Hopf quasi triangular algebra. Its representations form a braided monoidal modular category with explicitly known universal braiding morphisms R_{12} , R_{21}. The point is that (up to normalisation) the mapping class group representations, in our case the matrices S and T, can be identified with Markov traces of intertwiners defined from coloured ribbon links. In particular, S_{ij} corresponds to the i, j coloured Hopf link and T_i to the twist θ (or v^{-1} in the [20] convention). We then obtain (as explained in the Appendix)

$$\begin{aligned} S^\alpha_{(a,\tilde\chi),(b,\tilde\chi')} &= S^\alpha_{(e,1),(e,1)} \,\mathrm{Tr}_{(a,\tilde\chi),(b,\tilde\chi')} \Big(R_{21}R_{12}\Big)^* \\ &= \frac{1}{|G|} \sum_{g\in K_a, g'\in K_b\cap C_G(g)} \Big(\frac{\beta_g(g',x^{-1})\beta_{g'}(g,y^{-1})}{\beta_g(x^{-1},h)\beta_{g'}(y^{-1},h')}\Big)^* \,\tilde\chi(h)^*\,\tilde\chi'(h')^*, \\ &= \frac{1}{|G|} \sum_{g\in K_a, g'\in K_b\cap C_G(g)} \Big(\frac{\beta_a(x,g')\beta_a(xg',x^{-1})\beta_b(y,g)\beta_b(yg,y^{-1})}{\beta_a(x,x^{-1})\beta_b(y,y^{-1})}\Big)^* \,\tilde\chi(h)^*\,\tilde\chi'(h')^*, \end{aligned} \tag{5.23}$$

where $g = x^{-1}ax = y^{-1}h'y,\ g' = y^{-1}by = x^{-1}hx,\ h \in C_G(a),\ h' \in C_G(b)$, and

$$T^\alpha_{(a,\tilde\chi),(b,\tilde\chi')} = \delta_{a,b}\delta_{\tilde\chi,\tilde\chi'}\frac{\tilde\chi(a)}{\tilde\chi(e)}\,T^\alpha_{(e,1),(e,1)}, \tag{5.24}$$

where $T^\alpha_{(e,1),(e,1)}$ can equal any third root of 1 (i.e. c is a multiple of 8), as for the untwisted data. The normalisation $S^\alpha_{(e,1),(e,1)} = \frac{1}{|G|}$ can be obtained from the orthogonality relations (5.11),(5.12) of projective characters.

The phases β_g here are defined by (5.15). Note that they are evaluated in (5.23) on elements which are not in $C_G(a)$ or $C_G(b)$. Unfortunately this makes the derivation of (5.20) from (5.23) more difficult — see question (1) in §7.

If we let n be the cohomological order of α, then the β_a will also have nth roots of 1 as its values. Thm. 6.5.15 in [2] then implies that the projective β_a-characters will have values in $\mathbb{Q}[\xi_{n\,e(G)}]$. Hence the entries of S^α and T^α will also lie in that field. Note that this field specialises to $\mathbb{Q}[\xi_{e(G)}]$ in the untwisted ($n = 1$) case, which was our previous result.

That S^α and T^α depend only on the cohomology class $\alpha \in H^3(G, U(1))$, is clear from the $D^\alpha(G)$ interpretation. A direct derivation of this for CT α is sketched in [4].

5.3 Analysis of twisted modular data

It is important to realise that the 2-cocycle β_e in (5.15) is identically 1. Thus $(e, \chi) \in \Phi^\alpha$ for any $\chi \in \mathrm{Irr}(G)$, and we obtain the useful formula

$$S^\alpha_{(e,\chi),(b,\tilde\chi')} = \frac{1}{|C_G(b)|}\tilde\chi'(e)\,\chi(b)^* \tag{5.25}$$

We immediately see from this that once again all quantum dimensions will be integers, and $(a, \tilde{\chi}) \in \Phi^\alpha(G)$ will be a simple current iff $a \in Z(G)$ and $\tilde{\chi}$ is degree-one (which implies β_a is coboundary).

Rationality of the entries $S_{(e,1),(b,\tilde{\chi}')}$ implies all Galois parities $\epsilon_\sigma(a, \tilde{\chi}) = +1$, and also that the vacuum $(e, 1)$ is fixed by all Galois automorphisms, exactly as before.

From (5.25) we also learn about the Galois action on arbitrary primaries. Choose $\ell \in \mathbb{Z}^\times_{|G|^2}$, then $\sigma_\ell(a, \tilde{\chi}) = (a_\ell, \tilde{\chi}_\ell)$, where a_ℓ denotes the element in $K_{a^\ell} \cap R$ as before, and where $\tilde{\chi}_\ell$ is some projective β_{a_ℓ}-character with dimension equal to that of $\tilde{\chi}$. To see this, consider

$$\chi(a_\ell)^* = \sigma_\ell \frac{S^\alpha_{(e,\chi),(a,\tilde{\chi})}}{S^\alpha_{(e,1),(a,\tilde{\chi})}} = \sigma_\ell \chi(a)^* = \chi(a^\ell)^* \tag{5.26}$$

for all $\chi \in \mathrm{Irr}(G)$, and hence $a_\ell \in K_{a^\ell}$. In particular, specialising to $\ell = -1$ tells us about charge conjugation.

Proposition 1(a),(c),(e),(f) are thus exactly as before. As mentioned before, the order of T^α will divide ne, where n is the order of α, so in particular the order of T^α will always divide $|G|^2$. We also see directly from (5.23) that $S^\alpha_{(a,\tilde{\chi}),(b,\tilde{\chi}')} = 0$ unless $K_b \cap C_G(a)$ has β_a-regular elements and $K_a \cap C_G(b)$ has β_b-regular elements. Thm. 1 becomes

Theorem 3. Let S and T be the Kac-Peterson matrices corresponding to an affine algebra $X_r^{(1)}$ at some level $k \geq 1$ (where X_r is simple). Let G be a finite group with $S^\alpha(G) = S$ and $T^\alpha(G) = \varphi T$ for some third root φ of 1. Then either:

(i) as before, either $(X_r, k) = (E_8, 1)$ and $G = \{e\}$, or $(X_r, k) = (D_{8n}, 1)$ and $G = \mathbb{Z}_2$;

(ii) $(X_r, k) = (A_{n^2-1}, 1)$ and $G = \mathbb{Z}_n$, n odd, for a specific twist;

(iii) $(X_r, k) = (B_{(m^2-1)/2}, 2)$ and $G = \mathfrak{D}_m$, m odd, for a specific twist.

The proof is very similar to that of Theorem 1, the only difference being the specific handling of the finitely many algebras and levels which survive the Galois and quantum dimension arguments. For example, use the formulae $S_{00} = \frac{1}{\sqrt{r+1}}$ and $c = r$ for $A_r^{(1)}$ level 1. The demonstration of *(ii)* and *(iii)* is made explicit in section 6.

We would also like an analogue of Thm.2. This is more difficult, but a key observation is that $|\Phi^\alpha| \geq 2k(G) - 1$. Indeed, $\beta_e \equiv 1$ gives us $k(G)$ primaries of the form (e, χ), and the remaining $k(G) - 1$ conjugacy classes K_a will each contribute $r(a, \beta_a) \geq 1$ primaries. Also important is the observation made in §6.2 that β_a will always be coboundary when $C_G(a) \cong \mathbb{Z}_n^2$ for some n.

Theorem 4. The only groups with at most 20 primaries are $\mathbb{Z}_1$, $\mathbb{Z}_2$, $\mathbb{Z}_3$, $\mathfrak{S}_3$, $\mathfrak{A}_4$, $\mathbb{Z}_4$, $\mathbb{Z}_2 \times \mathbb{Z}_2$, $\mathfrak{D}_5$, $\mathfrak{S}_4$, $\mathfrak{D}_4$, and the order 48 Frobenius group $\mathbb{Z}_2^4 \times_f \mathbb{Z}_3$ (defined in [35]), with at least 1, 4, 9, 8, 14, 16, 16, 16, 18, 19, and 19 primaries.

The proof is like that of Thm.2, using the tables of [35]. For instance, we know it is sufficient to consider up to class number $k(G) = 8$. Consider e.g. $G = \mathfrak{S}_4$: it has $k(G) = 5$ and centralisers $\mathfrak{S}_4$, $\mathfrak{D}_4$, $\mathbb{Z}_4$, $\mathbb{Z}_2 \times \mathbb{Z}_2$, and $\mathbb{Z}_3$. Thus a lower bound for $|\Phi^\alpha|$ is $5 + 2 + 4 + 4 + 3 = 18$.

In §3.3 we gave a basis in terms of which the untwisted S and T become permutation matrices. The analogue of this for the twisted data is as follows [11]. Let $C^\alpha(G_{comm})$ denote the space of all functions $f : G \times G \to \mathbb{C}$ for which $f(a, b) = 0$ unless a and b commute, and which obey the formula

$$f(x^{-1}ax, x^{-1}bx) = \frac{\beta_a(x, x^{-1}bx)}{\beta_a(b, x)} f(a, b) \tag{5.27}$$

Then S and T act on $C^\alpha(G_{comm})$ by $(Sf)(a, b) = \beta_b(a, a^{-1})^* f(b, a^{-1})$ and $(Tf)(a, b) = \beta_a(a, b)\, f(a, ab)$. See Questions 5 and 7 of §7. Incidentally, this action is completely natural in the case of twisted partition functions which involve projective representations of the symmetry group in some twisted sectors, and follows from the action of the modular group on the homological cycles of the torus — see [39] for examples in WZW models.

6 Twisted examples

We give in this final section a few examples of twisted finite group modular data, in order to give a flavour as to how they differ from the untwisted ones.

6.1 Abelian cyclic groups

One can easily illustrate the previous formalism in the case of a cyclic group $G = \mathbb{Z}_n$. Write $\langle\cdot\rangle : \mathbb{Z} \to \{0, 1, \ldots, n-1\}$ for reduction modulo n. One has $H^3(\mathbb{Z}_n, U(1)) = \mathbb{Z}_n$, and the following explicit representatives

$$\alpha_q(g_1, g_2, g_3) = \exp\Big\{2\mathrm{i}\pi q g_1(g_2 + g_3 - \langle g_2 + g_3\rangle)/n^2\Big\}, \tag{6.1}$$

where $q \in \mathbb{Z}_n$ parametrizes the different classes.

One easily computes that $\beta_a(h, g) = \alpha_q(a, h, g)$ is a coboundary for every q (expected since $M(\mathbb{Z}_n) = 0$). One finds $\sigma(h|g) = e^{4\mathrm{i}\pi qhg/n^2}$.

The linear characters of $\mathbb{Z}_n$ are $\chi_\ell(a) = e^{2\mathrm{i}\pi a\ell/n}$ for $\ell \in \mathbb{Z}_n$, and the modular matrices take the simple forms

$$S^{\alpha_q}_{(a,\chi_\ell),(a',\chi_{\ell'})} = \frac{1}{n}\,\exp\Big\{-2\mathrm{i}\pi[2qaa' + n(a\ell' + a'\ell)]/n^2\Big\}, \tag{6.2}$$

$$T^{\alpha_q}_{(a,\chi_\ell),(a,\chi_\ell)} = \exp\Big\{2\mathrm{i}\pi[qa^2 + na\ell]/n^2\Big\}. \tag{6.3}$$

Note that the charge conjugation $C = S^2$ is given $C(0, \chi_\ell) = (0, \chi_{-\ell})$ and $C(a, \chi_\ell) = (n - a, \chi_{-\ell-2q})$ if $a \neq 0$.

The identity corresponds to $(0, \chi_0)$, and as in the untwisted case, all primary fields are simple currents. The Verlinde formula yields the fusion coefficients

$$N^{(a'',\chi_{\ell''})}_{(a,\chi_\ell),(a',\chi_{\ell'})} = \delta_{a'',\langle a+a'\rangle}\,\delta_{\ell'',\ell+\ell'+2q(a+a'-a'')/n}. \tag{6.4}$$

This is in agreement with the charge conjugation, if one thinks of the conjugate of a field ϕ as the unique field ϕ^* such that the fusion $\phi \times \phi^*$ contains the identity. The fusion group (the group of simple currents) is isomorphic to $\mathbb{Z}_f \times \mathbb{Z}_{n^2/f}$ with $f = \mathrm{GCD}(2q, n)$.

The entries of S and T lie in $\mathbb{Q}(\xi_{n^2})$, which has Galois group $\mathbb{Z}_{n^2}^\times$. It is not difficult to see that the Galois action on the primaries is by fusion powers (as is always the case for simple currents):

$$\sigma_h(a,\chi_\ell) = (a,\ell)^{\times h}, \qquad h \in \mathbb{Z}_{n^2}^\times. \tag{6.5}$$

The physical invariants are known in all cases, since all primaries are simple currents. Their number varies much with the value of q (of f). Two extreme cases are $f=1$ ('maximal' twisting) for which the number of physical invariants is equal to $\sigma_0(n^2)$, the number of divisors of n^2 [40], and $f=n$ (no twisting), for which their number is $2(n+1)$ if n is odd prime [27].

We close this simple example by showing that it gives, for a specific twisting, the affine modular data of su(n^2), level 1, if n is an odd integer.

One may first make a few simple observations. The central charge of su$(n^2)_1$ is equal to $c \equiv n^2-1 \equiv 0 \pmod 8$ for n odd. The affine quantum dimensions $S_{0,j}/S_{0,0}=1$ all equal 1, so all affine primaries are simple currents, and form a group isomorphic to $\mathbb{Z}_{n^2}$. Thus one may hope for a relation with twisted $G=\mathbb{Z}_n$ data where the twist obeys $f=\mathrm{GCD}(q,n)=1$.

The affine primaries can be labelled by integers $j=0,1,2,\ldots,n^2-1$ modulo n^2. The affine matrices S and T are

$$S^{\mathrm{aff}}_{j,j'} = \frac{1}{n}\, e^{2\mathrm{i}\pi jj'/n^2}, \tag{6.6}$$

$$T^{\mathrm{aff}}_{j,j} = T_{0,0}\, e^{2\mathrm{i}\pi j(n^2-j)/2n^2}, \tag{6.7}$$

where $T_{0,0}=e^{2\mathrm{i}\pi c/24}$ is some third root of unity, which we will ignore.

It is now a simple matter to see that the two sets of matrices exactly coincide provided one chooses the twisting parameter as $q=\frac{n^2-1}{2}$. The bijection $j \leftrightarrow (a,\chi_\ell)$ between the two sets of primary fields is given by $j=a-n\ell$. Note that for this specific value of q, the fusion coefficients (6.4) amount to the addition modulo n^2.

6.2 Abelian non-cyclic groups

The simplest non-cyclic group is $G=\mathbb{Z}_n^2$, but it leads to nothing really new. The cohomology group $H^3(\mathbb{Z}_n^2,U(1))=\mathbb{Z}_n^3$ has three generators, but all 3-cocycles α lead to β's which are all coboundaries. Thus all twistings are CT, despite the fact that the Schur multiplier $M(\mathbb{Z}_n^2)=\mathbb{Z}_n$ is not trivial. (This fact was important for the proof of Thm.4.)

More interesting is the case $G=\mathbb{Z}_n^3$, for which $M(\mathbb{Z}_n^3)=\mathbb{Z}_n^3$ and $H^3(\mathbb{Z}_n^3,U(1))=\mathbb{Z}_n^7$. Following [41, 42], the generators of H^3 can be taken to be (same notations as above, the group elements are triplets $a=(a_1,a_2,a_3)$)

$$\alpha_I^{(j)}(a,b,c) = \exp\Big\{2\mathrm{i}\pi a_j(b_j+c_j-\langle b_j+c_j\rangle)/n^2\Big\}, \qquad 1\le j\le 3, \tag{6.8}$$

$$\alpha_{II}^{(jk)}(a,b,c) = \exp\Big\{2\mathrm{i}\pi a_j(b_k+c_k-\langle b_k+c_k\rangle)/n^2\Big\}, \qquad 1\le j<k\le 3, \tag{6.9}$$

$$\alpha_{III}(a,b,c) = \exp\Big\{2\mathrm{i}\pi a_1b_2c_3/n\Big\}. \tag{6.10}$$

An arbitrary 3-cocycle is a monomial in the generators, but only those which involve a non-trivial power of α_{III} define non-CT twistings. In other words, all α which contain a fixed cocycle of type III give rise to 2-cocycles β_a which are cohomologically equivalent, and hence lead to theories with the same number of primaries. In order to give a first feeling for non-CT twistings, we will compute the number of primary fields. It is sufficient to take α of type III, namely $\alpha = \alpha_{III}^q$, for $q \in \mathbb{Z}_n$. The 2-cocycles one obtains are then

$$\beta_a(b,c) = \exp\Big\{2\mathrm{i}\pi q(a_1b_2c_3 - b_1a_2c_3 + b_1c_2a_3)/n\Big\}. \tag{6.11}$$

Given a, we want to count the number of classes b (elements here) which are β_a-regular, i.e. which satisfy $\beta_a(b,c) = \beta_a(c,b)$ for all c. Taking successively $c = (1,0,0), (0,1,0)$ and $(0,0,1)$, the β_a-regular elements b are those which satisfy

$$a_2b_3 - a_3b_2 \equiv a_1b_3 - a_3b_1 \equiv a_1b_2 - a_2b_1 \equiv 0 \pmod f, \tag{6.12}$$

where $f = n/\mathrm{GCD}(q,n)$. The number of solutions $(b_1,b_2,b_3) \in \mathbb{Z}_n^3$ to this modular linear system is equal to $n^3 \cdot [\mathrm{GCD}(a_1,a_2,a_3,f)/f]^2$, which is the result announced in (5.13).

It remains to sum those numbers for all a to obtain the number of primaries. The result is an arithmetical function, best expressed in terms of the prime decomposition of $f = \prod_p p^{k_p}$:

$$|\Phi^\alpha| = \frac{n^6}{f^3} \prod_{\substack{p|f \\ p \text{ prime}}} \Big[(p^{k_p} - 1)(1 + p^{-1} + p^{-2}) + 1\Big]. \tag{6.13}$$

The modular matrices can be given quite explicitly in the general case, for all n and for any type of 3-cocycle. However, they are complicated arithmetic functions of the various parameters, something that obscures the structure. To simplify, we consider here the case when n is an odd prime number, and when the 3-cocycle is α_{III}.

When G is abelian, all factors in the formula (5.23) for S^α that involve the cocycles drop out, and we are left with the simple expressions:

$$S^\alpha_{(a,\tilde\chi),(b,\tilde\chi')} = \frac{1}{|G|}\tilde\chi^*(b)\,\tilde\chi'^*(a), \qquad T^\alpha_{(a,\tilde\chi),(b,\tilde\chi')} = \delta_{a,b}\,\delta_{\tilde\chi,\tilde\chi'}\,\frac{\tilde\chi(a)}{\tilde\chi(e)}, \tag{6.14}$$

where $\tilde\chi$ and $\tilde\chi'$ are respectively β_a- and β_b-projective characters, for the cocycles given above in (6.11) with $q = 1$.

It remains to compute the projective characters. To simplify, consider n an odd prime. One then finds n inequivalent irreducible β_a-projective representations of dimension n if a is not the identity, while there are of course n^3 representations of dimension 1 if $a = e$. Depending on the value of $a = (a_1,a_2,a_3)$, the characters are given in the following table, where it is implicit that the element $g = (g_1,g_2,g_3)$ must be β_a-regular for the character not to vanish. In the first three cases, the character label u runs over $\mathbb{Z}_n$, and in the last column, $\vec u$ takes all values in $\mathbb{Z}_n^3$.

	$a_1 \neq 0$	$a_1 = 0,\ a_2 \neq 0$	$a_1 = a_2 = 0,\ a_3 \neq 0$	$a_1 = a_2 = a_3 = 0$
$\tilde\chi(g)$	$n\,\xi_n^{a_1^{-1}ug_1 - a_1^{-1}a_2a_3g_1^2/2}$	$n\,\xi_n^{a_2^{-1}ug_2}$	$n\,\xi_n^{a_3^{-1}ug_3}$	$\xi_n^{\vec u\cdot\vec g}$

The condition that g must be β_a-regular makes the components of a and g play a symmetrical role. If a_2 is also invertible for instance, then (6.12) yields $a_1^{-1}g_1 = a_2^{-1}g_2$, so that the first character value is also equal to $\tilde{\chi}(g) = n\,\xi_n^{a_2^{-1}ug_2 - a_1a_2^{-1}a_3g_2^2/2}$.

The primary fields are thus $(e, \chi_{\vec{u}})$ and $(a, \tilde{\chi}_u)$, for a total of $|\Phi^\alpha| = n^3 + (n^3-1)n = n^4 + n^3 - n$.

The formulae for S and T are now straightforward to establish. Taking the condition of β-regularity into account, one finds that S is almost block-diagonal:

$$S^\alpha_{(a,\tilde{\chi}_u),(b,\tilde{\chi}_{u'})} =$$
$$\frac{1}{n}\begin{pmatrix} \frac{1}{n^2} & \frac{1}{n}\xi_n^{-u_1b_1-u_2b_2-u_3b_3} & \frac{1}{n}\xi_n^{-u_2b_2-u_3b_3} & \frac{1}{n}\xi_n^{-u_3b_3} \\ \frac{1}{n}\xi_n^{-u_1'a_1-u_2'a_2-u_3'a_3} & \begin{matrix}\xi_n^{-ua_1^{-1}b_1-u'b_1^{-1}a_1+(a_2a_3b_1+b_2b_3a_1)/2} \\ \times\delta(b_2-a_1^{-1}a_2b_1)\,\delta(b_3-a_1^{-1}a_3b_1)\end{matrix} & 0 & 0 \\ \frac{1}{n}\xi_n^{-u_2'a_2-u_3'a_3} & 0 & \begin{matrix}\xi_n^{-ua_2^{-1}b_2-u'b_2^{-1}a_2} \\ \times\delta(b_3-a_2^{-1}a_3b_2)\end{matrix} & 0 \\ \frac{1}{n}\xi_n^{-u_3'a_3} & 0 & 0 & \xi_n^{-ua_3^{-1}b_3-u'b_3^{-1}a_3} \end{pmatrix}, \tag{6.15}$$

where the blocks correspond to the subsets $\{a=e\}$, $\{a_1 \neq 0\}$, $\{a_1 = 0,\ a_2 \neq 0\}$, and $\{a_1 = a_2 = 0,\ a_3 \neq 0\}$.

The T matrix is particularly simple

$$T_{(a,\tilde{\chi}),(a,\tilde{\chi})} = \begin{cases} 1 & \text{for } a = e = (0,0,0), \\ \xi_n^{u-a_1a_2a_3/2} & \text{otherwise.} \end{cases} \tag{6.16}$$

One may check that they satisfy the expected relations $S^2 = (ST)^3 = C$ with the charge conjugation given by $C(e,\chi_{\vec{u}}) = (e, \chi_{-\vec{u}})$ and $C(a,\tilde{\chi}_u) = (a^{-1}, \tilde{\chi}_{u-a_1a_2a_3})$ for $a \neq e$. More generally, the Galois transformations on the primary fields take a somewhat unusual form[‖]

$$\sigma_\ell(a,\tilde{\chi}_u) = \begin{cases} (e, \chi_{\ell\vec{u}}) & \text{for } a = e, \\ (a^\ell, \tilde{\chi}_{\ell^2u+a_1a_2a_3\ell^2(\ell-1)/2}) & \text{for } a \neq e, \end{cases} \qquad \ell \in \mathbb{Z}_n^\times. \tag{6.17}$$

All Galois parities are equal to $+1$. One also checks the relation $\sigma_{\ell^2}T_{(a,\tilde{\chi}),(a,\tilde{\chi})} = T_{\sigma_\ell(a,\tilde{\chi}),\sigma_\ell(a,\tilde{\chi})}$.

Finally the fusion algebra can be computed, which shows a structure radically different from the untwisted or CT case. Here too, the fusion coefficients generically involve the group law and the structure constants for the irreducible characters. Since the latter have degree 1 or n, the fusion of two primary fields may contain 1, n or n^2 primary fields, with possible multiplicities (they turn out to be 1 or n only). The resulting formulae are tedious to write in full form as various cases need be distinguished. As an illustration, we give the coefficients

---

[‖] The unusual factor ℓ^2 in front of u (instead of ℓ) is a consequence of the insertion of factors a_i^{-1} in front of u in the projective characters. Those insertions are purely conventional and help make the symmetry in the components a_i manifest.

when $a, b, c \neq e$:

$$N^{(c,\tilde{\chi}_{u''})}_{(a,\tilde{\chi}_u),(b,\tilde{\chi}_{u'})} = \delta(a{+}b{-}c) \begin{cases} 1 \quad \text{for } c_1 = 0 \text{ and } a_1, b_1 \neq 0, \\ \Big[n\,\delta(a \text{ is } \beta_b\text{-reg})\,\delta(a_1^{-1}u + b_1^{-1}u' + a_2 b_3 - c_1^{-1}u'') \\ \qquad + \delta(a \text{ is not } \beta_b\text{-reg}) \Big] \quad \text{for } c_1 \neq 0 \text{ and } a_1, b_1 \text{ not both } 0, \\ \Big[n\,\delta(a \text{ is } \beta_b\text{-reg})\,\delta(a_2^{-1}u + b_2^{-1}u' - c_2^{-1}u'') \\ \qquad + \delta(a \text{ is not } \beta_b\text{-reg}) \Big] \quad \text{for } a_1, b_1 = 0 \text{ and } a_2, b_2 \neq 0, \\ \Big[n\,\delta(a \text{ is } \beta_b\text{-reg})\,\delta(a_3^{-1}u + b_3^{-1}u' - c_3^{-1}u'') \\ \qquad + \delta(a \text{ is not } \beta_b\text{-reg}) \Big] \quad \text{for } a_1, a_2, b_1, b_2 = 0 \text{ and } a_3, b_3 \neq 0. \end{cases} \tag{6.18}$$

An intriguing observation made in [42] (what he called *electric/magnetic duality*) is that the modular data for $\mathbb{Z}_2^3$ twisted by α_{III} *equals* that of untwisted $\mathfrak{D}_4$ (for an appropriate identification of primary fields), while the twist $\alpha_I^{(1)}\alpha_{III}$ yields the $\mathfrak{Q}_4$ modular data. We will address this again in Question **(8)** in §7.

6.3 Odd dihedral groups

The simplest non-abelian groups are the dihedral groups $\mathfrak{D}_m$. Their Schur multipliers are equal to 0 or $\mathbb{Z}_2$ for m odd or even respectively. For m odd, all centralisers of elements of $\mathfrak{D}_m$ also have trivial Schur multipliers, implying that all twistings of the modular data will be CT. Despite that fact, we will precisely consider m odd here[**], since we want to show that a particular CT twisting of the $\mathfrak{D}_m$ modular data yields nothing but the affine modular data of the odd orthogonal series B_ℓ at level 2, and for $m = \sqrt{2\ell+1}$.

The relevant group theoretic data for $\mathfrak{D}_m$ have been recalled in section 3.2. The number of primary fields is the same for all twistings, and given by $|\Phi| = \frac{m^2+7}{2}$.

The third cohomology group $H^3(\mathfrak{D}_m, U(1)) = \mathbb{Z}_{2m}$ is cyclic and so all 3-cocycles are powers of some generator. They have been very explicitly determined in [41]. Write the elements of $\mathfrak{D}_m$ as $g = s^A\,r^a$ for $A = 0, 1$ and $a = 0, 1, \ldots, m-1$. The group law then takes the form

$$(A, a)(B, b) = (\langle A + B\rangle_2, \langle (-1)^B a + b\rangle_m) \tag{6.19}$$

where the notation $\langle x\rangle_n$ means taking the residue of x modulo n between 0 and $n-1$. Then the 3-cocycles are given by [41]

$$\alpha((A, a), (B, b), (C, c)) = \exp\left\{ -\frac{2\mathrm{i}\pi p}{m^2} \Big[(-1)^{B+C} a[(-1)^C b + c - \langle (-1)^C b + c\rangle_m] + \frac{m^2}{2} ABC \Big] \right\}, \tag{6.20}$$

where $p = 0, 1, 2, \ldots, 2m-1$ labels the cohomology classes.

We now proceed to compute the matrices S and T from the formulas (5.20) and (5.21). We first compute

$$G(e, g) = \mathfrak{D}_m, \quad G(r^k, r^l) = \mathfrak{D}_m, \quad G(s, s) = \{e, s\}, \quad G(s, r^a) = \emptyset. \tag{6.21}$$

[**] The specific case $m = 3$ has been treated in [6].

In particular, the last equality implies $S^\alpha_{(s,\chi),(r^k,\chi')} = 0$. The remaining entries of S^α only require knowing the following values of σ, which easily follow from (5.15), (5.18) and (5.22),

$$\sigma(e|g) = 1, \qquad \sigma(s|s) = (-1)^p, \qquad \sigma(r^a|r^b) = \exp\left(\frac{-4\mathrm{i}\pi pab}{m^2}\right). \tag{6.22}$$

The rest is just a matter of a few calculations. We will write the two modular matrices with their rows and columns indexed by

$$(e,\psi_0), (e,\psi_1), (s,1), (s,\chi \neq 1), (e,\chi_i), (r^k,\chi_\gamma), \tag{6.23}$$

where χ_γ are characters of the group $\mathbb{Z}_m$, with values $\chi_\gamma(a) = \mathrm{e}^{-2\mathrm{i}\pi a\gamma/m}$. The indices i and γ run from 1 to $\frac{m-1}{2}$ and m respectively.

One finds

$$S^\alpha = \frac{1}{2m}\begin{pmatrix} 1 & 1 & m & m & 2 & 2 \\ 1 & 1 & -m & -m & 2 & 2 \\ m & -m & (-1)^p m & (-1)^{p+1} m & 0 & 0 \\ m & -m & (-1)^{p+1} m & (-1)^p m & 0 & 0 \\ 2 & 2 & 0 & 0 & 4 & 4\cos\frac{2\pi i\gamma}{m} \\ 2 & 2 & 0 & 0 & 4\cos\frac{2\pi i\gamma}{m} & 4\cos\frac{2\pi(2pkk'+\gamma k'+\gamma' k)}{m^2} \end{pmatrix}, \tag{6.24}$$

and

$$T^\alpha = \mathrm{diag}\Big[1, 1, \mathrm{e}^{4\mathrm{i}\pi p/8}, -\mathrm{e}^{4\mathrm{i}\pi p/8}, 1, \mathrm{e}^{2\mathrm{i}\pi(pk^2-mk\gamma)/m^2}\Big]. \tag{6.25}$$

On the affine side, the alcôve of B_ℓ level 2 contains $\ell+4$ primary fields, corresponding to the weights: 0, $2\omega^1$, $\omega^1+\omega^\ell$, ω^ℓ and ν^j, defined as $\nu^j = \omega^j$ for $1 \leq j \leq \ell-1$, and $\nu^\ell = 2\omega^\ell$. The conformal central charge is equal to 2ℓ, which is multiple of 8 if ℓ is a multiple of 4. For simplicity, we will use the height variable, $n = 2\ell+1$.

The affine S matrix, with the primary fields labelled as above, is equal to [43]

$$S = \frac{1}{2\sqrt{n}}\begin{pmatrix} 1 & 1 & \sqrt{n} & \sqrt{n} & 2 \\ 1 & 1 & -\sqrt{n} & -\sqrt{n} & 2 \\ \sqrt{n} & -\sqrt{n} & \sqrt{n} & -\sqrt{n} & 0 \\ \sqrt{n} & -\sqrt{n} & -\sqrt{n} & \sqrt{n} & 0 \\ 2 & 2 & 0 & 0 & 4\cos\frac{2\pi jk}{n} \end{pmatrix}, \tag{6.26}$$

while the affine T is

$$T = T_{0,0} \cdot \mathrm{diag}\Big[1, 1, -\mathrm{e}^{2\mathrm{i}\pi\ell/8}, \mathrm{e}^{2\mathrm{i}\pi\ell/8}, \mathrm{e}^{\mathrm{i}\pi j(n-j)/n}\Big]. \tag{6.27}$$

The comparison of the two pictures is now easy. As far as the first four primary fields are concerned, the two sets of modular data coincide provided $m = \sqrt{n} = \sqrt{2\ell+1}$ and $p \equiv 0 \pmod 2$ (the individual identifications among the third and fourth fields depend on the value of $\ell \pmod 8$). It implies that the finite group and the affine theories have the same number of primaries, $\ell + 4 = \frac{m^2+7}{2}$.

The remaining ℓ fields, on the affine side, are the ν^j. They can be set in correspondence with the finite group primary fields (e,χ_i) and (r^k,χ_γ), depending on whether j is a multiple of m or not, via the following formula:

$$\nu^{im}\sim(e,\chi_i),\qquad \nu^{k+m\gamma}\sim(r^k,\chi_\gamma). \tag{6.28}$$

When i,k and γ run over their domain, the index j indeed takes all integer values from 1 to $\ell=\frac{n-1}{2}$.

One may then check that the two sets of modular matrices coincide for a specific choice of p. For $j=i\sqrt{n}$, one has $j(n-j)\equiv 0 \pmod{2n}$, while for $j=k+\sqrt{n}\gamma$, one finds

$$j(n-j)\equiv\tfrac{n-1}{2}k^2-k\gamma\sqrt{n}\equiv pk^2-mk\gamma \pmod{2n}, \tag{6.29}$$

provided one makes the choice $p\equiv\frac{n-1}{2} \pmod{2n}$. It gives the unique twisting for which the finite group modular data and the affine data coincide. That the S matrices are equal is done in the same way.

Hence infinitely many physical invariant classifications for CT-twisted nonabelian G were done in [33]. If we let $d=\sigma_0(m^2)-1$ denote the number of divisors $d'\le m$ of m^2, then the number of physical invariants of $\mathfrak{D}_m$ for the given twist α is $d(d+3)/2+4$. Since $\mathfrak{D}_3\cong\mathfrak{S}_3$, we get 'only' 9 physical invariants for twisted $\mathfrak{S}_3$ – still a large number considering the small number of primaries, but dwarfed by the 32 ones for the untwisted data.

7 Questions

We conclude by collecting a small number of the questions raised in this paper.

(1)[††] We have been unable to derive the CT formula (5.20), appearing in e.g. [6], from our general formula (5.23), except in special cases such as when G is abelian. Though this isn't strictly necessary, it would make a nice consistency check of the modular data. Our formula (5.23) for S^α has the strength that it is given explicitly in terms of quantities directly associated with G, but it has the weakness that it involves the 2-cocycles β_a away from $C_G(a)$, and this is what complicates our attempt to derive (5.20). The derivations in [4, 11] involve considering the β_a's at the centralisers only.

(2) It should be possible to generalise the observations in §4.2 by considering the relations of the modular data for G with that of normal subgroups and quotient groups. This should yield an analogue of "conformal embeddings" for this data.

(3) Can we recover the character table from the matrices S and T? Do non-isomorphic groups have different S and T? These are big questions. Probably the answer to the first is yes, and to the second is no. It turns out to be very difficult to identify a group from its character table together with nice additional information – perhaps the modular data provides a means? A natural place to look for nonisomorphic groups with identical modular data are the order 16 groups with identical group algebras, or Brauer pairs (i.e. groups with identical character tables and identical power maps $K_a\mapsto K_{a^n}$).[‡‡] Perhaps relevant is [44], which proves that two groups have the same character table iff their group algebras are isomorphic as quasi-Hopf algebras.

[††] We thank Peter Bántay for correspondence regarding this point.

[‡‡] We thank John McKay for bringing Brauer pairs to our attention.

(4) We see in places a tantalising hint of some sort of duality between the group element component of the primary field, and its character component (see e.g. §4.2). Is there any way to make this precise?

(5) Does the $\mathrm{SL}_2(\mathbb{Z})$ representation obtained from the finite group modular data, factor through a congruence subgroup? Presumably the answer is always yes. Certainly it is true for untwisted data. The easiest way to see this uses the permutation-like representation of [6, 11, 12], so a natural starting point for the twisted data would involve the basis given at the end of §5.3.

(6) An important fact for affine modular data is the Kac-Peterson formula, which provides a useful interpretation for the eigenvalues $S_{\lambda\mu}/S_{0\mu}$ of the fusion matrices. It would be highly desirable to find out what form if any that takes here.

(7) What is the analogue for the affine modular data of the basis discussed at the end of §5.3, in which S and T appear as generalised permutation matrices?

(8) As mentioned at the end of §6.2, twisted $\mathbb{Z}_2^3$ modular data yields [42] that of untwisted $\mathfrak{D}_4$ and $\mathfrak{Q}_4$ modular data. It is natural to expect that there are many more such examples: e.g. circumstantial evidence (such as quantum dimensions and numbers of primaries) suggests that appropriately twisted $\mathbb{Z}_p^3$ would yield the modular data for the Heisenberg group (consisting of all 3×3 upper triangular matrices with 1's down the diagonal and entries in $\mathbb{Z}_p$), or the order p^3 generalisation of $\mathfrak{D}_4$ (presentation $\langle a, b \,|\, a^{p^2} = b^p = b^{-1}aba^{-1-p} = e\rangle$). This is probably the analogue of "rank-level duality" for this finite group data. Note that it is not a coincidence that $\mathbb{Z}_2^3$ and $\mathfrak{D}_4$ both have the same order — if the matrices S are to be equal, their entries $S_{0,0}$ must agree and hence the two groups must have equal order. Again, perhaps relevant is [44], which may supply a starting point for a general theory.

Pasquier, J.B. Zuber. This paper was initiated at Oberwolfach and partially written at IHES, and we thank both for their hospitality.

A Appendix

We sketch here the derivation of formula (5.24) for T^α. A basis of $D^\alpha(G)$ is labelled by pairs (g, x) of group elements with algebra product

$$(g, x) \cdot (k, y) \ := \delta_{g,xkx^{-1}} \ \beta_g(x, y) \ (g, xy). \tag{A.1}$$

Now, $D^\alpha(G)$ is semi-simple and finite-dimensional over $\mathbb{C}$, so its irreducibles $R(a, \tilde{\rho})$ are subrepresentations of the regular one. They can be described as follows [7]. The representation space for $R_{(a,\tilde{\rho})}$ is spanned by vectors $|x_j\rangle \otimes |w\rangle$, and the action is give by

$$R_{(a,\tilde{\rho})}(g, x)|x_j\rangle \otimes |w\rangle = \delta_{g,x_k a x_k^{-1}} \ \frac{\beta_g(x, x_j)}{\beta_g(x_k, h)} \ |x_j\rangle \otimes \ \tilde{\rho}(h)|w\rangle, \tag{A.2}$$

where x_j are coset representatives for $G/C_G(a)$ and $(x_k, h) \in G/C_G(a) \times C_G(a)$ are uniquely defined by $x\ x_j = x_k h$. Here $\tilde{\rho}$ denotes a projective irreducible β_a-representation of $C_G(a)$ obtained by restriction of the regular representation of $D^\alpha(G)$.

Contact with the regular representation has been made by Altschuler and Coste [20]. Let us give here an account of it. The central element $v^{-1} = \sum_{k \in G}(k, k)$ is easily diagonalised: For each conjuguacy class K_a of G denote by $e(a)$ the common order of its elements, then

$$\omega_a := \prod_{j=0}^{e(a)-1} \alpha(g, g^j x, x^{-1} g x) \tag{A.3}$$

is independent of the choice of $g \in K_a$ and $x \in G$.

Then all eigenvalues of v^{-1} are the $e(a)$-th roots of the ω_a's. For each such root λ, each $g \in K_a$ and each class $\{g^j x\}$ of $G/\langle g \rangle$, an eigenvector $\psi_\lambda[g, x]$ is easily constructed.

That these eigenvalues of projective β_a-representations are given in terms of (roots of) values of a 3-cocycle raises the interesting group theoretic question: is this a clever way of classifying or putting together all projective representations of a finite group in terms of 3-cocycles for extensions inside which it is a centraliser ?

The central element v is a constant on each $R_{(a,\tilde{\rho})}$, for convenience let us rather focus on v^{-1}, which has a simpler expression and on its eigenvalues: they are necessarily $e(a)$-th roots of the important quantities ω_a, numbers which should be considered as tabulation data of any 3-cocycle. All of their $e(a)$-th roots are eigenvalues of v^{-1}.

The following nice identity satisfied by the twisted non abelian 2-cocycle and valid for any $a, x \in G$, is due to Altschuler:

$$\beta_{xax^{-1}}(xax^{-1},\ x) = \beta_{xax^{-1}}(x,\ a) = \alpha(xax^{-1}, x, a) \tag{A.4}$$

and is proved by direct evaluation in terms of the 3-cocycle α. From it we get the remarkably simple expression: $R_{(a,\tilde{\rho})}(v^{-1})\ \ |x_j\rangle \otimes |w\rangle = \ |x_j\rangle \otimes\ \tilde{\rho}(a)|w\rangle = \lambda\ |x_j\rangle \otimes |w\rangle$ (here $|w\rangle$ spans the representation space of $\tilde{\rho}$. Because of the expression of v^{-1} the quotient of cocycles which appear in $R_{(a,\tilde{\rho})}$ becomes here independent of $x = x_j = x_k$ and in fact equal to 1.

Since for $h \in C_G(a)$,

$$\beta_a(h,\ a) = \beta_a(a,\ h) = \alpha(a, h, a) \tag{A.5}$$

we easily get, using an induction on j for $h = a^j$: $\tilde{\alpha}(a)^{e(a)} = \omega_a I$, $\tilde{\alpha}(a)$ central and equal to λI.

SKETCH OF A PROGRAM FOR UNIVERSAL AUTOMORPHIC FUNCTIONS TO CAPTURE MONSTROUS MOONSHINE

IGOR FRENKEL AND ROBERT PENNER

Abstract. We review and reformulate old and prove new results about the triad $\mathrm{PPSL}_2(\mathbb{Z}) \subseteq \mathrm{PPSL}_2(\mathbb{R}) \circlearrowright ppsl_2(\mathbb{R})$, which provides a universal generalization of the classical automorphic triad $\mathrm{PSL}_2(\mathbb{Z}) \subseteq \mathrm{PSL}_2(\mathbb{R}) \circlearrowright psl_2(\mathbb{R})$. The leading P or p in the universal setting stands for *piecewise*, and the group $\mathrm{PPSL}_2(\mathbb{Z})$ plays at once the role of universal modular group, universal mapping class group, Thompson group T and Ptolemy group. In particular, we construct and study new framed holographic coordinates on the universal Teichmüller space and its symmetry group $\mathrm{PPSL}_2(\mathbb{R})$, the group of piecewise $\mathrm{PSL}_2(\mathbb{R})$ homeomorphisms of the circle with finitely many pieces, which is dense in the group of orientation-preserving homeomorphisms of the circle. We produce a new basis of its Lie algebra $ppsl_2(\mathbb{R})$ and compute the structure constants of the Lie bracket in this basis. We define a central extension of $ppsl_2(\mathbb{R})$ and compare it with the Weil-Petersson form. Finally, we construct a $\mathrm{PPSL}_2(\mathbb{Z})$-invariant 1-form on the universal Teichmüller space formally as the Maurer-Cartan form of $ppsl_2(\mathbb{R})$, which suggests the full program for developing the theory of automorphic functions for the universal triad which is analogous, as much as possible, to the classical triad. In the last section we discuss the representation theory of the Lie algebra $ppsl_2(\mathbb{R})$ and then pursue the universal analogy for the invariant 1-form $E_2(z)dz$, which gives rise to the spin 1 representation of $psl_2(\mathbb{R})$ extended by the trivial representation. We conjecture that the corresponding automorphic representation of $ppsl_2(\mathbb{R})$ yields the bosonic CFT_2. Relaxing the automorphic condition from $\mathrm{PSL}_2(\mathbb{Z})$ to its commutant allows the increase of the space of 1-forms six-fold additively in the classical case and twelve-fold multiplicatively in our universal case. This leads to our ultimate conjecture that we can realize the Monster CFT_2 via the automorphic representation for the universal triad. This conjecture is also bolstered by the links of both the universal Teichmüller and the Monster CFT_2 theories to the three-dimensional quantum gravity.

Keywords: universal Teichmüller space, Thompson group T, loop algebra for sl_2, Weil-Petersson form, Maurer-Cartan form, Monstrous Moonshine, three dimensional quantum gravity

Date: December 31, 2020.

Introduction

The idea of studying a universal Teichmüller space that contains the union of images of all classical Teichmüller spaces goes back to Lipman Bers [1], who considered the group of all quasisymmetric mappings of the circle $\mathbb{S}^1$ to itself modulo the Möbius group $\mathrm{PSL}_2(\mathbb{R})$.

Further development of the classical Teichmüller spaces [23] and their applications to string theory led the second-named author to a new model [24] of the universal Teichmüller space based on the group, denoted $\mathrm{Homeo}_+(\mathbb{S}^1)$, of all orientation-preserving self-homeomorphisms of $\mathbb{S}^1$ with the compact-open topology modulo the Möbius group. The problem of providing a parametrization for the new larger model of universal Teichmüller space and the corresponding group of homeomorphisms of $\mathbb{S}^1$ was also resolved in [24] by identification of the latter group with the space $\mathcal{T}ess'$ of all ideal tesselations of the hyperbolic plane together with a choice of distinguished oriented edge, or simply doe, that is,

$$\mathrm{Homeo}_+(\mathbb{S}^1) \approx \mathcal{T}ess'. \tag{0.1}$$

In particular, the identity element in $\mathrm{Homeo}_+(\mathbb{S}^1)$ corresponds to a special tesselation called the Farey tesselation. It is obtained by applying the modular group $\mathrm{PSL}_2(\mathbb{Z})$ to the doe running from 0 to ∞. In view of the isomorphism (0.1), one can consider coordinates on $\mathcal{T}ess = \mathcal{T}ess'/\mathrm{PSL}_2(\mathbb{R})$ as a measure of the distortion of a given tesselation from the specified Farey tesselation by so called shearing coordinates associated to every nonoriented edge of the Farey tesselation, or equivalently to the elements of $\mathrm{PSL}_2(\mathbb{Z})/(\mathbb{Z}/2)$, where the $\mathbb{Z}/2$ subgroup reverses the orientation of edges. The shearing coordinates can be realized as logarithms of cross-ratios of certain hyperbolic lengths and are invariant under the action of the Möbius group. As a result we obtain an injection

$$\mathrm{Homeo}_+(\mathbb{S}^1)/\mathrm{PSL}_2(\mathbb{R}) \to \prod_{e\in\{\text{edges}\}} \mathbb{R}_+^e, \tag{0.2}$$

where $\mathbb{R}_+^e$ is a copy of $\mathbb{R}_+$ associated to the edge e.

Two questions arise in relation to the parametrization (0.2): the first is how to characterize its image, and the second is how to circumvent the factorization by the Möbius group and obtain directly the coordinates of $\mathrm{Homeo}_+(\mathbb{S}^1)$ itself. To answer these questions, we introduce new

---

It is a pleasure to acknowledge the hospitality of the Institut des Hautes Études Scientifiques, where this work began, and in particular the excellent assistance of Fanny Dufour with the figures.

holographic coordinates and framings in Sections 2 and 3 the paper. These new coordinates are actually based upon elaborations of the shearing coordinates defined on a decorated bundle from [23] over the universal Teichmüller space which was central also in [24].

The shearing coordinates as well as our holographic coordinates admit especially simple transformation under the dense subgroup $\mathrm{PPSL}_2(\mathbb{R}) \subseteq \mathrm{Homeo}_+(\mathbb{S}^1)$. This subgroup in its turn contains a discrete subgroup $\mathrm{PPSL}_2(\mathbb{Z}) \subseteq \mathrm{PPSL}_2(\mathbb{R})$ of piecewise $\mathrm{PPSL}_2(\mathbb{Z})$ homeomorphisms with rational breakpoints between pieces. Elements of $\mathrm{PPSL}_2(\mathbb{Z})$ turn out automatically to be once-continuously differentiable on the circle. This pair of groups contains the classical pair $\mathrm{PSL}_2(\mathbb{Z}) \subseteq \mathrm{PSL}_2(\mathbb{R})$, which is the first hint towards the new extended theory of automorphic forms.

Another discrete group that is indispensable in the Teichmüller theory is the mapping class group or Teichmüller modular group. In our universal context it is realized by the group of the Farey-type tesselations which coincide with the Farey tesselation outside of a finite polygon and known as the Ptolemy group Pt, also introduced in [24].

More precisely, the *flip* on an edge e in a tesselation is defined by replacing it by the other diagonal of the quadrilateral complementary to $\cup(\tau - \{e\})$ in $\mathbb{D}$; if e is the doe, then the flip on it is enhanced by inducing the orientation coming from the counter-clockwise rotation of e. The *Ptolemy group(oid)* Pt has objects given by tesselations with doe of $\mathbb{D}$ which coincide with the Farey tesselation outside of a finite polygon and morphisms given by finite compositions of flips. Triangulations with doe are combinatorially rigid, and this allows flips to be labeled by edges of a fixed tesselation, so words in these labels render Pt in fact a group. Furthermore, $\mathrm{PSL}_2(\mathbb{Z})$ sits inside Pt as those tesselations which are identical to the Farey tesselation except perhaps for the location of the doe.

The remarkable fact of the universal setting is that under the isomorphism (0.1), these two discrete subgroups of $\mathrm{Homeo}_+(\mathbb{S}^1)$ coincide $\mathrm{PPSL}_2(\mathbb{Z}) \approx \mathrm{Pt}$. Furthermore, this universal mapping class group is also isomorphic to the celebrated Thompson group T, so

$$\text{Thompson T} \approx \mathrm{PPSL}_2(\mathbb{Z}) \approx \text{Ptolemy Pt}. \tag{0.3}$$

The rich combinatorial structure of T is studied in [5] and numerous sequels. In particular, T admits a presentation by means of two generators and certain relations similar to those of the modular group.

The classical theory of automorphic forms on $\mathrm{PSL}_2(\mathbb{R})$ involves, besides the classical modular group $\mathrm{PSL}_2(\mathbb{Z})$, also the large class of discrete subgroups $\Gamma \subseteq \mathrm{PSL}_2(\mathbb{R})$ commensurable with the modular group. In our universal setting, one considers a similar class of infinite discrete groups $\mathrm{P}\Gamma$ associated to such subgroups $\Gamma \subseteq \mathrm{PSL}_2(\mathbb{R})$. By definition, $\mathrm{P}\Gamma$ is the subgroup of $\mathrm{Homeo}_+(\mathbb{S}^1)$ consisting of piecewise Γ homeomorphisms with finitely many rational breakpoints. To study these groups, one can consider again the paving, i.e., decomposition into finite-sided congruent ideal polygons, determined by the action of Γ on the doe from 0 to ∞. In Section 1, we consider the special case when $\Gamma = \mathrm{PSL}_2(\mathbb{Z})'$ is the commutant of the modular group. We also review the results of [19] about the class of finitely generated such groups $\mathrm{P}\Gamma$, which turn out to be precisely the groups of genus zero. This is a hint towards Monstrous Moonshine, and we conclude Section 1 with the problem of characterizing those $\Gamma \subseteq \mathrm{PSL}_2(\mathbb{Z})$ that occur in Monstrous Moonshine in these terms.

In the classical theory of automorphic functions, besides the pair of groups $\mathrm{PSL}_2(\mathbb{Z}) \subseteq \mathrm{PSL}_2(\mathbb{R})$, the Lie algebra $psl_2 = psl_2(\mathbb{R})$ plays a pivotal role; we employ this notation psl_2 in the current discussion instead of the more standard notation $sl_2 = sl_2(\mathbb{R})$ simply to emphasize the relationship with the associated Lie group. To develop the universal counterpart of the classical theory, one requires a suitable Lie algebra for the topological group $\mathrm{Homeo}_+(\mathbb{S}^1)$. It has been argued in [20] that this infinite-dimensional counterpart is precisely the algebra of piecewise sl_2 vector fields on the circle with finitely many pieces and rational breakpoints between them. This Lie algebra was denoted psl_2, where the where the p stood for *piecewise*. In the present paper, this Lie algebra will be denoted $ppsl_2 = ppsl_2(\mathbb{R})$ to emphasize its relationship with the group $\mathrm{PPSL}_2(\mathbb{R})$. In Sections 4 and 5, we continue the study of this Lie algebra $ppsl_2$. In particular following [20], we find a basis parametrized by the edges of the Farey tesselation, or equivalently by $\mathrm{PSL}_2(\mathbb{Z})/(\mathbb{Z}/2)$, and explicitly derive the commutation relations in this basis. In the next Section 6, we define the central extension of the Lie algebra $ppsl_2$ viewed as a loop algebra and compare it with the central extension given by the universal Weil-Petersson 2-form first studied in [24], which naturally extends the classical Weil-Petersson Kähler form computed in [25].

All three structures of our universal triad

$$\mathrm{PPSL}_2(\mathbb{Z}) \subseteq \mathrm{PPSL}_2(\mathbb{R}) \circlearrowright ppsl_2(\mathbb{R}) \tag{0.4}$$

are combined in our construction of an automorphic 1-form on the universal Teichmüller space in Section 7. This construction is one of the main results of the paper, and it is the first step towards our program of developing the theory of automorphic forms for the triad (0.4). Since $\mathrm{PPSL}_2(\mathbb{R})$ allows for irrational breakpoints, the triad (0.4) should more properly be written $\mathrm{PPSL}_2(\mathbb{R}) \supseteq \mathrm{PPSL}_2(\mathbb{Z}) \circlearrowright ppsl_2(\mathbb{R})$. One might simply restrict to rational breakpoints for $\mathrm{PPSL}_2(\mathbb{R})$ as well in order to ensure (0.4), but let us not dwell on this perhaps interesting detail.

Though the proposed new theory is expected to be of a higher level of complexity than the usual theory for the classical triad

$$\mathrm{PSL}_2(\mathbb{Z}) \subseteq \mathrm{PSL}_2(\mathbb{R}) \circlearrowright psl_2(\mathbb{R}),$$

one can pursue the analogy with the classical case whenever possible. In particular, we argue that our automorphic 1-form on the universal Teichmüller space has its classical counterpart in the 1-form $E_2(z)dz$ on the hyperbolic plane, the universal cover of the classical modular curve, where $E_2(z)$ is the non-holomorphic weight two covariant Eisenstein series.

In Appendix B, we study its lift to an automorphic function on $\mathrm{PSL}_2(\mathbb{R})$ and show that the resulting lift generates an indecomposable representation of $psl_2(\mathbb{R})$ with a one-dimesional sub-representation. This indecomposable representation together with its conjugate, and common one-dimensional representation, can be characterized as the harmonic subspace of automorphic functions, i.e., it is annihilated by the Laplace operator. Though the realization of the holomorphic and antiholomorphic discrete series of weights $4, 6, 8, \dots$ by the automorphic functions is well known, the case of weight 2 has not appeared in the literature to the best of our knowledge. Yet it is exactly an analogue of this special automorphic form which arises in our construction of a $\mathrm{PPSL}_2(\mathbb{Z})$-invariant 1-form on universal Teichmüller space in the formal guise of the Maurer-Cartan form of $\mathrm{PPSL}_2(\mathbb{R})$.

Our example of this universal automorphic form opens a new program of research in this subject for the triad (0.4), as discussed in Section 8. One of the first challenges is to find an analogue of the indecomposable representation generated by the lift of the 1-form $E_2(z)dz$ in our universal setting. Our conjecture explained in Section 8 is that this is the infinite symmetric power $S^\infty V$ of the bosonic space that appears in the classical theory, so that $S^\infty V$ is the free bosonic field and is one of the simplest CFT_2.

The theory of automorphic forms instantly enlarges various spaces by relaxing the the automorphic property to smaller discrete groups. Thus, the passage from $\mathrm{PSL}_2(\mathbb{Z})$ to its commutant $\mathrm{PSL}_2(\mathbb{Z})'$ of index six increases the space V additively 6-fold. Similarly, we expect that replacing $\mathrm{PPSL}_2(\mathbb{Z})$ by $\mathrm{PPSL}_2(\mathbb{Z})'$ will yield a correspondingly multiplicative increase of $S^\infty V$. Thus, we expect that this mechanism will allow the construction of the Monstrous CFT_2 of [12], and in other words capture the Monster as in the title of this paper.

In fact at the end of Section 8, we explain this from the other end of the theory by recalling that Monstrous Moonshine allows one to attach a genus zero subgroup $\Gamma \subseteq \mathrm{PSL}_2(\mathbb{R})$ to every conjugacy class of the Monster group. Then one can construct as above a Γ-invariant 1-form $E_2^\Gamma(z)dz$, where $E_2^\Gamma(z)$ is again the non-holomorphic weight two covariant Eisenstein series. This can be lifted to a representation V^Γ of $\mathrm{PSL}_2(\mathbb{R})$ isomorphic to V but realized by a different space of automorphic functions. Then the universal analogue is conjectured to yield a twisted Monster representation Λ^Γ as in in [10], and the comparison of Λ and Λ^Γ should reveal the Monster in the universal automorphic realization. It will be interesting to see the correspondence between the Thompson-like groups $\mathrm{P}\Gamma \subseteq \mathrm{PPSL}_2(\mathbb{R})$ introduced in Section 1 and the Monster Moonshine groups $\Gamma \subseteq \mathrm{PSL}_2(\mathbb{R})$, both of which are genus zero and satisfy certain additional properties [6, 7]

Our conjecture on the relationship between automorphic forms on the universal Teichmüller space and the Monster CFT_2 is strongly supported by the links of both subjects to yet another: three-dimensional quantum gravity. In fact, the link with universal Teichmüller theory has a long history in the physics literature going back to [33]. More recently, a rigorous definition of the universal phase space of AdS_3 gravity was given in [29], and it was proven there that it can be identified with the cotangent bundle over the universal Teichmüller space in its Bers formulation. Thus, one could expect that the space of states of AdS_3 quantum gravity can be realized in some class of functions on the universal Teichmüller space. However, it was also understood in the physics literature that the Bers version of universal Teichmüller space must be enlarged to account for all states related to black holes. Indeed, such enlargement was an original motivation for [24].

It was argued in [35] that the general philosophy of $\mathrm{AdS}_3/\mathrm{CFT}_2$ correspondence suggests that the space of states of the simplest pure quantum gravity is precisely the Monster CFT_2 constructed in [12]. This correspondence was further supported by the explanation of Monstrous Moonshine, and in particular by the mysterious genus zero property, from the point of view of twisted state sums of three-dimensional quantum gravity [10]. However in spite of all these tantalizing observations, a rigorous mathematical theory of three-dimensional quantum gravity is still missing. Thus, we believe that the development of the theory of universal automorphic representations can help to build a Monstertrap for all the Moonshine and at the same time help us to understand the true nature of three-dimesional quantum gravity.

1. Farey tesselation and modular group

Let $\mathbb{Z} \subseteq \mathbb{Q} \subseteq \mathbb{R} \subseteq \mathbb{C}$ denote the integers, rational, real and complex numbers, respectively, with $\hat{\mathbb{Z}} \subseteq \hat{\mathbb{Q}} \subseteq \hat{\mathbb{R}} \subseteq \hat{\mathbb{C}}$ denoting their respective one-point compactifications by the point ∞ at infinity. Set $i = \sqrt{-1}$.

The open unit disk $\mathbb{D}$ in the complex plane $\mathbb{C}$ is identified with the Poincaré disk model of the hyperbolic plane in the standard way, where the boundary unit circle $\mathbb{S}^1$ is identified with the circle at infinity. Also consider the upper half-plane $\mathcal{U} = \{z = x + iy \in \mathbb{C} : y > 0\}$. The *Cayley transform*

$$\begin{aligned} C : (\mathcal{U}, \hat{\mathbb{R}}) &\to (\mathbb{D}, \mathbb{S}^1) \\ s &\mapsto \frac{s-i}{s+i} \end{aligned}$$

induces an isomorphism of pairs.

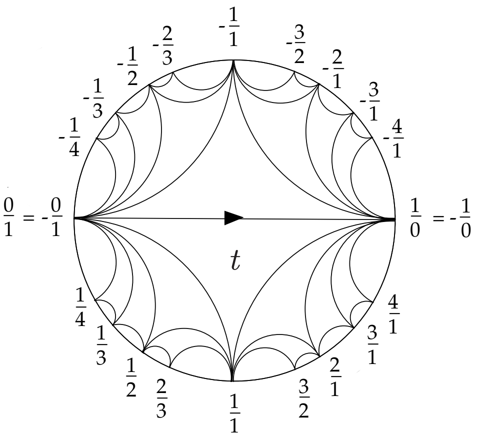

Figure 1. The first several generations of the Farey tesselation τ_* of the Poincaré disk $\mathbb{D}$ with its distinguished oriented edge.

Let t denote the ideal hyperbolic triangle with vertices $\pm 1, -i \in \mathbb{S}^1$ as in Figure 1, and consider the group $\mathcal{R}$ generated by reflections in the sides of t. Define the *Farey tesselation* τ_* to be the full $\mathcal{R}$-orbit of the frontier of t. τ_* has a distinguished oriented edge given by the interval from -1 to $+1$. A direct Euclidean construction of τ_* with a discussion of its history and number theoretic significance is given in [26, §3.1].

More generally, an arbitrary *tesselation* of $\mathbb{D}$ is a locally finite collection τ of hyperbolic geodesics decomposing $\mathbb{D}$ into complementary ideal triangles. Geodesics in τ are called its *edges*, and τ itself is regarded as a set of edges. Let $\tilde{\tau}$ denote the set of all oriented edges of τ, and if $e \in \tilde{\tau}$, then let $|e| \in \tau$ denote the unoriented edge underlying e. A *distinguished oriented edge* or *doe* on τ is the specification of an element $e \in \tilde{\tau}$. Let $\tau^0 \subseteq \mathbb{S}^1$ denote the set of all *vertices* of τ, namely, the collection of all endpoints of all edges in τ.

As is well-known, $\hat{\mathbb{Q}} \approx \tau_*^0$ under the Cayley transform, namely,

$$C\ (p/q) = \frac{p - iq}{p + iq} = \frac{p^2 - q^2}{p^2 + q^2} - i\ \frac{2pq}{p^2 + q^2} \in \mathbb{S}^1,$$

as indicated in Figure 1, and we shall refer to these points as the *rational points* of $\mathbb{S}^1$. We abuse notation slightly and sometimes let $\frac{p}{q} \in \hat{\mathbb{Q}}$ denote the point $C(p/q) \in \mathbb{S}^1$. $\frac{p}{q} \in \hat{\mathbb{Q}}$ is said to be of *generation* g if the radial arc in $\mathbb{D}$ from the origin to $\frac{p}{q}$ meets the interior of $g \geqslant 0$ distinct ideal triangles complementary to τ_*. The standard doe of τ_* runs between the two rational points of generation zero, from $\frac{0}{1}$ to $\frac{1}{0}$.

Another canonical tesselation of $\mathbb{D}$ with doe is the *dyadic tesselation* τ_d, which has the same doe as the Farey tesselation, and indeed the same generation one vertices as well, and which is recursively characterized by the property that one vertex of each triangle complementary to τ_d bisects the angle between its other two vertices. Thus, one has $\tau_d^0 = \{e^{2\pi i(1-k)} : k \in \mathbb{Z}\}$, the points in the circle with dyadic rational arguments. In contrast, τ_*^0 consists of points in the circle with rational rectilinear coordinates.

The *modular group*

$$\mathrm{PSL}_2 = \mathrm{PSL}_2(\mathbb{Z}) \subseteq \mathcal{R}$$

of integral fractional linear transformations is the subgroup of $\mathcal{R}$ consisting of compositions of an even number of reflections, or in other words, the group of two-by-two integral matrices A of unit determinant modulo the equivalence relation generated by identifying A with $-A$. More generally, the *Möbius group*

$$M\ddot{o}b = \mathrm{PSL}_2(\mathbb{R}) \supseteq \mathrm{PSL}_2$$

consists of the two-by-two unimodular matrices over $\mathbb{R}$ modulo the same equivalence relation. *Möb* is the group of orientation-preserving hyperbolic isometries of $\mathbb{D}$.

In particular, $A = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in \mathrm{PSL}_2$ *acts on the right* (here following Gauss) on the rational points by

$$A : \frac{p}{q} \;\mapsto\; \frac{pd - qb}{qa - pc},$$

so the edge $e_A = (doe).A$ has initial point $-\frac{b}{a} = \frac{b+ia}{b-ia}$ and terminal point $-\frac{d}{c} = \frac{d+ic}{d-ic}$.

The *Thompson group* T is the collection of all orientation-preserving piecewise homeomorphisms of $\mathbb{S}^1$ with finitely many breakpoints among τ_d^0 which are affine in the coordinate θ on each piece. Recall from the Introduction the group $\mathrm{PPSL}_2(\mathbb{Z})$ of all piecewise $\mathrm{PSL}_2(\mathbb{Z})$ homeomorphisms of $\mathbb{S}^1$ with finitely many breakpoints among the Farey rationals τ_*^0. In fact, the Thompson group T is conjugate in $\mathrm{Homeo}(\mathbb{S}^1)_+$ to $\mathrm{PPSL}_2(\mathbb{Z})$, where the conjugating homeomorphism fixes the endpoints of the doe and maps the Farey tesselation to the dyadic tesselation of $\mathbb{D}$ in the natural way; this conjugating homeomorphism was first studied by Minkowski in [21] for its remarkable analytic properties.

Here are two standard propositions which are the starting points of our discussion:

Proposition 1.1. *The modular group* PSL_2 *leaves setwise invariant the Farey tesselation* τ_**, mapping* $\cup\tau_*$ *onto* $\cup\tau_*$*. Any orientation-preserving homeomorphism of the circle leaving invariant* τ_* *in this manner lies in* PSL_2*. The modular group acts simply transitively on* $\tilde{\tau}_*$*. A fundamental domain for the action of the modular group on* $\mathcal{U}$ *is given by* $\{x + iy \in \mathcal{U} : x^2 + y^2 > 1 \text{ and } |x| < \frac{1}{2}\}$. □

Proposition 1.2. *A generating set for* PSL_2 *is given by any pair of*

$$R = \begin{pmatrix} 0 & -1 \\ 1 & 1 \end{pmatrix},\ S = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix},\ T = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix},\ U = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix},$$

and $S^2 = 1 = R^3$ *is a complete set of relations in the generators* $R = T^{-1}U$ *and* $S = TU^{-1}T$*, so* $\mathrm{PSL}_2 \approx \mathbb{Z}/2 * \mathbb{Z}/3$*. In fact,* $T^{-1} = R^2S$ *and* $U = SR^2$ *are each of infinite order and are conjugate in* PSL_2. □

Complete relations in the generators U and T are given by $T^{-1}UT^{-1} = TU^{-1}T = UT^{-1}U = U^{-1}TU^{-1}$, with these so-called braiding relations reflecting the fact that PSL_2 is also the mapping class group of the once-punctured torus with U and T representing Dehn twists.

Geometrically, the elliptic element S setwise fixes $|e_I|$ and reverses the orientation of the doe e_I, R is the elliptic transformation cyclically permuting the vertices of the triangle to the right of the doe, and U (respectively T) is the parabolic transformation with the fixed point $\frac{0}{1}$ (respectively $\frac{1}{0}$) which cyclically permutes the incident edges of τ_* in the counter-clockwise sense about $\frac{0}{1}$ (respectively the clockwise sense about $\frac{1}{0}$). Typical aspects of our enumeration of oriented edges by elements of PSL_2 are illustrated in Figure 2.

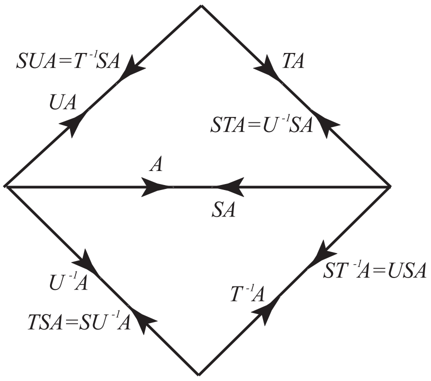

Figure 2. Enumeration of oriented edges near $|e_A| \in \tau_*$.

We turn our attention now to the *commutant* PSL_2' of PSL_2, namely, the subgroup of PSL_2 generated by the group commutators $aba^{-1}b^{-1}$, for $a, b \in \mathrm{PSL}_2$. As follows immediately from Proposition 1.2, the quotient $\mathrm{PSL}_2/\mathrm{PSL}_2' \approx \mathbb{Z}/6$.

Proposition 1.3. *Consider an element of* PSL_2 *written as a word* $W = W(U,T)$ *in the generators* U *and* T. *Then the coset of the element* W *in* $\mathrm{PSL}_2/\mathrm{PSL}_2'$ *is given by the residue modulo six of the total exponent sum of* W *in the letters* U *and* T^{-1}.

Proof. Each of U and T^{-1} is infinite order and maps to the generator of $\mathbb{Z}/6 \approx \mathrm{PSL}_2/\mathrm{PSL}_2'$. Since U and T^{-1} are conjugate in PSL_2, the word W may be written as a product of conjugates of U, which thus abelianizes to the exponent sum of U in this expression of W times the generator of $\mathbb{Z}/6$. □

Corollary 1.4. *Fix any triangle complementary to* $\cup\tau_*$ *and consider the six possible orientations on its frontier edges. The labels in* PSL_2 *of these six oriented edges span the six commutant cosets. Furthermore,* PSL_2' *corresponds to the collection* $\mathcal{C} \subseteq \tilde{\tau}_*$ *of oriented edges determined by the following conditions: the doe lies in* $\mathcal{C}$*; suppose an oriented edge*

$e \in \tilde{\tau}_*$ lying in $\mathcal{C}$ has ideal endpoint $v \in \mathbb{S}^1$, then every third edge of τ_* incident on v also lies in $\mathcal{C}$ with alternating orientations around v.

Proof. For the first part, consideration of Figure 2 shows that for the triangle to the right of the doe, we must show that the PSL_2'-cosets of $I, S, US, T^{-1} = T^{-1}, TS, U^{-1}$ are distinct. These have respective expressions in U, T given by I, $UT^{-1}U$, $U^2T^{-1}U$, T^{-1}, $TUT^{-1}U$, U^{-1} with respective total exponent sums in U and T^{-1} given by $0, 3, 4, 1, 2$, $-1 \equiv 5$. The general case follows upon conjugation.

For the second part, we likewise argue for the doe with the general result then following by conjugation. For the doe we must prove that $SU^{\pm 1}, SU^{\pm 2} \notin \mathcal{C}$ and $SU^{\pm 3} \in \mathcal{C}$ (since obviously $U^{\pm 1}, U^{\pm 2} \notin \mathcal{C}$) and likewise for T instead of U. To this end, we write $SU = UT^{-1}U^2$, $SU^{-1} = UT^{-1}$, $SU^2 = UT^{-1}U^3$, $SU^{-2} = UT^{-1}U^{-1}$, $SU^3 = UT^{-1}U^4$ and $SU^{-3} = UT^{-1}U^{-2}$ with respective total exponent sums in U and T^{-1} given by $4, 2, 5, -1, 6 \equiv 0, 0$ as required. □

The theory of the Ptolemy-Thompson group can be compared in richness only with the modular group. It is natural to ask what is the wider class of similar groups that have similar properties as $\mathrm{PPSL}_2(\mathbb{Z})$. In the case of the modular group, such a class is embodied into so-called arithmetic groups, namely, subgroups of $\mathrm{PSL}_2(\mathbb{R})$ which are commensurable with $\mathrm{PSL}_2(\mathbb{Z})$. They have an important common property with the modular group: their ideal compactification points in $\mathbb{D}/\Gamma$ are again $\hat{\mathbb{Q}}$. Thus, the piecewise Γ subgroups of $\mathrm{PPSL}_2(\mathbb{R})$, denoted by $\mathrm{P}\Gamma$, for Γ arithmetic, might serve as a natural generalization of $\mathrm{PPSL}_2(\mathbb{Z})$.

The first question one might ask about these groups $\mathrm{P}\Gamma$ is when they are finitely generated. The answer is contained in the dissertation of Laget [19]: if and only if Γ is of genus zero. But this is a hint towards a possible connection with Monstrous Moonshine, where the genus zero property also plays a key role. The groups Γ that appear in Monstrous Moonshine also have the width 1 property, namely the Farey-type tesselation or paving obtained by the action of Γ on the edge $(0, \infty)$ in $\mathbb{D}$ is 1-periodic.

These three conditions on Γ of arithmeticity, genus zero property and width 1 restrict the number of possible Γ to the large but finite number 6486 according to [8]. On the other hand, there are 194 conjugacy classes in the Monster, which give rise to groups Γ with the same three properties as above, with some identifications that reduce the number of groups Γ involved in Monster Moonshine to 171 [6]. The problem that we want to address in this conclusion to the section is:

How to characterize the Monster Moonshine Γ among arithmetic, genus 0, width 1 groups from the properties of the piecewise Γ groups $\mathrm{P}\Gamma$.

So the Monster began to show up already in Thompson-like groups. But to capture it, we shall need other aspects of our universal automorphic triad: The universal Teichmüller space and the corresponding Lie algebra which we shall review and study in the next sections.

2. Framed holographic coordinates

We shall regard $ppsl_2$ as an appropriate limit of copies of sl_2, one copy at each Farey rational point in $\mathbb{S}^1$. To take the limit, we require suitable coordinates on ideal polygons in which to calculate representations, and this section is dedicated to this end. Let us begin with the basic "lambda length" coordinates (sometimes called Penner coordinates) which we recall from [23, 26].

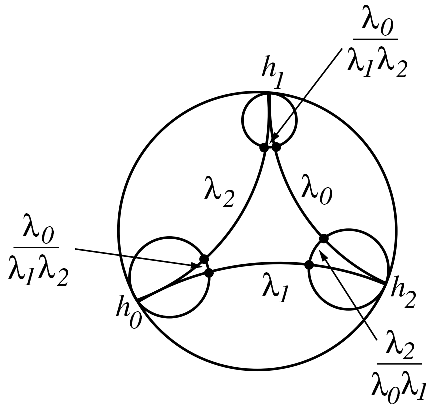
A *decorated ideal n-gon* is an ideal polygon of n sides in hyperbolic space together with n horocycles, one centered at each of its ideal vertices. One such coordinate is associated to each of the $2n-3$ edges in an ideal triangulation of the n-gon including its frontier edges. As in the Introduction, there is a basic move, called a *flip*, on the interior edge of such a triangulation, where one removes the edge so as to produce a complimentary ideal quadrilateral and then replaces it with the other diagonal of this quadrilateral to finally produce another ideal triangulation.

Theorem 2.1. *Fix some $n \geqslant 3$ and consider a* decorated *ideal n-gon P in $\mathbb{D}$. Suppose that the frontier edges of P are labeled and choose an ideal triangulation Δ of P. Then the moduli space of such decorated polygons up to the natural action of Möb is given by the assignment of one real lambda length $\lambda = \sqrt{\exp \ell}$ to each unoriented edge $e \in \Delta$, where ℓ is the signed hyperbolic distance along e between the horocycles centered at its endpoints, taken with a positive sign if and only if these horocycles are disjoint. Moreover, the lambda lengths are governed by the Ptolemy equation*

$$ef = ac + bd$$

whenever f arises from a flip on e in the quadrilateral bounded by a, b, c, d in this counter-clockwise cyclic order, here identifying an edge with its lambda length for convenience. □

Beyond the lambda lengths, other basic coordinates are the *h-lengths* assigned to any ideal vertex v of a decorated polygon P by taking the hyperbolic distance along the horocycle centered at v between the incident frontier edges of P. A fundamental formula illustrated in Figure 3 relates lambda lengths and h-lengths in a triangle, where $\frac{\lambda_i}{\lambda_j\lambda_k}$ is the h-length opposite the edge λ_i, for $\{i,j,k\}=\{0,1,2\}$, and we here and hereafter again often conflate an edge with its lambda length for convenience. It follows that the product of h-lengths of consecutive vertices is the reciprocal square of the lambda length of the edge they span, i.e., $\big(\frac{\lambda_i}{\lambda_j\lambda_k}\big)\big(\frac{\lambda_j}{\lambda_i\lambda_k}\big)=\frac{1}{\lambda_k^2}$, so either the triple of lambda lengths λ_i, for $i=0,1,2$ or the triple of h-lengths $\frac{\lambda_i}{\lambda_j\lambda_k}$, for $\{i,j,k\}=\{0,1,2\}$, give coordinates on the moduli space of $M\ddot{o}b$-orbits of decorated ideal triangles by the previous result.



$\frac{\lambda_0}{\lambda_1\lambda_2}$
h_1
λ_2
λ_0
$\frac{\lambda_0}{\lambda_1\lambda_2}$
λ_1
h_0
h_2
$\frac{\lambda_2}{\lambda_0\lambda_1}$

Figure 3. Three horocycles h_i whose centers span a decorated ideal triangle with opposite lambda lengths λ_i and adjacent h-lengths $\frac{\lambda_i}{\lambda_j\lambda_k}$ for $\{i,j,k\}=\{0,1,2\}$.

Corollary 2.2. [Holographic parameters on a decorated polygon]: *For any $n\geqslant 3$, the moduli space of decorated ideal n-gons P up to the action of $M\ddot{o}b$ is parametrized by the assignment of the lambda length of each frontier edge together with the assignment of the h-length of each vertex of P. These parameters are constrained by three rational equations.*

Proof. The proof is by induction on n, and the basis step $n=3$ was just discussed. For the induction, choose consecutive edges a,b of P with intermediate vertex w, let T be the triangular convex hull of $\{a,b\}$, α,β the respective h-lengths in T opposite the endpoints of a,b distinct from w, and let γ denote the h-length at w of T. Consider also the h-lengths α',β' of the same vertices but in P rather than T.

Now consider the closure Q of the complement of T in P. Thus Q is an ideal $(n-1)$-gon which inherits all the moduli of P *except* that the respective h-lengths in Q at u and v are taken to be $\alpha'-\alpha$ and $\beta'-\beta$. The inductive hypothesis therefore applies to Q with these parameters, and hence also to P with parameters α', β' at u, v. Notice the constraint that $\alpha\beta$ equals the reciprocal square of the lambda length of $T \cap Q$. This constraint in T accounts for dimension reduction to confirm that the three rational constraints in Q persist in P. □

The significance of this parametrization arises upon consideration of the *Ptolemy groupoid* $\mathrm{Pt}(P)$ of an ideal polygon P whose objects are the ideal triangulations of P with interior doe, and whose morphisms are the flips along interior edges, where the flip on the doe e induces an orientation on the resulting edge and is of order four, whereas the flip on any other edge is of order two; these are the *face relations.* The flips on any two edges which do not lie in the frontier of a common triangle commute, and these are the *commutativity relations.* The *pentagon relations* arise from the serial sequence of flips alternating between two edges lying in the frontier of a common triangle, which has order five, unless one of these edges is the doe, in which case the order is ten. See [23, 24, 26] for further details.

According to Proposition 4.5 in [24] and remarks in [23, 24], we have

Theorem 2.3. *Finite sequences of flips supported on the interior of an ideal polygon P act transitively on the collection of all its triangulations with interior doe. It follows that flips generate* $\mathrm{Pt}(P)$. *Furthermore, a complete set of relations are given by the face, commutativity and pentagon relations.* □

So here finally is the significance of the holographic parameters: Taking the quotient by flips evidently renders meaningless the notion of lambda lengths of interior edges, these edges being precisely the data are obliterated. However, the lambda lengths of its frontier edges and the h-lengths of its vertices survive flips on interior edges to give parameters on the quotient. This explains our mechanism of holography.

We must go a bit further still in order to derive useful coordinates. An ordered triple of pairwise distinct points in the circle is a member of the configuration space

$$C_3 = \{(u, v, w) \in (\mathbb{S}^1)^3 : u, v, w \text{ are pairwise distinct}\},$$

on which *Möb* acts simply transitively according to Proposition 1.1. A *framing on an ideal polygon* is the specification of an arbitrary element of C_3, whose members need not be among the vertices of the polygon. A framed ideal polygon does not necessarily contain any doe, though an interior doe in a triangulation evidently determines an *associated framing* given by the respective initial and terminal points of the doe followed by the third vertex of the triangle immediately to the right of the doe.

An ordered triple $(u, v, w) \in C_3$ uniquely determines a unit tangent vector in $\mathbb{D}$ as follows. There is a unique geodesic g asymptotic to u and v, and the orthogonal projection of w onto g provides a point $p \in \mathbb{D}$. The unit tangent vector to g at p, where g is oriented with w on its right, finally provides the asserted unit vector associated to (u, v, w). In these coordinates on the unit tangent bundle to $\mathbb{D}$, the almost complex structure is furthermore conveniently described by $(u, v, w) \mapsto (w, x, v)$, where $\mathbb{S}^1 \ni x \neq w$ is the endpoint of the geodesic through p which is asymptotic to w.

Remark 2.4. The term “framing” is motivated by instantons, where the incorporation of framing dramatically simplifies the formulas and accounts for the gauge group, cf. [3]. The same phenomena occur here: the framing kills both the $M\ddot{o}b$ action and the three relations on holographic parameters in order to produce finally useful coordinates.

To explain the utility of the new coordinates, let us consider lambda and h-lengths in the upper half space model $\mathcal{U}$. A decorated ideal n-gon P is uniquely determined by a collection of pairwise disjoint points $s_i \in \hat{\mathbb{R}} = \mathbb{R} \cup \{\infty\}$, for $i = 1, \cdots, n$, together with a collection of Euclidean diameters δ_i of corresponding horocycles and perhaps the y-coordinate δ_∞ of a horocycle about ∞. Evidently these are actually coordinates, not just parameters, as they satisfy no relations other than pairwise inequality among the $\{s_i\}_1^n$.

The collection of pairs (s_i, δ_i), for $i = 1, \ldots, n$, are called *framed holographic coordinates* on the space of all decorated ideal polygons, and these are our desired coordinates. To explain the relationship with framed polygons, take a fixed copy of $\mathbb{D}$ and choose a fixed Cayley map $C^{-1} : \mathbb{D} \to \mathcal{U}$. Thus, given a $M\ddot{o}b$-orbit of decorated ideal polygon in $\mathbb{D}$ with framing $(u, v, w) \in C_3$, there is a well-defined decorated ideal polygon in $\mathcal{U}$ gotten by post-composing C with the unique Möbius transformation mapping $C^{-1}(u), C^{-1}(v), C^{-1}(w)$ to the respective points $\frac{0}{1}, \frac{1}{0}, \frac{1}{1}$.

We have proved

Theorem 2.5. *The moduli space of all framed decorated ideal n-gons modulo the action of Möb is given by the pairwise distinct n-tuples $\{s_i\}_1^n$ of centers of horocycles in $\hat{\mathbb{R}}$ with Euclidean diameters $\{\delta_i\}_1^n$ called the* framed holographic coordinates $\{(s_i, \delta_i) : 1 \leqslant i \leqslant n\}$. *The action of $A = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in$ Möb on these coordinates is the usual right fractional linear action $s_i \mapsto \frac{ds_i - b}{-cs_i + a}$ on the $\{s_i\}_1^n$, while the $\{\delta_i\}_1^n$ scale by the derivative of A at s, so $\delta_i \mapsto \frac{\delta_i}{(a-cs_i)^2}$.* □

Proof. The only point requiring clarification is the transformation law for δ coordinates, which follows from the fact [23, 26] that Euclidean diameters of horocycles scale by the derivative under a Möbius transformation. □

Remark 2.6. It is unsurprising that our framed holographic coordinates are reminiscent of the dihedral coordinates of [4] since the latter, which pertain only to the case of planar surfaces, are effectively related to the antecedent lambda lengths from [23] for any punctured surface, which are elaborated in the new coordinates.

Turning finally to stabilization given a framing $\mathcal{F} = (u, v, w) \in C_3$, define the matrix

$$L_{\mathcal{F}} = \frac{1}{(w-v)(u-w)(v-u)} \begin{pmatrix} v(u-w) & u(w-v) \\ u-w & w-v \end{pmatrix} \in \mathrm{SL}_2(\mathbb{R}),$$

which maps $(u, v, w) \mapsto (\frac{0}{1}, \frac{1}{0}, \frac{1}{1})$ under the right action, and given a second framing $\bar{\mathcal{F}}$, define

$$L_{\mathcal{F}}^{\bar{\mathcal{F}}} = L_{\mathcal{F}} \circ L_{\bar{\mathcal{F}}}^{-1} = \begin{pmatrix} a_{\mathcal{F}}^{\bar{\mathcal{F}}} & b_{\mathcal{F}}^{\bar{\mathcal{F}}} \\ c_{\mathcal{F}}^{\bar{\mathcal{F}}} & d_{\mathcal{F}}^{\bar{\mathcal{F}}} \end{pmatrix} \in \mathrm{SL}_2(\mathbb{R}).$$

Now, given holographic coordinates $\{(s_i, \delta_i)\}_1^n$ with framing $\mathcal{F} = (u, v, w)$ and given (s, δ) with $s \notin \{s_i\}_1^n$, there is a unique $i^* \in \{1, \ldots, n\}$ with $s_{i^*} < s < s_{i^*+1}$. For $j = 1, \ldots, n+1$, define

$$(\bar{s}_j, \bar{\delta}_j) = \begin{cases} (s_j, \delta_j), & \text{if } j \leqslant i^*; \\ (s, \delta), & \text{if } j = i^* + 1; \\ (s_{j+1}, \delta_{j+1}), & \text{if } j > i^*, \end{cases}$$

and given a framing $\bar{\mathcal{F}} = (\bar{u}, \bar{v}, \bar{w})$ on $\{(\bar{s}_j, \bar{\delta}_j)\}_1^{n+1}$, finally let

$$\begin{aligned} s_k' &= (\bar{s}_k) L_{\mathcal{F}}^{\bar{\mathcal{F}}}, \\ \delta_k' &= (\bar{\delta}_k) \frac{d}{ds}\left((\bar{s}_k) L_{\mathcal{F}}^{\bar{\mathcal{F}}} \right), \end{aligned}$$

for $k = 1, \ldots, n+1$.

Corollary 2.7. *In the notation above, the mapping*

$$\{(s_i,\delta_i)\}_1^n \mapsto \{(s_i',\delta_i')\}_1^{n+1}$$

describes the stablization of framed holographic coordinates. In particular, if the framing $(u,v,w)=(\bar{u},\bar{v},\bar{w})$ *is constant, then the stablization is given by inclusion and re-indexing.* □

Remark 2.8. Furthermore according to [23, 26], the lambda length between (s,δ) and (s',δ') for $s,s'\neq\infty$ is given by $(\delta\delta')^{-\frac{1}{2}}|s-s'|$ and between (s,δ) and (∞,δ_∞) is given by $(\delta_\infty/\delta)^{\frac{1}{2}}$. On the level of the holographic parameters in Proposition 2.2 and in the foregoing notation, let c denote the lambda length of the edge between s_{i*} and s_{i*+1}, and let h_{i*} and h_{i*+1} denote the respective nearby h-lengths. If a,b denote the respective lambda lengths of the decorated edges between s and s_{i*}, s_{i*+1}, then after stabilization, the h-lengths at s_{i*}, s and s_{i*+1} are respectively given by $h_{i*}+\frac{b}{ac}$, $\frac{c}{ab}$ and $h_{i*+1}+\frac{a}{bc}$.

3. Framed and decorated homemorphisms of $\mathbb{S}^1$

Having developed framings on polygons as an alternative to the specification of a doe in the previous section, let us revisit from this framed point of view a basic result, Theorem 2.3 of [24], whose proof we first recall.

Theorem 3.1. *The space*

$$\mathcal{T}ess' = \{\text{tesselations of } \mathbb{D} \text{ with doe}\}$$

with topology induced by the Hausdorff topology on $\cup\tau\subset\mathbb{D}$ *is naturally homeomorphic to the space*

$$\mathrm{Homeo}_+ \approx \mathcal{T}ess'$$

with the compact-open topology.

Proof. Given $f\in\mathrm{Homeo}_+$, the image $\tau=f(\tau_*)$ of the Farey tesselation is another tesselation of $\mathbb{D}$, and the canonical doe $e_I\in\tau_*$ maps to the doe $e=f(e_I)$ of $\tau'=(\tau,e)\in\mathcal{T}ess'$ by definition. For the inverse map given a tesselation $\tau'=(\tau,e)$ with doe $e\in\tau$, begin by mapping the respective initial and terminal points of e_I to the initial and terminal points of e. Continue by mapping the further points in τ_*^0 of the respective triangles containing $|e_I|$ complementary to τ_* to the left and right of e_I in τ_* to those to the left and right of e in τ. Proceed in this way, essentially relying on the combinatorial rigidity of a tesselation with doe, in order to define $f^0 : \tau_*^0 \to \tau^0$, an order-preserving injection between dense subsets by construction. Using that a tesselation is locally-finite in $\mathbb{D}$ by definition, f^0 is seen to be a surjection as well, which thus interpolates a homeomorphism $f_{\tau'} \in \mathrm{Homeo}_+$ called the *characteristic map* of τ'. That the bijective assignment $\tau' \leftrightarrow f_{\tau'}$ is bicontinuous for the stated topologies is clear, completing the proof. ☐

A *framing on a tesselation* τ of $\mathbb{D}$ is the specification of an element of the configuration space C_3 of distinct triples in $\mathbb{S}^1$, whose members are not required to lie in τ^0, where the framed version of the basic result is

Corollary 3.2. *The space*

$$\mathcal{T}ess^f = \{\text{tesselations of } \mathbb{D}\}$$

is naturally homeomorphic to $\mathcal{T}ess' \approx \mathrm{Homeo}_+$*.*

Proof. As before for polygons, a doe e for τ determines an associated framing, and this gives an inclusion $\mathcal{T}ess' \subset \mathcal{T}ess^f$. Conversely given a framing (u, v, w) on the tesselation τ, choose a doe e_1 on τ with associated framing (u_1, v_1, w_1), let $L_1 = L_{u,v,w}^{u_1,v_1,w_1} \in M\ddot{o}b$ as in the previous section, and define

$$\tau'(\tau, u, v, w, e_1) = L_1^{-1} \circ f_{\tau_1'}(\tau_*) \in \mathcal{T}ess'$$

with its doe induced from e_I on τ_*.

We claim that $\tau_1' = \tau'(\tau, u, v, w, e_1)$ is independent of the choice of doe e_1 and to this end choose another doe e_2 on τ with associated framing (u_2, v_2, w_2), let $\tau_2' = \tau'(\tau, u, v, w, e_2)$ and $L_2 = L_{u,v,w}^{u_2,v_2,w_2}$. The composition $(L_2^{-1} \circ f_{\tau_2'})^{-1} \circ (L_1^{-1} \circ f_{\tau_1'})$ lies in PSL_2 by Lemma 1.1 since it leaves τ_* invariant, and in fact, it must be the identity since it furthermore pointwise fixes u, v, w. It follows that τ_1' and τ_2' have the same characteristic maps, and hence $\tau_1' = \tau_2'$ as tesselations with doe.

The assignment $(\tau, u, v, w) \mapsto L_1^{-1} \circ f_{\tau_1'}$ is thus a well-defined inverse to the inclusion $\mathcal{T}ess' \subseteq \mathcal{T}ess^f$ induced by associated framings, which is thus a homeomorphism as required. ☐

Let us emphasize that framings thus replace distinguished oriented edges in all regards: from determining global affine coordinates in this section, to the identification of $\mathcal{T}ess^f \approx \mathcal{T}ess'$ with Homeo_+, to the isomorphisms $\mathrm{Pt} \approx \mathrm{T} \approx \mathrm{PPSL}_2(\mathbb{Z})$ as well as their actions on tesselations.

It is straight-forward to describe the group structure on $\mathcal{T}ess^f$ induced by composition of homeomorphisms in Homeo_+ but difficult to visualize on the level of tesselations, except in special cases.

Proposition 3.3. *Consider framings $\mathcal{F}_X$ on the Farey tesselation τ_* associated to does e_X for $X \in PSL_2$. Then*

$$(\tau_*, \mathcal{F}_A) \circ (\tau_*, \mathcal{F}_B) = (\tau_*, \mathcal{F}_{BA}),$$

with the analogous statement holding for any tesselation. □

Next we introduce decorated versions of the foregoing spaces and begin by defining

$$\widetilde{\mathcal{T}ess^f} = \{\text{decorated and framed tesselations of } \mathbb{D}\},$$

where a *decoration* on a tesselation τ is the specification of one horocycle centered at each point of τ^0, so there is a natural forgetful mapping to $\widetilde{\mathcal{T}ess^f} \to \mathcal{T}ess^f$, whose fiber can be identified with $\mathbb{R}^\omega$.

Taking the quotient by the *Möb*-action on framings, we have

$$\begin{aligned} \mathcal{T}ess^f/M\ddot{o}b \approx \mathcal{T}ess^n &= \left\{\text{tesselations } \tau : \tfrac{0}{1}, \tfrac{1}{1}, \tfrac{1}{0} \in \tau^0\right\}, \\ \widetilde{\mathcal{T}ess^f}/M\ddot{o}b \approx \widetilde{\mathcal{T}ess^n} &= \left\{\text{decorated tesselations } \tau : \tfrac{0}{1}, \tfrac{1}{1}, \tfrac{1}{0} \in \tau^0\right\} \end{aligned}$$

where the superscript n stands for *normalized.* Notice that the Farey tesselation τ_* is itself already normalized.

As for the analogous elaboration of circle homemorphisms, first define spaces

$$\text{Homeo}_+^n = \{f \in \text{Homeo}_+ : f(t) = t \text{ for } t = \tfrac{0}{1}, \tfrac{1}{1}, \tfrac{1}{0}\}$$

of *normalized* homeomorphisms, so $\mathcal{T}ess^n \approx \text{Homeo}_+^n$ as Homeo_+^n-spaces. Next define the decorated version

$$\widetilde{\text{Homeo}_+^n} = \{(\tilde{f}, f) : f \in \text{Homeo}_+^n \text{ covered by } \tilde{f} : \widetilde{\mathcal{T}ess^n} \to \widetilde{\mathcal{T}ess^n}\}$$

with the natural group structure, making $(\tilde{f}, f) \mapsto f$ a group homomorphism $\widetilde{\text{Homeo}_+^n} \to \text{Homeo}_+^n$. There is analogously an isomorphism $\widetilde{\text{Homeo}_+^n} \approx \widetilde{\mathcal{T}ess^n}$ of $\widetilde{\text{Homeo}_+^n}$-spaces, where (identity,identity) corresponds to the Farey tesselation with its canonical decoration $\tilde{\tau}_*$, namely, the one determined by the condition that the horocycles at endpoints of any common geodesic are taken to be osculating.

This leads to the commutative cube

$$\begin{tikzcd}
\widetilde{\mathcal{T}ess^f} \arrow[rr, "\approx"] \arrow[dd] \arrow[dr] & & \widetilde{\mathrm{Homeo}_+} \arrow[dd] \arrow[dr] & \\
& \mathcal{T}ess^f \arrow[rr, "\approx"] \arrow[dd] & & \mathrm{Homeo}_+ \arrow[dd] \\
\widetilde{\mathcal{T}ess^n} \arrow[rr, "\approx"] \arrow[dr] & & \widetilde{\mathrm{Homeo}^n_+} \arrow[dr] & \\
& \mathcal{T}ess^n \arrow[rr, "\approx"] & & \mathrm{Homeo}^n_+
\end{tikzcd}$$

where $\widetilde{\mathrm{Homeo}_+}$ is defined by pull-back, the vertical maps are principal $M\ddot{o}b$-bundles, and the maps out of the plane of the page are $\mathbb{R}^\omega$-bundles.

Theorem 3.4. *Lambda lengths on edges of* τ_* *give global affine coordinates on* $\widetilde{\mathcal{T}ess^n} \subseteq \mathbb{R}_+^{\tau_*}$. *Indeed, there is an explicit construction of a Möb-orbit of tesselations of* $\mathbb{D}$ *with doe from the assignment of a putative lambda length to each edge of* τ_*. $\square$

The proof of this result as Theorem 3.1 in [24] provides the explicit recursive construction of a $M\ddot{o}b$-orbit of decorated tesselations of $\mathbb{D}$ with doe from the assignment of a putative lambda length to each edge of τ_*, in analogy to the proof of Theorem 2.1. The canonical decoration $\tilde{\tau}_*$ on τ_*, or in other words the identity element of the group $\widetilde{\mathrm{Homeo}^n_+}$, corresponds to taking all these lambda length coordinates equal to unity. In the classical setting of a suitably decorated punctured surface of finite topological type uniformized by a torsion free subgroup of finite-index in PSL_2, or a so-called *punctured arithmetic surface*, the classical lambda length coordinates on decorated Teichmüller space from [23] are likewise all unity, so this identity element in $\widetilde{\mathrm{Homeo}^n_+}$ may be regarded as the universal punctured arithmetic surface.

Remark 3.5. It is not difficult to descend these lambda length coordinates on the bottom-back of the previous commutative cube to its bottom-front by assigning cross ratios $\frac{ac}{bd}$, or shear coordinates $\ln\frac{ac}{bd}$, instead of lambda lengths e to each edge, where e is the diagonal of the quadrilateral with frontier edges a, b, c, d in this cyclic order; see [24].

We next discuss framed tesselations as limits of framed polygons. To this end, notice that there is the natural linear ordering on $\hat{\mathbb{Q}}$ arising from the lexicographic ordering on pairs given by Farey generation followed by the counter-clockwise order in $\mathbb{S}^1$ starting from $\frac{0}{1}$, and there is thus an induced bijective enumeration $\mathbb{Z}_{\geqslant 0} \to \hat{\mathbb{Q}}$.

Remark 3.6. This is the raison d'être for the Farey construction. Indeed, the mineralogist Farey published without proof this solution to the long-standing open problem of producing an explicit bijective enumeration of the rational numbers, and the proof was essentially immediately supplied by Cauchy.

Construction 3.7. Suppose that $S \subseteq \mathbb{S}^1$ is a countable dense subset enumerated by the bijection $\mu : \mathbb{Z}_{\geqslant 0} \to S$. Construct a function $f_\mu : \hat{\mathbb{Q}} \to S$ as follows. For the basis step of our recursive construction, define $f_\mu(\frac{0}{1}) = \mu(0)$ and $f_\mu(\frac{1}{0}) = \mu(1) \in \mathbb{S}^1$. Recursively suppose that the images of the Farey points of generation at most $g \geqslant 0$ have been defined. This collection of image points decomposes $\mathbb{S}^1$ into 2^{g+1} open circular intervals. Each such interval with endpoints $x = f_\mu(\frac{p}{q}), y = f_\mu(\frac{r}{s})$ contains a point $z \in S$ of least index $\mu^{-1}(z)$, and we define $f_\mu(\frac{p+r}{q+s}) = z$ in this case, thereby extending the function f_μ to generation $g + 1$. We furthermore derive a collection $\tau_\mu = \{f_\mu(e) : e \in \tau_*\}$ of geodesics with doe $f_\mu(e_I)$, where $f_\mu(e)$ denotes the geodesic in $\mathbb{D}$ with endpoints the f_μ-image of the endpoints of $e \in \tau_*$.

Suppose that $\mu : \mathbb{Z}_{\geqslant 0} \to S$ is a bijective enumeration of a countable dense subset $S \subseteq \mathbb{S}^1$. A circular interval $I \subseteq \mathbb{S}^1$ with endpoints $x, y \in S$ is said to be *solid* provided $\mu^{-1}(z) > \max\{\mu^{-1}(x), \mu^{-1}(y)\}$ for every z in the interior of I. The enumeration μ is said to be *convergent* if every infinite proper nested family $I_0 \supsetneq I_1 \supsetneq \cdots$ of solid open intervals is disjoint from S, that is, $S \cap \bigcap_{j \geqslant 0} I_j = \varnothing$.

For any $e \in \tau_*$ other than the doe, exactly one of the circular intervals in $\mathbb{S}^1$ complementary to its endpoints is solid, and the Farey enumeration of $\hat{\mathbb{Q}}$ is convergent by definition of the Farey ordering. We may always assume that an enumeration of a countable dense subset is indexed by the Farey tesselation in its canonical linear ordering.

Proposition 3.8. *For any convergent bijective enumeration $\hat{\mathbb{Q}} \to S$ of a countable dense subset $S \subset \mathbb{S}^1$, Construction 3.7 yields a bijection $f_\mu : \hat{\mathbb{Q}} \to S$ and a tesselation $\tau_\mu = f_\mu(\tau_*)$ with doe. Conversely, if $f_\mu : \hat{\mathbb{Q}} \to S$ is a bijection, then τ_μ is a tesselation, and μ must be convergent.*

Proof. Suppose that μ is convergent and $z \in S$. For $g \geqslant 0$, let I_g denote the component of $\mathbb{S}^1 - \{f_\mu(x) : x \in \hat{\mathbb{Q}} \text{ is of generation at most } g\}$ which contains z. It follows that $I_0 \supsetneq I_1 \supsetneq \cdots$ is a nested family of solid intervals. This sequence must terminate, for otherwise $z \in S \cap \bigcap_{g \geqslant 0} I_g \neq \varnothing$ contradicts convergence of μ. Thus, f_μ maps onto S and is injective by construction, and so is a bijection.

To see that $\tau_\mu = f_\mu(\tau_*)$ is locally finite, suppose in order to derive a contradiction that a sequence of points in $e_i = f_\mu(e_i')$, for $i \geqslant 1$ and $e_i' \in \tau_*$, accumulates at some point in $\mathbb{D}$. It follows that e_i limits to some geodesic e_∞ in $\mathbb{D}$. Since the $\{e_i\}$ are pairwise disjoint in $\mathbb{D}$ by construction, we may assume that they all lie on one side of e_∞. By density of S in $\mathbb{S}^1$, there is some $z \in S$ on the other side of e_∞, and it lies in the f_μ-image of some generation g point of $\hat{\mathbb{Q}}$ by the already established surjectivity. Taking a further subsequence if necessary, the complementary intervals to the endpoints of e_i that contains z are solid. The generation of these endpoints is therefore bounded above by g, so that $\{e_i\}$ is a finite set, as required. The same argument shows that each component of $\mathbb{D} - \cup\tau_\mu$ is an ideal triangle, so τ_μ is indeed a tesselation.

Conversely, suppose that $f_\mu : \mathbb{Q} \to S \subseteq \mathbb{S}^1$ is surjective and $z \in S \cap \bigcap_{j \geqslant 1} I_j$ for some nested sequence $I_0 \supsetneq I_1 \supsetneq \cdots$ of solid intervals with endpoints in S. The point $z \in S$ must a fortiori have some fixed generation, which bounds above the generations of the endpoints of the intervals. Since there are only finitely many points of any given generation, the sequence must terminate, as required. $\square$

It is an easy matter now to stabilize nested, decorated and framed ideal polygons:

Theorem 3.9. *Consider a nested sequence*

$$P_0 \subseteq P_1 \subseteq \cdots \subseteq P_g \subseteq P_{g+1} \subseteq \cdots$$

of ideal polygons with a common framing $\mathcal{F} \in C_3$, where P_0 is a geodesic, P_g has 2^{g+1} sides for $g \geqslant 1$, and $P_{g+1} - P_g$ consists of 2^g ideal triangles, for all $g \geqslant 0$. If the union of the ideal vertices of all the polygons is dense, then there is a well-defined limiting tesselation also framed by $\mathcal{F}$, and any such is conversely given by such a limit. The analogous statement holds for decorated framed polygons and decorated framed tesselations. Moreover, the tuple of framed holographic coordinates

$$(s_{\frac{0}{1}}, \delta_{\frac{0}{1}}), (s_{\frac{1}{0}}, \delta_{\frac{1}{0}}), (s_{\frac{1}{1}}, \delta_{\frac{1}{1}})(s_{-\frac{1}{1}}, \delta_{-\frac{1}{1}}), \ldots$$

in $(\hat{\mathbb{R}} \times \mathbb{R}_{>0})^\omega$ *of decorated polygons in the weak topology given in their natural Farey ordering, where the* $\{s_i\}$ *are required to be pairwise distinct and* $\cup\{s_i\}$ *to be dense in* $\hat{\mathbb{R}}$, *provide global coordinates on* $\widetilde{\mathcal{T}ess^f} \approx \widetilde{\mathrm{Homeo}}_+$. $\square$

4. The Lie algebra *ppsl*$_2$

Let $sl_2 = sl_2(\mathbb{R})$ denote the usual Lie algebra of traceless two-by-two real matrices with generators $e = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$, $f = \left(\begin{smallmatrix} 0 & 0 \\ 1 & 0 \end{smallmatrix}\right)$ and $h = \left(\begin{smallmatrix} +1 & 0 \\ 0 & -1 \end{smallmatrix}\right)$ and Lie brackets $[h, e] = 2e$, $[h, f] = -2f$ and $[e, f] = h$. (Context will distinguish the notational inconvenience of determining between $e \in sl_2$ or $e \in \tilde{\tau}$.)

Exponentiating $\left(\begin{smallmatrix} \alpha & \beta \\ \gamma & -\alpha \end{smallmatrix}\right) \in sl_2$ yields a one-parameter family of diffeomorphisms giving rise to a vector field on the circle which is given by

$$\{(\gamma + \beta) \cos \theta + 2\alpha \sin \theta + (\gamma - \beta)\} \frac{\partial}{\partial \theta},$$

where $\frac{\partial}{\partial \theta}$ denotes the constant unit vector field on $\mathbb{S}^1$ and θ its usual angular coordinate. A vector field A on $\mathbb{S}^1$ arising in this way is called a *(global) sl_2 vector field*, and we write $A \in sl_2$ in this case. The values of an sl_2 vector field at any three distinct points in $\mathbb{S}^1$ determine it uniquely. In case two vector fields ϑ_1 and ϑ_2 on $\mathbb{S}^1$ differ by a global sl_2 vector field, then we shall write $\vartheta_1 \doteq \vartheta_2$.

More generally, a vector field ϑ on $\mathbb{S}^1$ is a *piecewise sl_2 vector field* if $\mathbb{S}^1$ decomposes into *finitely many* open connected circular intervals with pairwise disjoint interiors whose endpoints are among the rational points of $\mathbb{S}^1$ so that ϑ restricts on the interior of each such interval to some global sl_2 vector field. $ppsl_2$ denotes the collection of all such vector fields including the possibility of no breakpoints, namely $sl_2 \subseteq ppsl_2$ itself. The endpoints of the *maximal such intervals* are called the *breakpoints* of ϑ itself. There are no restrictions on the behavior of ϑ at its breakpoints (except that the breakpoints, if any, are rational), and indeed $\vartheta \in ppsl_2$ may not even be defined at its breakpoints in general, in which case its value is implicitly given as the average of the two one-sided limits.

Remark 4.1. Let us parenthetically recall a seminal result of Dirichlet, which he proved in Berlin at age 24 thereby besting the top mathematicians of his day: the Fourier series of a piecewise smooth function with finitely many pieces converges pointwise to the function itself except at the breakpoints where it is the average of its two one-sided limits.

A bracket $[\vartheta_1, \vartheta_2] \in ppsl_2$ of two $\vartheta_1, \vartheta_2 \in ppsl_2$ is defined in the natural way: the resulting vector field has preliminary breakpoints given by the union of those of ϑ_1 and those of ϑ_2, and on each complementary component in $\mathbb{S}^1$ of this union, the bracket is given by the usual bracket on sl_2. It may happen that the actual breakpoints of $[\vartheta_1, \vartheta_2]$ form a proper subset of the preliminary breakpoints since we demand maximality of intervals complementary to the actual breakpoints.

Consider breakpoints $\pm 1, \pm i \in \mathbb{S}^1 \subseteq \mathbb{C}$, so the complementary intervals lie in respective quadrants I-IV in the complex plane enumerated as usual in the counterclockwise sense beginning with quadrant I where both coordinates are non-negative, and define

$$\Lambda(s) = \begin{cases} \begin{pmatrix} s & s-s^{-1} \\ 0 & s^{-1} \end{pmatrix}, & \text{on quadrant I;} \\ \begin{pmatrix} s^{-1} & 0 \\ s-s^{-1} & s \end{pmatrix}, & \text{on quadrant II;} \\ \begin{pmatrix} s^{-1} & 0 \\ s^{-1}-s & s \end{pmatrix}, & \text{on quadrant III;} \\ \begin{pmatrix} s & s^{-1}-s \\ 0 & s^{-1} \end{pmatrix}, & \text{on quadrant IV,} \end{cases}$$

for $s \in \mathbb{R} - \{0\}$, a one-parameter family in $\mathrm{PPSL}_2(\mathbb{R})$. It is not difficult to check that each $\Lambda(s)$ is moreover once-continuously differentiable on $\mathbb{S}^1$ including at its breakpoints.

Since lambda lengths are *Möb*-invariant, it is clear that $\Lambda(s)$ leaves invariant all lambda lengths on τ_* with any decoration, except the lambda length of the doe, which it scales by a factor s. Thus, $\Lambda(s)$ is a one-parameter family in $\mathrm{PPSL}_2(\mathbb{R})$ scaling just one affine lambda length coordinate, or in other words a multiplicative coordinate deformation.

More specifically, $\Lambda(s) \in \mathrm{PPSL}_2(\mathbb{R})$ is a one-parameter family which on each circular interval determined by the intersection of a quadrant with $\mathbb{S}^1$ is a hyperbolic transformation whose axis is spanned by the endpoints of the interval. In the parlance of the Thurston school, an *earthquake* is an element of $\mathrm{PPSL}_2(\mathbb{R})$ with two pieces, one of which is the identity and the other is a hyperbolic transformation whose axis is asymptotic to the breakpoints. Thus, $\Lambda(s)$ is a special one-parameter family of compositions of four earthquakes, where the four hyperbolic translations are chosen in order to produce homeomorphisms $\Lambda(s)$ that are once-continuously differentiable on $\mathbb{S}^1$.

The derivative of $\Lambda(s)$ with respect to s at $s = 1$ is the extremely special element $\vartheta \in ppsl_2$ illustrated in Figure 4 and called the *mother* *wavelet*. It is the basic building block of $ppsl_2$. Justification for the appellate "wavelet" used here is given in [27].

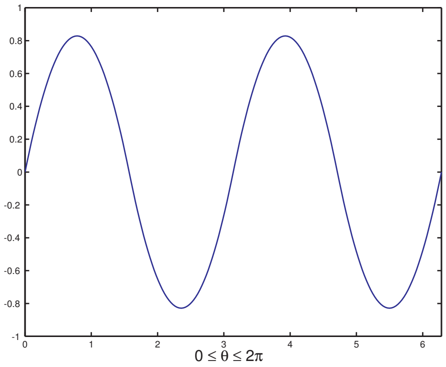


Figure 4. The mother wavelet ϑ.

Direct computation confirms that the mother wavelet ϑ is given by

$$\vartheta = \begin{cases} +h + 2e, & \text{in quadrant I;} \\ -h + 2f, & \text{in quadrant II;} \\ -h - 2f, & \text{in quadrant III;} \\ +h - 2e, & \text{in quadrant IV} \end{cases}$$

and vanishes at each of its breakpoints, where it is once-continuously differentiable. Notice that in general if an element of $ppsl_2$ is *twice* continuously differentiable at a breakpoint, then it is not actually a breakpoint at all, that is, if two elements of $M\ddot{o}b$ agree to second order at a point, then they must coincide.

Let us employ the adjoint action on each piece and define the *(arithmetic) wavelets*

$$\vartheta_A(\theta) = A^{-1}\vartheta_A(\theta.A)A, \text{ for } A \in \mathrm{PSL}_2,$$

where the right A-action on $\theta \in \mathbb{S}^1$ is the natural one. A short calculation shows that $\vartheta_S = \vartheta_I = \vartheta$, and therefore if A_+, A_- correspond to the two different orientations on a common edge, i.e., if $A_\mp = SA_\pm$ then $\vartheta_{A_+} = \vartheta_{A_-}$. It follows that for any unoriented edge we have $|e_A| = |e_{SA}|$, and there is a corresponding vector field $\vartheta_{|e_A|} = \vartheta_A = \vartheta_{SA}$.

Now for each $A \in \mathrm{PSL}_2$, define a corresponding $X_A \in sl_2$ where X_A and ϑ_A take the same values at the three points $\pm 1, -i \in \mathbb{S}^1$, or in other words at Farey points $\frac{0}{1}, \frac{1}{0}, \frac{1}{1}$, and define the *normalization*

$$\bar{\vartheta}_A = \vartheta_A - X_A, \text{ for } A \in \mathrm{PSL}_2.$$

It is not difficult to compute X_A explicitly for $A \in \mathrm{PSL}_2$.

Here and herein we shall deviate slightly from the notation of previous works, which we first recall.

Following [20, 26] for each $A \in \mathrm{PSL}_2$, define for each $A \in \mathrm{PSL}_2$ the infinite sums

$$\bar{\phi}_A = \sum_{n \geqslant 0} \bar{\vartheta}_{U^n A} \text{ and } \bar{\phi}^*_A = \sum_{n \leqslant 0} \bar{\vartheta}_{U^n A}$$

respectively called *normalized left and right fans* and the further infinite sums

$$\bar{\psi}_A = \sum_{n \geqslant 0} n \; \bar{\vartheta}_{U^n A} \text{ and } \bar{\psi}^*_A = \sum_{n \leqslant 0} n \; \bar{\vartheta}_{U^n A}$$

respectively called *normalized left* and *right hyperfans*. We have added bars to the notation for normalized (hyper)fans from earlier work and keep the undecorated symbol for more natural normalizations to be introduced in the next section. It is not difficult to compute that $\sum_{n \geqslant 0} X_{U^n A}$ diverges thus explaining the need for normalization.

Assuming for the moment that these sums converge, as we shall discuss presently, there is the following prescribed consequence of this "hyperfan formalism" given by infinite sums of infinite sums in this way.

Proposition 4.2. *For each $A \in \mathrm{PSL}_2$, we have*

$$\bar{\psi}_A = \sum_{n \geqslant 1} \bar{\phi}_{U^n A} \text{ and } \bar{\psi}^*_A = \sum_{n < 0} \bar{\phi}^*_{U^n A},$$

as well as

$$\begin{aligned} \bar{\psi}_A - \bar{\psi}_{UA} &= \bar{\phi}_{UA} \text{ and } \bar{\phi}_A - \bar{\phi}_{UA} = \vartheta_A, \\ \bar{\psi}^*_{UA} - \bar{\psi}^*_A &= \bar{\phi}^*_A \text{ and } \bar{\phi}^*_{UA} - \bar{\phi}^*_A = \vartheta^*_A \end{aligned}$$

□

Corollary 4.3. *For each $A \in \mathrm{PSL}_2$, equating $\bar{\vartheta}_A = \bar{\vartheta}_{SA}$ gives the so-called* USA relation

$$\begin{aligned} \bar{\psi}_{UA} - 2\bar{\psi}_A + \bar{\psi}_{U^{-1}A} &= \bar{\psi}_{USA} - 2\bar{\psi}_{SA} + \bar{\psi}_{U^{-1}SA}, \\ \bar{\psi}^*_{UA} - 2\bar{\psi}^*_A + \bar{\psi}^*_{U^{-1}A} &= \bar{\psi}^*_{USA} - 2\bar{\psi}^*_{SA} + \bar{\psi}^*_{U^{-1}SA}. \end{aligned}$$

□

The formulas in Proposition 4.2 and Corollary 4.3 thus follow immediately from the hyperfan formalism and the symmetry $\bar{\vartheta}_A = \bar{\vartheta}_{SA}$. The catch is showing that the putative (hyper)fans converge. However, notice that convergence of $\sum n x_n$ implies that of $\sum x_n$, so the hyperfan formalism follows from convergence of hyperfans alone.

In the remainder of this section, we shall recall results from [20] which in particular give sense to the *normalized* (hyper)fans as elements of $ppsl_2$, and indeed converge pointwise uniformly on compacta. The harmonic analysis of normalized hyperfans is discussed in Appendix A.

The **first big surprise** is that in fact normalized fans and hyperfans have only finitely many breakpoints and lie in $ppsl_2$, even though they are defined by infinite sums. Indeed, a fan always has exactly three breakpoints and is described by a continuous but not differentiable function on the circle, and a hyperfan always has exactly two breakpoints described by a function on the circle which is discontinuous at exactly one point. Such is the nature of telescoping for normalized (hyper)fans, which are *not enjoyed* by unnormalized (hyper)fans.

For example, $\bar{\phi}_U$ takes values $-2e$ on quadrant I, $2(h-f)$ on quadrant II and vanishes on quadrants III and IV, while $\bar{\psi}_I$ takes values $-2e$ on quadrants I and II and vanishes on quadrants III and IV. In fact, one finds that $\bar{\psi}_I + \bar{\psi}_I^*$ is the global sl_2 vector field $-2e$, and together with the fact that $\psi_A \doteq A^{-1}\psi_I A$ by construction, it follows that the span of the left hyperfans together with sl_2 contains the right hyperfans. We shall therefore henceforth restrict our attention to the former and drop the appellate "left" tacitly taking only left fans and hyperfans. There is an entirely parallel discussion using right fans and hyperfans.

Just as one might suspect, bracketing destroys one degree of smoothness. Brackets of normalized wavelets are similarly expressed as finite sums of normalized fans while brackets of normalized fans are expressed in terms of normalized hyperfans.

The **second big surprise** is that here the algebra closes with the additive basis of normalized left hyperfans, i.e., brackets of hyperfans are finite linear combinations of hyperfans.

Summarizing several of the main achievements in [20], to which we refer the reader for proofs of the first two big surprises, we have

Theorem 4.4. *The set of normalized left hyperfans together with the generators $e, f, h \in sl_2$ give an additive spanning set for the vector space $ppsl_2$ which is closed under bracketing. Moreover, the collection of USA relations in Corollary 4.3, one for each edge of τ_*, gives a complete set of relations among normalized left hyperfans.* □

In fact, there is an error in the proof in [20] that normalized left hyperfans span $ppsl_2$ which is corrected in Theorem 2.1 of [27] as follows.

Theorem 4.5. *Define orientations on the edges of τ_* with the orientation from $\frac{0}{1}$ to $\frac{1}{0}$ as usual and otherwise always pointing from lower to* *higher generation in the Farey enumeration, and denote this set of oriented edges* $\mathcal{O} \subset \tilde{\tau}_*$. *Then* $\mathcal{B} = \{\bar{\psi}_A : A \in \mathcal{O}\}$ *together with* $e, f, h \in sl_2$ *is an additive basis for* $ppsl_2$. $\square$

5. The new formalism for $ppsl_2$

The normalization of vector fields in the previous section was necessary in order to guarantee their pointwise convergence and assure the hyperfan formalism. However from the point of view of representation theory, the failure of exact equality in favor of equality $\bar{\psi}_A \doteq A^{-1}\bar{\psi}_I A$ up to global sl_2 vector fields introduces untoward complications. Furthermore from the point of view of physics, the treatment of sl_2 in the previous section represents merely an additional copy of sl_2 essentially decoupled from the higher Fourier modes, not the creation/annihilation and energy operators one might anticipate.

Let us remedy both of these deficiencies by defining *(unnormalized)* (or really differently normalized) *hyperfans* as follows:

$$\psi_I = \begin{cases} e, & \text{on quadrants I and II;} \\ 0, & \text{on quadrants III and IV,} \end{cases}$$

thus dropping the pre-factor -2 from before and furthermore guaranteeing the desired conjugacy formula by defining

$$\psi_A(\theta) = A^{-1}\psi_I(\theta.A)A, \text{ for } A \in \mathrm{PSL}_2.$$

It thus follows that $B^{-1}\psi_A B = \psi_{AB}$.

The **third big surprise**, which is new to this paper, is that sl_2 is actually in the finitely supported span of these new hyperfans, as we next prove.

Proposition 5.1. *For* $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{PSL}_2$, *define*

$$\Psi_A = \psi_{STA} - 2\psi_{SA} + \psi_{ST^{-1}A} - \{\psi_{UA} - 2\psi_A + \psi_{U^{-1}A}\}.$$

Then we have the identity

$$\Psi_A = \{c(d+b) + a(d-b)\}h \; + \; (d^2 - b^2 + 2bd)e \; + \; (a^2 - c^2 - 2ac)f.$$

In particular

$$\Psi_I = h + e + f, \;\; \Psi_T = 2e + f, \;\; \Psi_{U^{-1}} = e + 2f,$$

whence

$$\begin{pmatrix} h \\ e \\ f \end{pmatrix} = \frac{1}{3}\begin{pmatrix} 3 & -1 & -1 \\ 0 & 2 & -1 \\ 0 & -1 & 2 \end{pmatrix}\begin{pmatrix} \Psi_I \\ \Psi_T \\ \Psi_{U^{-1}} \end{pmatrix}$$

Proof. The reader will recognize Ψ_A as the difference of the two sides of the USA relation which holds for normalized hyperfans and fails by a global sl_2 for unnormalizaed hyperfans. The proposition follows from direct computation using that $\gamma - 2\beta = 2\alpha - \delta$, where

$$\begin{aligned} \alpha &= A^{-1}eA = cdh + d^2e - c^2f, \ \beta = (SA)^{-1}eSA = abh + b^2e - a^2f, \\ \gamma &= (UA)^{-1}e(UA) = (c+a)(d+b)h + (d+b)^2e - (c+a)^2f \\ &= (STA)^{-1}e(STA), \\ \delta &= (U^{-1}A)^{-1}e(U^{-1}A) = (c-a)(d-b)h + (d-b)^2e - (c-a)^2f \\ &= (ST^{-1}A)^{-1}e(ST^{-1}A). \end{aligned}$$

□

We shall refer to the expression for Ψ_A in terms of e, f, h given in Proposition 5.1 as the *USA identity* for $A \in \mathrm{PSL}_2$.

Theorem 5.2. *The hyperfans $\{\psi_A : A \in \mathrm{PSL}_2\}$ span $ppsl_2$, a complete set of relations on them is given by the USA identities as A varies over* PSL_2*, and $\{\psi_A : A \in \mathcal{O}\}$ provides a basis for $ppsl_2$, where $\mathcal{O} \subset \tilde{\tau}$ is given in Theorem 4.5.*

Proof. In the old formalism, the span of normalized hyperfans together with e, f, h was shown to be all of $ppsl_2$. This contains all unnormalized hyperfans by definition; indeed, $\psi_A \doteq \bar{\psi}_A$, and the reverse inclusion follows from the last part of the previous proposition. For the second assertion, suppose that $\sum \alpha_A \psi_A = 0$ is a finite linear relation among the unnormalized hyperfans. It follows that then $\sum \alpha_A \bar{\psi}_A \doteq 0$, and since both sides of this equation vanish at $\frac{0}{1}, \frac{1}{0}, \frac{1}{1}$, it must be that in fact $\sum \alpha_A \bar{\psi}_A = 0$, whence this relation is a consequence of the USA relations by Theorem 4.4. A non-trivial finite linear relation among $\{\psi_A : A \in \mathcal{O}\}$ likewise gives such a relation on $\{\bar{\psi}_A : A \in \mathcal{O}\}$, which would contradict Theorem 4.5. □

Another favorable aspect of the new formalism is that the structure constants of $ppsl_2$ admit an explicit if not entirely trivial expression, and it is to this end that we dedicate the remainder of this section. The next two results follow from direct and elementary computation, which are left to the reader.

Proposition 5.3. *In the basis e, f, h for sl_2, the adjoint $x \mapsto A^{-1}xA$ of $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in sl_2$ is given by the matrix*

$$M_A = \begin{pmatrix} d^2 & -b^2 & 2bd \\ -c^2 & a^2 & -2ac \\ cd & -ab & ad+bc \end{pmatrix},$$

and so

$$M_A^{-1} = M_{A^{-1}} = \begin{pmatrix} a^2 & -b^2 & -2ab \\ -c^2 & d^2 & 2cd \\ -ac & bd & ad+bc \end{pmatrix}.$$

□

Just as ψ_I takes values $e \in sl_2$ on quadrants I and II and vanishes on quadrants III and IV, we have the following analogous result for $f, h \in sl_2$.

Proposition 5.4. *$\psi_S + f$ and $\psi_I + \psi_{US} - \psi_S - \psi_{U^{-1}} - f$ each have support on quadrants I and II with the former taking there the value f and the latter the value h.* □

Now in order to compute the bracket $[\psi_B, \psi_A]$, for $A, B \in \mathrm{PSL}_2$, it suffices to compute simply $[\psi_I, \psi_A]$, since we have

$$(*) \qquad [\psi_B, \psi_A] = [B^{-1}\psi_I B, \psi_A] = B^{-1}[\psi_I, \psi_{AB^{-1}}]B.$$

To this end with $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$, there are four essential cases:

Case 1: $0 \leqslant -\frac{d}{c} < -\frac{b}{a}$, so e_A lies in the bottom half plane oriented from right to left.

Case 2: $0 \leqslant -\frac{b}{a} < -\frac{d}{c}$, so e_A lies in the bottom half plane oriented from left to right.

Case 3: $-\frac{d}{c} < -\frac{b}{a} \leqslant 0$, so e_A lies in the top half plane oriented from left to right.

Case 4: $-\frac{b}{a} < -\frac{d}{c} \leqslant 0$, so e_A lies in the top half plane oriented from right to left.

In each case, the support of ψ_A lies to the left of e_A by definition. In Case 1, the supports are therefore disjoint, and so $[\psi_I, \psi_A] = 0$. In Case 2, the support of ψ_I is contained in the support of ψ_A, and the bracket is supported on quadrants I and II taking value $-c^2h + 2cde$, which is given according to Proposition 5.4 by

$$\begin{aligned}-c^2(\psi_I + \psi_{US} - \psi_S - \psi_{U^{-1}} - f) + 2cd\psi_I \\ = c(2d-c)\psi_I + c^2(\psi_S + \psi_{U^{-1}} - \psi_{US} + f).\end{aligned}$$

Case 3 is more challenging requiring Proposition 5.3. We compute

$$M_A^{-1}\begin{pmatrix}2cd\\0\\-c^2\end{pmatrix} = \begin{pmatrix}2ac(ad+bc)\\-4c^3d\\-c^2(3ad+bc)\end{pmatrix},$$

whence

$$\begin{aligned}[\psi_I, \psi_A] &= 2ac(ad+bc)\psi_A - 4c^3d(\psi_{SA} + A^{-1}fA)\\ &\quad - c^2(3ad+bc)\{\psi_A + \psi_{USA} - \psi_{SA} - \psi_{U^{-1}} - A^{-1}fA\}.\end{aligned}$$

Case 4 is still a bit more involved since $[\psi_I, \psi_A]$ perhaps has two components and can be expressed as the difference $\mu-\nu$, where μ is supported on quadrants I and II taking value $2cde-c^2h$, and ν is supported on the region to the left of e_{SA} and taking the same value there. Meanwhile, Proposition 5.4 gives the expression

$$\mu = c(2d-c)\psi_I + c^2(\psi_S + \psi_{U^{-1}} - \psi_{US} + f)$$

as in Case 2. For the other term ν, we compute

$$\begin{aligned}M_{SA}^{-1}\begin{pmatrix}2cd\\0\\-c^2\end{pmatrix} &= \begin{pmatrix}c^2 & -d^2 & -2cd\\-a^2 & b^2 & 2ab\\ac & -bd & -(ad+bc)\end{pmatrix}\begin{pmatrix}2cd\\0\\-c^2\end{pmatrix}\\ &= \begin{pmatrix}4c^3d\\-2ac(ad+bc)\\c^2(3ad+bc)\end{pmatrix},\end{aligned}$$

whence

$$\begin{aligned}\nu =& 4c^3d\psi_{SA} - 2ac(ad+bc)(\psi_A + (SA)^{-1}fSA)\\ &+ c^2(3ad+bc)\{\psi_{SA} + \psi_{UA} - \psi_A - \psi_{U^{-1}SA} - (SA)^{-1}fSA\}.\end{aligned}$$

Putting all this together, a little further computation finally proves

Theorem 5.5. *For* $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{PSL}_2$, *we have*

$$[\psi_I, \psi_A] = \begin{cases} 0, \text{ if } 0 \leqslant -\frac{d}{c} < -\frac{b}{a}; \\[2ex] c(2d-c)\psi_I + c^2(\psi_S + \psi_{U^{-1}} - \psi_{US} + f), \\ \quad \text{if } 0 \leqslant -\frac{b}{a} < -\frac{d}{c}; \\[2ex] 2ac(ad+bc)\psi_A - 4c^3 d(\psi_{SA} + A^{-1} f A) \\ -\, c^2(3ad+bc)\{\psi_A + \psi_{USA} - \psi_{SA} - \psi_{U^{-1}} - A^{-1} f A\}, \\ \quad \text{if } -\frac{d}{c} < -\frac{b}{a} \leqslant 0; \\[2ex] c(2d-c)\psi_I + c^2(\psi_S + \psi_{U^{-1}} - \psi_{US} + f) \\ -\, 4c^3 d\psi_{SA} + 2ac(ad+bc)(\psi_A + (SA)^{-1} f AS) \\ -\, c^2(3ad+bc)\{\psi_{SA} + \psi_{UA} - \psi_A - \psi_{U^{-1}SA} - (SA)^{-1} f AS\}, \\ \quad \text{if } -\frac{b}{a} < -\frac{d}{c} \leqslant 0. \end{cases}$$

□

It is worth noting that $[\psi_I, \psi_A] = 0$ if $c = 0$ and that to complete the calculation of brackets in the basis $\{\psi_A : A \in \mathcal{O}\}$, one must still conjugate as in equation (*) and finally use the constructive proof of our Theorem 5.2 given in [20] to express several of the resulting hyperfans in terms of this basis. The point, however, is that brackets are explicitly computable in the new formalism in contrast to the old.

6. Three 2-forms

As before, let $\frac{\partial}{\partial\theta}$ denote the counter-clockwise unit vector field on $\mathbb{S}^1$ in its usual angular coordinate θ and $L_n = ie^{in\theta}\frac{\partial}{\partial\theta}$, for $n \in \mathbb{Z}$, denote the usual generators for the *Witt algebra*, satisfying for $m, n \in \mathbb{Z}$ the bracket identity $[L_m, L_n] = (m-n)\ L_{m+n}$. The Witt algebra is naturally regarded [30] as the tangent space at the identity to the manifold $\mathrm{Diff}_+ = \mathrm{Diff}_+(\mathbb{S}^1)$ of real-analytic orientation-preserving diffeomorphisms of $\mathbb{S}^1$.

As the tangent space to $\mathrm{Homeo}_+ \supseteq \mathrm{Diff}_+$ as in Section 3, $ppsl_2$ contains the Witt algebra; this inclusion is explicitly computed in Theorem A.1. Conversely for $A \in \mathrm{PSL}_2$, the Fourier expansion of the normalized wavelets $\bar{\vartheta}_A$ (given in Theorem A.2) or hyperfans ψ_A (given in Proposition A.4), describes how $ppsl_2$ lies inside the topological closure of the Witt algebra.

The quotient manifold $\mathrm{Diff}_+/M\ddot{o}b$, has tangent space at the identity given by the span of L_n, for $n^2 > 1$, that is, the span of $e, f, h \in sl_2$ is naturally identified with the span of L_{-1}, L_0, L_{+1}. As likewise follows from Section 3, the quotient $\mathrm{Homeo}_+^n \approx \mathrm{Homeo}_+/M\ddot{o}b$ can be identified with the space $\mathcal{T}ess^n$ of all normalized tesselations of $\mathbb{D}$, and the natural bundle $\widetilde{\mathcal{T}ess^n} \to \mathcal{T}ess^n$ over this space admits global affine lambda length coordinates.

There are the following several 2-forms defined on these spaces, which are compared in this section:

- The (pull-back from $\mathcal{T}ess^n$ of the) universal Weil-Petersson (WP) Kähler 2-form [25, 24] to $\widetilde{\mathcal{T}ess^n} \approx \widetilde{\mathrm{Homeo}_+^n}$ is given by

$$\omega = -2\sum d\mathrm{log}a \wedge d\mathrm{log}b \ + \ d\mathrm{log}b \wedge d\mathrm{log}c \ + \ d\mathrm{log}c \wedge d\mathrm{log}a,$$

where the sum is over the set of all triangles complementary to τ_* in $\mathbb{D}$ and the triangle has edges, here conflated with lambda lengths as usual, in the clockwise order a, b, c in the orientation on the underlying surface. This sum converges provided the homeomorphism is $C^{\frac{3}{2}+\epsilon}$ smooth on $\mathbb{S}^1$, cf. [32].

- The Kirillov-Kostant (KK) form [18, 32] is defined on $\mathrm{Diff}_+/M\ddot{o}b$ by

$$\kappa_a(L_m, L_n) = a(m^3 - m)\delta_{m,-n},$$

where $a \in \mathbb{C}$ and δ is the Kronecker delta function.

- The natural loop-algebra (LA) 2-cocycle [13] is defined by

$$\gamma(\psi^1, \psi^2) = \frac{1}{2\pi}\int_0^{2\pi} \mathrm{tr}\bigg(\psi^1(\theta) \cdot d\psi^2(\theta)\bigg),$$

where $\psi_1, \psi_2 \in sl_2^{\mathbb{S}^1}$ and tr denotes the trace. Our algebra $ppsl_2$ is a sub-algebra of a certain completion of $sl_2^{\mathbb{S}^1}$ on which this 2-cocycle still makes sense, and indeed integration by parts provides in this case the explicit expression

$$\gamma(\psi^1, \psi^2) = \frac{1}{2}\sum_{\theta \in \Pi(\psi^2)} \mathrm{tr}\bigg\{[\psi^1(\theta^+) + \psi^1(\theta^-)]\ [\psi^2(\theta^+) - \psi^2(\theta^-)]\bigg\}$$

for the 2-cocycle γ on $ppsl_2$, where $\Pi(\psi) \subset \hat{\mathbb{Q}} \subset \mathbb{S}^1$ denotes the set of breakpoints of ψ and $\theta^\pm$ denotes a point slightly $\frac{\text{beyond}}{\text{before}}$ the point

$\theta \in \Pi(\psi)$ in the counter-clockwise orientation on $\mathbb{S}^1$. One can verify directly that γ is a 2-cocycle by checking skew-symmetry and the 2-cocycle property, which follows from the 2-cocycle property for the first expression in this paragraph for γ on $sl_2^{\mathbb{S}^1}$.

In fact, these three 2-forms are pairwise identical up to overall constants, as we shall discuss. The constant for WP and LA will be computed here, and the constant for KK and WP was already calculated in Theorem 5.5 of [24], namely, we have

Theorem 6.1. *The WP Kähler 2-form* ω *and the KK form* κ_a *are related by*

$$\omega = \kappa_a, \text{ for } a = 2\pi i.$$

The computational proof in [24] using the basis of normalized arithmetic wavelets is involved and delicate depending upon the constraints on small Fourier modes described in Remark A.3.

Theorem 6.2. *The WP Kähler 2-form* ω *and the LA cocycle* γ *are related by*

$$\gamma = -4\omega.$$

Proof. Recall that $\Pi(\psi) \subset \hat{\mathbb{Q}} \subset \mathbb{S}^1$ denotes the (finite) set of breakpoints of $\psi \in ppsl_2$ and let $\bar{\vartheta}_A = \vartheta_A - X_A$, i.e., $\bar{\vartheta}_A$ is the normalized arithmetic wavelet and ϑ_A the unnormalized one. In particular, we have

$$\Pi(\bar{\vartheta}_A) = \Pi(\vartheta_A) = \Pi(\vartheta).A, \text{ for } A \in \mathrm{PSL}_2,$$

and moreover

$$\gamma(\bar{\vartheta}_A, \bar{\vartheta}_B) = \gamma(\bar{\vartheta}_A, \vartheta_B), \text{ for } A, B \in sl_2,$$

since X_B is both added and subtracted in a difference of $\bar{\vartheta}_B$-values in their contribution to γ. Thus

$$\gamma(\bar{\vartheta}_A, \bar{\vartheta}_B) = \gamma(\vartheta_A, \vartheta_B), \text{ for } A, B \in sl_2$$

as well by skew symmetry of γ.

We first claim that $\gamma(\bar\vartheta_A, \bar\vartheta_B) = 0$ if $\bar\vartheta_A$ takes a common value $Y_A \in sl_2$ at each point of $\Pi(\bar\vartheta_B)$. To see this, we compute

$$\begin{aligned}
\gamma(\bar\vartheta_A, \bar\vartheta_B) &= \gamma(\bar\vartheta_A, \vartheta_B) = \gamma(Y_A, \vartheta_B)\\
&= \sum_{\theta\in\Pi(\vartheta_B)} \operatorname{tr}\Big\{Y_A \cdot [\vartheta_B(\theta^+) - \vartheta_B(\theta^-)]\Big\}\\
&= \sum_{\theta\in\Pi(\vartheta)} \operatorname{tr}\Big\{Y_A \cdot [\vartheta_B(\theta^+.B) - \vartheta_B(\theta^-.B)]\Big\}\\
&= \operatorname{tr} \sum_{\theta\in\Pi(\vartheta)} Y_A\Big\{B^{-1}[\vartheta(\theta^+) - \vartheta(\theta^-)]B\Big\}\\
&= \operatorname{tr}\Big\{Y_A B^{-1}\Big(\sum_{\theta\in\Pi(\vartheta)} [\vartheta(\theta^+) - \vartheta(\theta^-)]\Big)B\Big\}\\
&= \operatorname{tr}\Big\{Y_A B^{-1}[4e + 2(f-e-h) - 4f + 2(h+f-e)]B\Big\}\\
&= \operatorname{tr}\, Y_A B^{-1} 0 B\\
&= 0.
\end{aligned}$$

It remains to consider $\gamma(\bar\vartheta_A, \bar\vartheta_{UA})$ and $\gamma(\bar\vartheta_A, \bar\vartheta_{TA})$, and we begin with the former. Let ξ_B, η_B denote the respective initial and terminal point of $e_B = e_I.B$, where e_I is the doe of τ_* as usual, so

$$\begin{aligned}
\Pi(\bar\vartheta_A) &= \{\xi_A, \eta_A, \eta_{U^{-1}A}, \eta_{UA}\},\\
\Pi(\bar\vartheta_{UA}) &= \{\xi_A, \eta_A, \eta_{UA}, \eta_{U^2A}\}.
\end{aligned}$$

Thus

$$\begin{aligned}
\gamma &= \gamma(\bar\vartheta_A, \bar\vartheta_{UA}) = \gamma(\vartheta_A, \vartheta_{UA})\\
&= \frac{1}{2} \sum_{\theta\in\Pi(\vartheta_{UA})} \operatorname{tr}\{[\vartheta_A(\theta^+) + \vartheta_A(\theta^-)][\vartheta_A(\theta^+) - \vartheta_A(\theta^-)]\},
\end{aligned}$$

so

$$2\gamma = \mathrm{tr}\left\{\begin{array}{l} \quad[\vartheta_A(\xi^+.A) + \vartheta_A(\xi^-.A)]\ [\vartheta_{UA}(\xi^+.A) - \vartheta_{UA}(\xi^-.A)] \\ +[\vartheta_A(\eta^+.A) + \vartheta_A(\eta^-.A)]\ [\vartheta_{UA}(\eta^+.A) - \vartheta_{UA}(\eta^-.A)] \\ +[\vartheta_A(\eta^+.UA) + \vartheta_A(\eta^-.UA)]\ [\vartheta_{UA}(\eta^+.UA) - \vartheta_{UA}(\eta^-.UA)] \\ +2[\vartheta_A(\eta^+.U^2A)]\ [\vartheta_{UA}(\eta^+.U^2A) - \vartheta_{UA}(\eta^-.U^2A)] \end{array}\right\}$$

$$= \mathrm{tr}\left\{\begin{array}{l} \quad[\vartheta(\xi^+) + \vartheta(\xi^-)]\ [(U)^{-1}\vartheta(\xi^+.U^{-1})U - (U)^{-1}\vartheta(\xi^-.U^{-1})U] \\ +[\vartheta(\eta^+) + \vartheta(\eta^-)]\ [(U)^{-1}\vartheta(\eta^+.U^{-1})U - (U)^{-1}\vartheta(\eta^-.U^{-1})U] \\ +[\vartheta(\eta^+.U) + A^{-1}\vartheta(\eta^-.U)]\ [(U)^{-1}\vartheta(\eta^+)U - (U)^{-1}\vartheta(\eta^-)U] \\ +2[\vartheta(\eta^+.U^2)]\ [(U)^{-1}\vartheta(\eta^+.U)U - (U)^{-1}\vartheta(\eta^-.U)U] \end{array}\right\}$$

$$= \mathrm{tr}\left\{\begin{array}{l} \quad\left[\begin{pmatrix}-1&0\\-2&1\end{pmatrix} + \begin{pmatrix}-1&0\\2&1\end{pmatrix}\right]\begin{pmatrix}1&0\\-1&1\end{pmatrix}\left[\begin{pmatrix}-1&0\\-2&1\end{pmatrix} - \begin{pmatrix}-1&0\\2&1\end{pmatrix}\right]\begin{pmatrix}1&0\\1&1\end{pmatrix} \\ +\left[\begin{pmatrix}1&2\\0&-1\end{pmatrix} + \begin{pmatrix}1&-2\\0&-1\end{pmatrix}\right]\begin{pmatrix}1&0\\-1&1\end{pmatrix}\left[\begin{pmatrix}1&-2\\0&-1\end{pmatrix} - \begin{pmatrix}-1&0\\-2&1\end{pmatrix}\right]\begin{pmatrix}1&0\\1&1\end{pmatrix} \\ +\left[\begin{pmatrix}-1&0\\2&1\end{pmatrix} + \begin{pmatrix}1&2\\0&-1\end{pmatrix}\right]\begin{pmatrix}1&0\\-1&1\end{pmatrix}\left[\begin{pmatrix}1&2\\0&-1\end{pmatrix} - \begin{pmatrix}1&-2\\0&-1\end{pmatrix}\right]\begin{pmatrix}1&0\\1&1\end{pmatrix} \\ +2\begin{pmatrix}-1&0\\2&1\end{pmatrix}\begin{pmatrix}1&0\\-1&1\end{pmatrix}\left[\begin{pmatrix}-1&0\\2&1\end{pmatrix} - \begin{pmatrix}1&2\\0&-1\end{pmatrix}\right]\begin{pmatrix}1&0\\1&1\end{pmatrix} \end{array}\right\}$$

$$\begin{aligned} &= \mathrm{tr}\left\{\begin{pmatrix}0&0\\-8&0\end{pmatrix} + \begin{pmatrix}0&-4\\-8&0\end{pmatrix} + \begin{pmatrix}-8&-8\\8&8\end{pmatrix} + 2\begin{pmatrix}4&2\\0&0\end{pmatrix}\right\} \\ &= 8, \end{aligned}$$

and accounting for the orientation and -2 in the expression above for the WP form yields the asserted constant $\gamma = -4\omega$.

Finally in the remaining case to compute $\gamma(\bar{\vartheta}_A, \bar{\vartheta}_{TA})$, replace $A \in \mathrm{PSL}_2$ by SUA, so that

$$\gamma(\bar{\vartheta}_{SUA}, \bar{\vartheta}_{TSUA}) = \gamma(\bar{\vartheta}_{UA}, \bar{\vartheta}_A) = +8$$

by skew symmetry since $\bar{\vartheta}_{SB} = \bar{\vartheta}_B$, for $B \in \mathrm{PSL}_2$, and

$$TSUA = TT^{-1}UT^{-1}UA = UT^{-1}UA = SA.$$

$\square$

7. Universal automorphic 1-form on $\mathrm{PPSL}_2(\mathbb{R})$

Given a decoration $\tilde{\tau}$ on a tesselation τ with framing framing $\mathcal{F}$, define

$$\xi_{\mathcal{F}} = \frac{1}{2} \sum_{A \in \mathrm{PSL}_2} \bar{\vartheta}_A \; d\log \lambda_{e_A} \in \Omega^1(\widetilde{\mathrm{Homeo}}{}^n_+, ppsl_2),$$

where $\bar{\vartheta}_A$ is the wavelet ϑ_A normalized with respect to $\mathcal{F}$, and λ_e denotes the lambda length of $e = e_A$. Alternatively, we may write $\xi_{\mathcal{F}} = \sum_{e \in \tau_*} \bar{\vartheta}_e \; d\log \lambda_e$ since $\vartheta_A = \vartheta_{SA}$ and $\lambda_e = \lambda_{e_A} = \lambda_{e_{SA}}$.

$\xi_{\mathcal{F}}$ is to be apprehended as a 1-form on the group $\widetilde{\mathrm{Homeo}}{}^n_+$ taking values in its Lie algebra $ppsl_2$. It evidently could be interpreted as the Maurer-Cartan form since the result of applying it to a multiplicative deformation of the lambda length, or in other words an additive deformation of the logarithm of the lambda length, is precisely the corresponding normalized vector field on $\mathbb{S}^1$ in its Lie algebra $ppsl_2$, as was discussed in Section 3.

More precisely, we have the diagram

$$\begin{tikzcd}
 & \widetilde{\mathrm{Homeo}}{}^n_+ \arrow[r, phantom, "\approx"] \arrow[d, "\pi"] & \widetilde{\mathrm{Homeo}}{}^n_+/M\ddot{o}b \arrow[d] \\
\mathrm{Homeo}_+ \arrow[r, shift left, "p"] & \mathrm{Homeo}^n_+ \arrow[l, shift left, "s_{\mathcal{F}}"] \arrow[r, phantom, "\approx"] & \mathrm{Homeo}_+/M\ddot{o}b,
\end{tikzcd}$$

where π is the forgetful map, p is the projection given by precomposition with $L^{\frac{0}{1},\frac{1}{0},\frac{1}{1}}_{f(\frac{0}{1}),f(\frac{1}{0}),f(\frac{1}{1})}$, and for any framing $\mathcal{F} = (u, v, w)$, the section $s_{\mathcal{F}}$ of p is given by precomposition with $L^{u,v,w}_{\frac{0}{1},\frac{1}{0},\frac{1}{1}}$. It is a tautology that if ω is the Maurer-Cartan form of Homeo_+, then $\xi_{\mathcal{F}} = \pi^* \circ s^*_{\mathcal{F}} \, \omega$.

Theorem 7.1. *For any fixed framing $\mathcal{F} \in C_3$, the Lie-algebra valued 1-form $\xi_{\mathcal{F}} \in \Omega^1(\widetilde{\mathrm{Homeo}}_+, ppsl_2)$ is invariant under flips.*

Proof. As a Lie algebra valued 1-form on a group, it is described by right-translating from the cotangent plane of the identity, and our computations will take place there.

Recall that the Farey tesselation τ_* admits a canonical decoration $\tilde{\tau}_*$ determined by the property that all the lambda lengths are constant equal to unity, and that this is the identity element of the group $\widetilde{\mathrm{Homeo}}{}^n_+$ as discussed in Section 3.

To establish notation, refer to Figure 1 and consider the four generation-zero and -one Farey points $\frac{1}{0}, -\frac{1}{1}, \frac{0}{1}, \frac{1}{1}$ decomposing $\mathbb{S}^1$ into four circular intervals which are conflated with the respective quadrants I,II,III and

IV containing them. The convex hull of these points is an ideal quadrilateral with oriented frontier edges $a = e_{ST}, b = e_{SU}, c = e_{U^{-1}}$ and $d = e_{T^{-1}}$ in this counter-clockwise order starting from $\frac{1}{0}$. The doe e_I will be denoted simply $e = e_I$, and the edge arising from its flip, with respective initial and terminal points $\frac{1}{1}$ and $-\frac{1}{1}$, will be denoted f.

The second-generation $-\frac{2}{1}, -\frac{1}{2}, \frac{1}{2}, \frac{2}{1}$ Farey points further decompose the circular intervals $\mathrm{I} = \mathrm{I}_- \cup \mathrm{I}_+, \ldots, \mathrm{IV} = \mathrm{IV}_- \cup \mathrm{IV}_+$ occurring in this counter-clockwise order starting from $\frac{1}{0}$. The Farey points of generation at most two together span an ideal octagon with oriented frontier edges e_{ST^2}, e_{SUT}, e_{TSU}, e_{SU^2}, $e_{U^{-2}}$, $e_{T^{-1}U^{-1}}$, $e_{U^{-1}T^{-1}}$, and $e_{T^{-2}}$ in this counter-clockwise order starting from $\frac{1}{0}$, as indicated in Figure 2.

The hyperbolic transformations which are primitive in PSL_2 along the respective axes e and f are given by the exponentials of $\left(\begin{smallmatrix} -1 & 0 \\ 0 & 1 \end{smallmatrix}\right)$ and $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, and along each of the other edges e_A above by the exponential of $X_A \in sl_2$ with

$$X_{ST} = \left(\begin{smallmatrix} 1 & 2 \\ 0 & -1 \end{smallmatrix}\right),\ X_{SU} = \left(\begin{smallmatrix} 1 & 0 \\ -2 & -1 \end{smallmatrix}\right),\ X_{U^{-1}} = \left(\begin{smallmatrix} -1 & 0 \\ -2 & 1 \end{smallmatrix}\right),\ X_{T^{-1}} = \left(\begin{smallmatrix} -1 & 2 \\ 0 & 1 \end{smallmatrix}\right),$$

and

$$\begin{aligned} X_{ST^2} &= \left(\begin{smallmatrix} 1 & 4 \\ 0 & -1 \end{smallmatrix}\right),\ X_{SUT} = \left(\begin{smallmatrix} 3 & 4 \\ -2 & -3 \end{smallmatrix}\right), \\ X_{TSU} &= \left(\begin{smallmatrix} 3 & 2 \\ -4 & -3 \end{smallmatrix}\right),\ X_{SU^2} = \left(\begin{smallmatrix} 1 & 0 \\ -4 & -1 \end{smallmatrix}\right), \\ X_{U^{-2}} &= \left(\begin{smallmatrix} -1 & 0 \\ -4 & 1 \end{smallmatrix}\right),\ X_{T^{-1}U^{-1}} = \left(\begin{smallmatrix} -3 & 2 \\ -4 & 3 \end{smallmatrix}\right), \\ X_{U^{-1}T^{-1}} &= \left(\begin{smallmatrix} -3 & 4 \\ -2 & 3 \end{smallmatrix}\right),\ X_{U^{-1}T^{-1}} = \left(\begin{smallmatrix} -1 & 4 \\ 0 & 1 \end{smallmatrix}\right). \end{aligned}$$

The proof is a direct computation and is omitted.

These are the logarithms of the component earthquakes for the wavelets ϑ_x, for $x \in \{a, b, c, d, e, f\}$, so it is not difficult to combine them four at a time and normalize with respect to the the standard framing $\mathcal{F} = (\frac{0}{1}, \frac{1}{0}, \frac{1}{1})$ on τ_*. One finds

$$\bar{\vartheta}_e = \vartheta_e = \begin{cases} \left(\begin{smallmatrix} -1 & -2 \\ 0 & 1 \end{smallmatrix}\right), & \text{on I;} \\ \left(\begin{smallmatrix} 1 & 0 \\ -2 & -1 \end{smallmatrix}\right), & \text{on II;} \\ \left(\begin{smallmatrix} 1 & 0 \\ 2 & -1 \end{smallmatrix}\right), & \text{on III;} \\ \left(\begin{smallmatrix} -1 & 2 \\ 0 & 1 \end{smallmatrix}\right), & \text{on IV,} \end{cases}$$

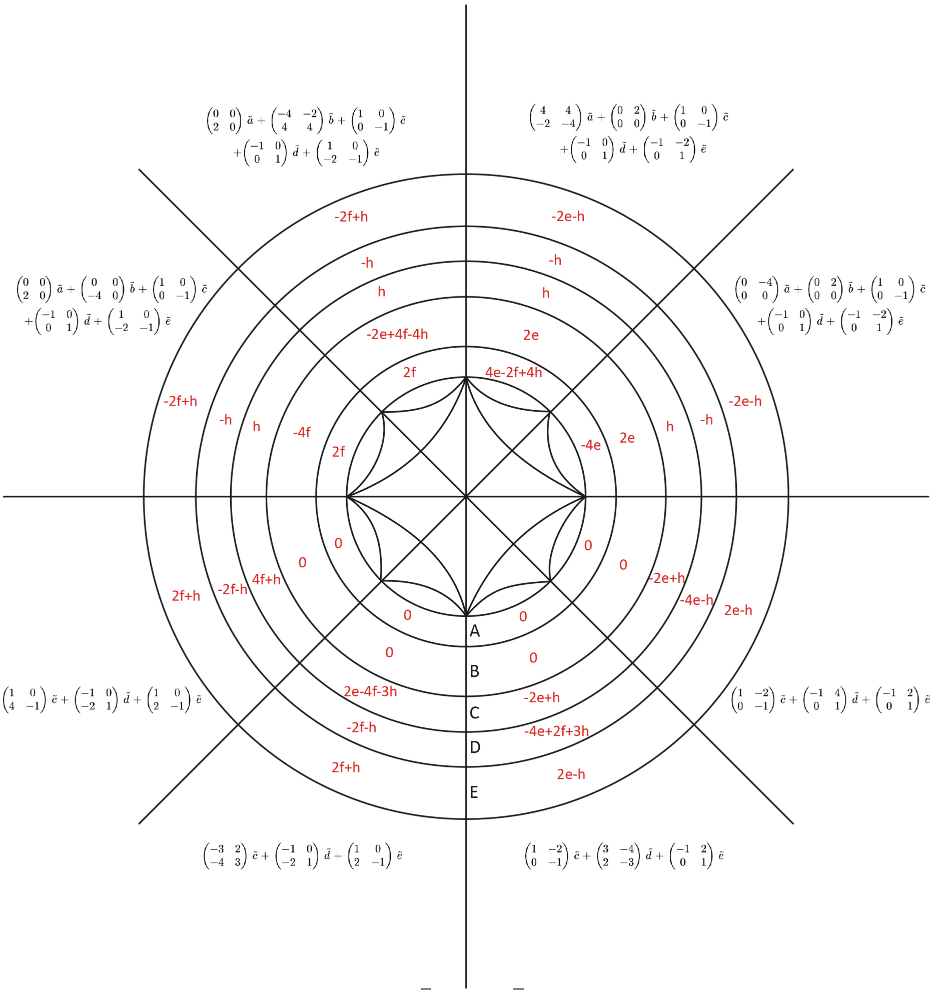
$$\vartheta_a = \begin{cases} \left(\begin{smallmatrix} -1 & -4 \\ 0 & 1 \end{smallmatrix}\right), & \text{on I}_-; \\ \left(\begin{smallmatrix} 3 & 4 \\ -2 & -3 \end{smallmatrix}\right), & \text{on I}_+; \\ \left(\begin{smallmatrix} -1 & 0 \\ -2 & 1 \end{smallmatrix}\right), & \text{on II;} \\ \left(\begin{smallmatrix} -1 & 0 \\ 0 & 1 \end{smallmatrix}\right), & \text{on III and IV,} \end{cases} \qquad \text{so } \bar{\vartheta}_a = \begin{cases} \left(\begin{smallmatrix} 0 & -4 \\ 0 & 0 \end{smallmatrix}\right), & \text{on I}_-; \\ \left(\begin{smallmatrix} 4 & 4 \\ -2 & -4 \end{smallmatrix}\right), & \text{on I}_+; \\ \left(\begin{smallmatrix} 0 & 0 \\ 2 & 0 \end{smallmatrix}\right), & \text{on II;} \\ \left(\begin{smallmatrix} 0 & 0 \\ 0 & 0 \end{smallmatrix}\right), & \text{on III and IV,} \end{cases}$$

$$\vartheta_b = \begin{cases} \left(\begin{smallmatrix} 1 & 2 \\ 0 & -1 \end{smallmatrix}\right), & \text{on I;} \\ \left(\begin{smallmatrix} -3 & -2 \\ 4 & 3 \end{smallmatrix}\right), & \text{on II}_-; \\ \left(\begin{smallmatrix} 1 & 0 \\ -4 & -1 \end{smallmatrix}\right), & \text{on II}_+; \\ \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right), & \text{on III and IV,} \end{cases} \quad \text{so } \bar{\vartheta}_b = \begin{cases} \left(\begin{smallmatrix} 0 & 2 \\ 0 & 0 \end{smallmatrix}\right), & \text{on I;} \\ \left(\begin{smallmatrix} -4 & -2 \\ 4 & 4 \end{smallmatrix}\right), & \text{on II}_-; \\ \left(\begin{smallmatrix} 0 & 0 \\ -4 & 0 \end{smallmatrix}\right), & \text{on II}_+; \\ \left(\begin{smallmatrix} 0 & 0 \\ 0 & 0 \end{smallmatrix}\right), & \text{on III and IV,} \end{cases}$$

$$\bar{\vartheta}_c = \vartheta_c = \begin{cases} \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right), & \text{on I and II;} \\ \left(\begin{smallmatrix} 1 & 0 \\ 4 & -1 \end{smallmatrix}\right), & \text{on III}_-; \\ \left(\begin{smallmatrix} -3 & 2 \\ -4 & 3 \end{smallmatrix}\right), & \text{on III}_+; \\ \left(\begin{smallmatrix} 1 & -2 \\ 0 & -1 \end{smallmatrix}\right), & \text{on IV,} \end{cases} \quad \text{and } \bar{\vartheta}_d = \vartheta_d = \begin{cases} \left(\begin{smallmatrix} -1 & 0 \\ 0 & 1 \end{smallmatrix}\right), & \text{on I and II;} \\ \left(\begin{smallmatrix} -1 & 0 \\ -2 & 1 \end{smallmatrix}\right), & \text{on III;} \\ \left(\begin{smallmatrix} 3 & -4 \\ 2 & -3 \end{smallmatrix}\right), & \text{on IV}_-; \\ \left(\begin{smallmatrix} -1 & 4 \\ 0 & 1 \end{smallmatrix}\right), & \text{on IV}_+ \end{cases}$$

As illustrated in Figure 5, letting $\tilde{x} = d\log\lambda_x$, for $x \in \{a, b, c, d, e, f\}$, and putting all of this together, we find that

$$\begin{aligned} &\sum_{x\in\{a,b,c,d,e\}} \bar{\vartheta}_x \; d\log\lambda_x \\ &= \begin{cases} \left(\begin{smallmatrix} 0 & -4 \\ 0 & 0 \end{smallmatrix}\right)\tilde{a} + \left(\begin{smallmatrix} 0 & 2 \\ 0 & 0 \end{smallmatrix}\right)\tilde{b} + \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)\tilde{c} + \left(\begin{smallmatrix} -1 & 0 \\ 0 & 1 \end{smallmatrix}\right)\tilde{d} + \left(\begin{smallmatrix} -1 & -2 \\ 0 & 1 \end{smallmatrix}\right)\tilde{e}, & \text{on I}_-; \\ \left(\begin{smallmatrix} 4 & 4 \\ -2 & -4 \end{smallmatrix}\right)\tilde{a} + \left(\begin{smallmatrix} 0 & 2 \\ 0 & 0 \end{smallmatrix}\right)\tilde{b} + \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)\tilde{c} + \left(\begin{smallmatrix} -1 & 0 \\ 0 & 1 \end{smallmatrix}\right)\tilde{d} + \left(\begin{smallmatrix} -1 & -2 \\ 0 & 1 \end{smallmatrix}\right)\tilde{e}, & \text{on I}_+; \\ \left(\begin{smallmatrix} 0 & 0 \\ 2 & 0 \end{smallmatrix}\right)\tilde{a} + \left(\begin{smallmatrix} -4 & -2 \\ 4 & 4 \end{smallmatrix}\right)\tilde{b} + \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)\tilde{c} + \left(\begin{smallmatrix} -1 & 0 \\ 0 & 1 \end{smallmatrix}\right)\tilde{d} + \left(\begin{smallmatrix} 1 & 0 \\ -2 & -1 \end{smallmatrix}\right)\tilde{e}, & \text{on II}_-; \\ \left(\begin{smallmatrix} 0 & 0 \\ 2 & 0 \end{smallmatrix}\right)\tilde{a} + \left(\begin{smallmatrix} 0 & 0 \\ -4 & 0 \end{smallmatrix}\right)\tilde{b} + \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)\tilde{c} + \left(\begin{smallmatrix} -1 & 0 \\ 0 & 1 \end{smallmatrix}\right)\tilde{d} + \left(\begin{smallmatrix} 1 & 0 \\ -2 & -1 \end{smallmatrix}\right)\tilde{e}, & \text{on II}_+; \\ \left(\begin{smallmatrix} 1 & 0 \\ 4 & -1 \end{smallmatrix}\right)\tilde{c} + \left(\begin{smallmatrix} -1 & 0 \\ -2 & 1 \end{smallmatrix}\right)\tilde{d} + \left(\begin{smallmatrix} 1 & 0 \\ 2 & -1 \end{smallmatrix}\right)\tilde{e}, & \text{on III}_-; \\ \left(\begin{smallmatrix} -3 & 2 \\ -4 & 3 \end{smallmatrix}\right)\tilde{c} + \left(\begin{smallmatrix} -1 & 0 \\ -2 & 1 \end{smallmatrix}\right)\tilde{d} + \left(\begin{smallmatrix} 1 & 0 \\ 2 & -1 \end{smallmatrix}\right)\tilde{e}, & \text{on III}_+; \\ \left(\begin{smallmatrix} 1 & -2 \\ 0 & -1 \end{smallmatrix}\right)\tilde{c} + \left(\begin{smallmatrix} 3 & -4 \\ 2 & -3 \end{smallmatrix}\right)\tilde{d} + \left(\begin{smallmatrix} -1 & 2 \\ 0 & 1 \end{smallmatrix}\right)\tilde{e}, & \text{on IV}_-; \\ \left(\begin{smallmatrix} 1 & -2 \\ 0 & -1 \end{smallmatrix}\right)\tilde{c} + \left(\begin{smallmatrix} -1 & 4 \\ 0 & 1 \end{smallmatrix}\right)\tilde{d} + \left(\begin{smallmatrix} -1 & 2 \\ 0 & 1 \end{smallmatrix}\right)\tilde{e}, & \text{on IV}_+. \end{cases} \end{aligned}$$



$\begin{pmatrix}0&0\\2&0\end{pmatrix}\tilde{a}+\begin{pmatrix}-4&-2\\4&4\end{pmatrix}\tilde{b}+\begin{pmatrix}1&0\\0&-1\end{pmatrix}\tilde{c}+\begin{pmatrix}-1&0\\0&1\end{pmatrix}\tilde{d}+\begin{pmatrix}1&0\\-2&-1\end{pmatrix}\tilde{e}$

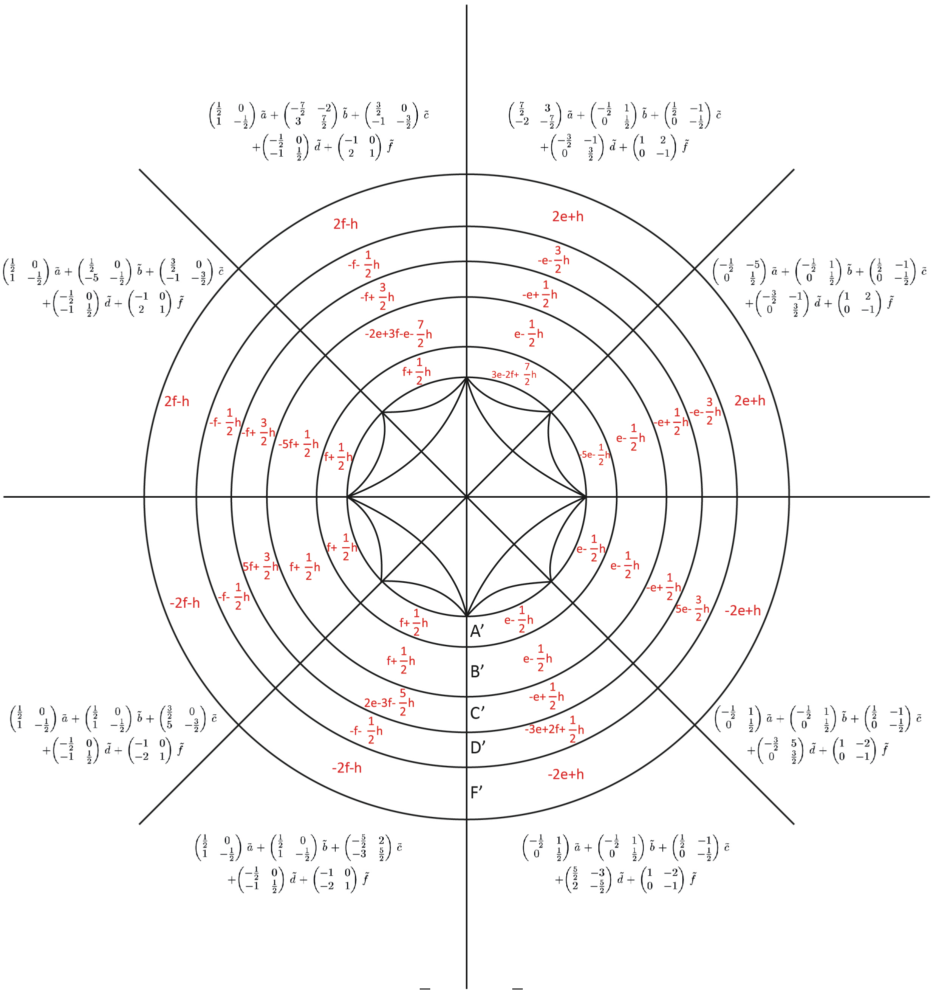
Figure 5. Depiction of $\bar{\vartheta}_a, \ldots, \bar{\vartheta}_e$ in the respective rings $A, \ldots, E$ and $\sum_{x\in\{a,b,c,d,e\}} \bar{\vartheta}_x \; d\log\lambda_x$ on the outside.

Let τ' denote the tesselation that arises from τ_* by a flip along the edge $e \in \tau_*$, let ϑ'_x denote the vectorfield on $\mathbb{S}^1$ corresponding in the natural way to the edge $x \in \{a, b, c, d, f\} \subseteq \tau'$, and let $\bar{\vartheta}'_x$ denote the normalization of ϑ'_x relative to the same framing $\mathcal{F}$. Thus, we have

$$\bar{\vartheta}'_f = \vartheta'_f = \bar{\vartheta}_e,$$

and a further consequence of the primitives for logarithms of hyperbolic transformations computed before is that



$\begin{pmatrix} \frac{1}{2} & 0 \\ 1 & -\frac{1}{2} \end{pmatrix} \tilde{a} + \begin{pmatrix} -\frac{7}{2} & -2 \\ 3 & \frac{7}{2} \end{pmatrix} \tilde{b} + \begin{pmatrix} \frac{3}{2} & 0 \\ -1 & -\frac{3}{2} \end{pmatrix} \tilde{c} + \begin{pmatrix} -\frac{1}{2} & 0 \\ -1 & \frac{1}{2} \end{pmatrix} \tilde{d} + \begin{pmatrix} -1 & 0 \\ 2 & 1 \end{pmatrix} \tilde{f}$

Figure 6. Depiction of $\bar{\vartheta}'_a, \ldots, \bar{\vartheta}'_f$ in the respective rings $A', \ldots D', F'$ and $\sum_{x\in\{a,b,c,d,f\}} \bar{\vartheta}'_x \; d\log\lambda_x$ on the outside.

$$\bar{\vartheta}'_a = \vartheta'_a + \begin{pmatrix} \frac{1}{2} & -1 \\ 0 & -\frac{1}{2} \end{pmatrix}, \text{ where } \vartheta'_a = \begin{cases} \left(\begin{smallmatrix} -1 & -4 \\ 0 & 1 \end{smallmatrix}\right), & \text{on I}_-; \\ \left(\begin{smallmatrix} 3 & 4 \\ -2 & -3 \end{smallmatrix}\right), & \text{on I}_+; \\ \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right), & \text{on II and III;} \\ \left(\begin{smallmatrix} -1 & 2 \\ 0 & 1 \end{smallmatrix}\right), & \text{on IV,} \end{cases}$$

$$\bar{\vartheta}'_b = \vartheta'_b + \begin{pmatrix} -\frac{1}{2} & 0 \\ -1 & \frac{1}{2} \end{pmatrix}, \text{ where } \vartheta'_b = \begin{cases} \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right), & \text{on I and IV;} \\ \left(\begin{smallmatrix} -3 & -2 \\ 4 & 3 \end{smallmatrix}\right), & \text{on II}_-; \\ \left(\begin{smallmatrix} 1 & 0 \\ -4 & -1 \end{smallmatrix}\right), & \text{on II}_+; \\ \left(\begin{smallmatrix} 1 & 0 \\ 2 & -1 \end{smallmatrix}\right), & \text{on III,} \end{cases}$$

$$\bar\vartheta'_c = \vartheta'_c + \begin{pmatrix} \frac12 & 0 \\ 1 & -\frac12 \end{pmatrix}, \text{ where } \vartheta'_c = \begin{cases} \left(\begin{smallmatrix} 0 & -1 \\ -1 & 0 \end{smallmatrix}\right), & \text{on I and IV;} \\ \left(\begin{smallmatrix} 1 & 0 \\ -2 & -1 \end{smallmatrix}\right), & \text{on II;} \\ \left(\begin{smallmatrix} 1 & 0 \\ 4 & -1 \end{smallmatrix}\right), & \text{on III}_-; \\ \left(\begin{smallmatrix} -3 & 2 \\ -4 & -1 \end{smallmatrix}\right), & \text{on III}_+, \end{cases}$$

$$\bar\vartheta'_d = \vartheta'_d + \begin{pmatrix} -\frac12 & 1 \\ 0 & \frac12 \end{pmatrix}, \text{ where } \vartheta'_d = \begin{cases} \left(\begin{smallmatrix} -1 & -2 \\ 0 & 1 \end{smallmatrix}\right), & \text{on I,;} \\ \left(\begin{smallmatrix} 0 & -1 \\ -1 & 0 \end{smallmatrix}\right), & \text{on II and III;} \\ \left(\begin{smallmatrix} -3 & 4 \\ -2 & 3 \end{smallmatrix}\right), & \text{on IV}_-; \\ \left(\begin{smallmatrix} -1 & 4 \\ 0 & 1 \end{smallmatrix}\right), & \text{on IV}_+. \end{cases}$$

Again putting all this together as illustrated in Figure 6, we find

$$\sum_{x\in\{a,b,c,d,f\}} \bar\vartheta'_x \; d\log\lambda_x$$
$$= \begin{cases} \begin{pmatrix} -\frac12 & -5 \\ 0 & \frac12 \end{pmatrix}\tilde a + \begin{pmatrix} -\frac12 & 1 \\ 0 & \frac12 \end{pmatrix}\tilde b + \begin{pmatrix} \frac12 & -1 \\ 0 & -\frac12 \end{pmatrix}\tilde c + \begin{pmatrix} -\frac32 & -1 \\ 0 & \frac32 \end{pmatrix}\tilde d + \left(\begin{smallmatrix} 1 & 2 \\ 0 & -1 \end{smallmatrix}\right)\tilde f, & \text{on I}_-; \\ \begin{pmatrix} \frac72 & 3 \\ -2 & -\frac12 \end{pmatrix}\tilde a + \begin{pmatrix} -\frac12 & 1 \\ 0 & \frac12 \end{pmatrix}\tilde b + \begin{pmatrix} \frac12 & -1 \\ 0 & -\frac12 \end{pmatrix}\tilde c + \begin{pmatrix} -\frac32 & -1 \\ 0 & \frac32 \end{pmatrix}\tilde d + \left(\begin{smallmatrix} 1 & 2 \\ 0 & -1 \end{smallmatrix}\right)\tilde f, & \text{on I}_+; \\ \begin{pmatrix} \frac12 & 0 \\ 1 & -\frac12 \end{pmatrix}\tilde a + \begin{pmatrix} -\frac72 & -2 \\ 3 & \frac72 \end{pmatrix}\tilde b + \begin{pmatrix} \frac32 & 0 \\ -1 & -\frac32 \end{pmatrix}\tilde c + \begin{pmatrix} -\frac12 & 0 \\ -1 & \frac12 \end{pmatrix}\tilde d + \left(\begin{smallmatrix} -1 & 0 \\ 2 & 1 \end{smallmatrix}\right)\tilde f, & \text{on II}_-; \\ \begin{pmatrix} \frac12 & 0 \\ 1 & -\frac12 \end{pmatrix}\tilde a + \begin{pmatrix} \frac12 & 0 \\ -5 & -\frac12 \end{pmatrix}\tilde b + \begin{pmatrix} \frac32 & 0 \\ -1 & -\frac32 \end{pmatrix}\tilde c + \begin{pmatrix} -\frac12 & 0 \\ -1 & \frac12 \end{pmatrix}\tilde d + \left(\begin{smallmatrix} -1 & 0 \\ 2 & 1 \end{smallmatrix}\right)\tilde f, & \text{on II}_+; \\ \begin{pmatrix} \frac12 & 0 \\ 1 & -\frac12 \end{pmatrix}\tilde a + \begin{pmatrix} \frac12 & 0 \\ 1 & -\frac12 \end{pmatrix}\tilde b + \begin{pmatrix} \frac32 & 0 \\ 5 & -\frac32 \end{pmatrix}\tilde c + \begin{pmatrix} -\frac12 & 0 \\ -1 & \frac12 \end{pmatrix}\tilde d + \left(\begin{smallmatrix} -1 & 0 \\ -2 & 1 \end{smallmatrix}\right)\tilde f, & \text{on III}_-; \\ \begin{pmatrix} \frac12 & 0 \\ 1 & -\frac12 \end{pmatrix}\tilde a + \begin{pmatrix} \frac12 & 0 \\ 1 & -\frac12 \end{pmatrix}\tilde b + \begin{pmatrix} -\frac52 & 2 \\ -3 & \frac52 \end{pmatrix}\tilde c + \begin{pmatrix} -\frac12 & 0 \\ -1 & \frac12 \end{pmatrix}\tilde d + \left(\begin{smallmatrix} -1 & 0 \\ -2 & -1 \end{smallmatrix}\right)\tilde f, & \text{on III}_+; \\ \begin{pmatrix} -\frac12 & 1 \\ 0 & \frac12 \end{pmatrix}\tilde a + \begin{pmatrix} -\frac12 & 1 \\ 0 & \frac12 \end{pmatrix}\tilde b + \begin{pmatrix} \frac12 & -1 \\ 0 & -\frac12 \end{pmatrix}\tilde c + \begin{pmatrix} \frac52 & -3 \\ 2 & -\frac52 \end{pmatrix}\tilde d + \left(\begin{smallmatrix} 1 & -2 \\ 0 & -1 \end{smallmatrix}\right)\tilde f, & \text{on IV}_-; \\ \begin{pmatrix} -\frac12 & 1 \\ 0 & \frac12 \end{pmatrix}\tilde a + \begin{pmatrix} -\frac12 & 1 \\ 0 & \frac12 \end{pmatrix}\tilde b + \begin{pmatrix} \frac12 & -1 \\ 0 & -\frac12 \end{pmatrix}\tilde c + \begin{pmatrix} -\frac32 & 5 \\ 0 & \frac32 \end{pmatrix}\tilde d + \left(\begin{smallmatrix} 1 & -2 \\ 0 & -1 \end{smallmatrix}\right)\tilde f, & \text{on IV}_+; \end{cases}$$

Using the fact that

$$\tilde e + \tilde f = \frac{1}{ac+bd}(\tilde a + \tilde b + \tilde c + \tilde d) = \frac12(\tilde a + \tilde b + \tilde c + \tilde d)$$

by the Ptolemy relation $ef = ac + bd$, since $a = b = c = d = 1$ for the identity element $\tilde\tau_*$, a computation with rather miraculous cancellations as illustrated in Figure 7 confirms that

$$\sum_{x\in\{a,b,c,d,e\}} \bar\vartheta_x \; d\log\lambda_x \;=\; \sum_{x\in\{a,b,c,d,e\}} \bar\vartheta'_x \; d\log\lambda_x,$$

as required to check invariance under the flip along the doe for the standard framing $\mathcal{F} = (\frac{0}{1}, \frac{1}{0}, \frac{1}{1})$.

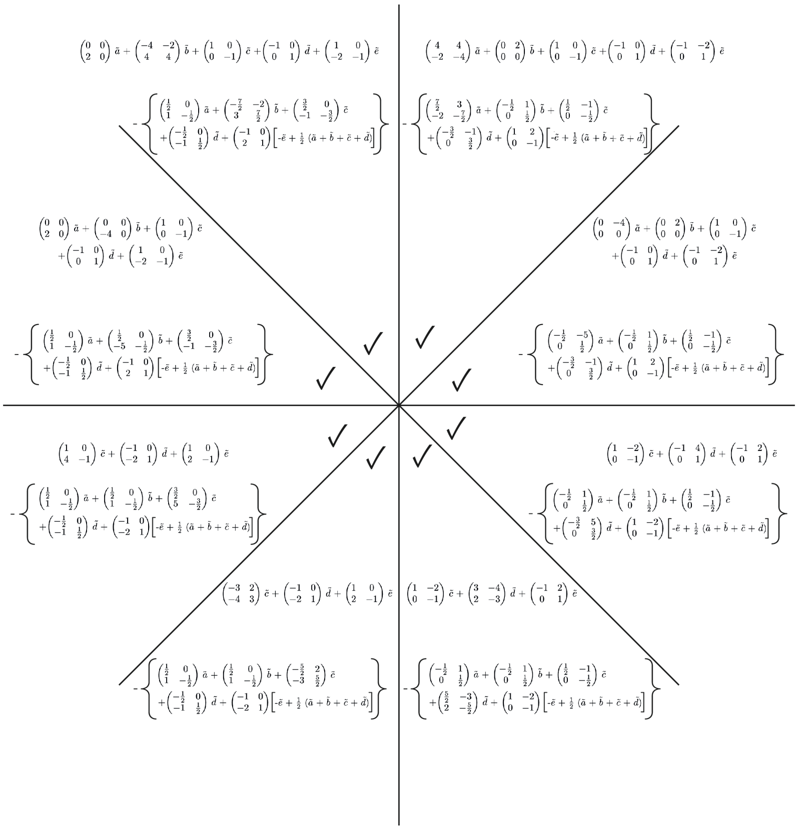

Figure 7. Difference between expressions in Figures 5 and 6 vanishes for all lambda lengths equal to unity, i.e., at the universal punctured arithmetic surface.

This establishes the invariance for a flip on the doe with the associated framing. In the general case first of all, the 1-form is invariant under push-forward by the Möbius group since lambda lengths are $M\ddot{o}b$-invariant, so we may assume that the framing is one that is associated to a doe. Likewise without loss of generality, we may assume that the flip is performed on the edge with endpoints $\frac{0}{1}, \frac{1}{0} \in \mathbb{S}^1$, with the doe however potentially located elsewhere.

Thus, the asserted invariance must be checked for the various possibilities of relative position of doe and the edge with endpoints $\frac{0}{1}, \frac{1}{0}$ to be flipped. In the presented computation, these two edges coincide, and there are four further cases to check depending upon which quadrant in $\mathbb{C} \supseteq \mathbb{D}$ contains the doe, thereby determining the normalization. These four similar but simpler calculations, each corresponding to a different normalization of the common unnormalized formulae already presented in the proof, are left as an exercise for the reader. $\square$

Consider an arbitrary framing $\mathcal{F}$ and let

$$\eta_\mathcal{F} = s^*_\mathcal{F}\, \omega \in \Omega^1(\mathrm{Homeo}_+/M\ddot{o}b),$$

which by general principles should satisfy

$$\underline{\text{Maurer} - \text{Cartan equation}}:\ 0 = d\eta_\mathcal{F} + \frac{1}{2}[\eta_\mathcal{F}, \eta_\mathcal{F}],\ \text{for any framing } \mathcal{F};$$

$$\underline{\text{Compatibility Equation}}: \eta_\mathcal{G} = \mathrm{Ad}(h^{-1}_{\mathcal{F}\mathcal{G}})\, \eta_\mathcal{F}\ +\ h^*_{\mathcal{F}\mathcal{G}}\, \omega_{M\ddot{o}b}, \text{for framings}$$

$\mathcal{F}, G,$ where $h_{\mathcal{F}\mathcal{G}} = s_\mathcal{G} \circ s^{-1}_\mathcal{F}$, Ad denotes the adjoint and $\omega_{M\ddot{o}b}$ is the Maurer-Cartan form on $M\ddot{o}b$.

Note that the Compatibility Equation together with the result for the flip on the doe with its associated framing would give an alternative proof of Theorem 7.1. This putative proof is a bit of a swindle because *there is no Maurer-Cartan form on the topological group* Homeo$_+$ except for the version here, and hence no a priori Compatibility Equation.

Remark 7.2. The expression for $\xi_\mathcal{F}$ as a Poincaré series in framed holographic coordinates is easily derived from Remark 2.8.

As we have noted, the form $\xi_\mathcal{F}$ is morally the Maurer-Cartan form in the sense that its value on the tangent vector $\frac{\partial}{\partial \ln \lambda_A}$ at the identity of $\mathrm{PPSL}_2(\mathbb{R})$ is the corresponding normalized element $\bar{\vartheta}_A$ of the Lie algebra $ppsl_2$. However, $\xi_\mathcal{F}$ has been shown here to be invariant under the lattice $\mathrm{PPSL}_2(\mathbb{Z})$ rather than under the full group $\mathrm{PPSL}_2(\mathbb{R})$, whose invariance we may conjecture. On the other hand, one might therefore more squarely regard $\xi_\mathcal{F}$ solely as an automorphic form, and this is the viewpoint of the next section.

8. Future perspectives

We conclude with a heuristic discussion of constructing the automorphic representation for our universal triad corresponding to the automorphic 1-form obtained in Section 7. To this end, we combine the original constructions of [34] and of Vaughan Jones [16, 17], also described in [22].

We recall from Appendix B that we have constructed an indecomposable automorphic representation V of $\mathrm{PSL}_2(\mathbb{R})$ by lifting the weight 2 Eisenstein series E_2. Viewed as the Lie algebra $psl_2 = psl_2(\mathbb{R})$ representation, it can be identified with the Laurent polynomial ring

$$V \approx \mathcal{O}(\mathbb{C}^\times) = \mathbb{C}[z^{\pm 1}].$$

with the psl_2 action given by

$$e = \frac{d}{dz},\ h = 2z\frac{d}{dz},\ f = z^2\frac{d}{dz}.$$

The space V has a natural multiplication map

$$V \to V \otimes V$$

which commutes with the action of psl_2. One can also identify the restricted dual space with Laurent 1-forms

$$V' \approx \Omega^1(\mathbb{C}^\times) = \mathbb{C}[z^{\pm 1}]dz,$$

with the pairing of V and V' given by the residue of the product at 0. This gives the dual map

$$V' \to V' \otimes V', \tag{8.1}$$

which can be used for the inductive limit construction as in [16, 17, 22].

Namely for any polygon P_γ with frontier γ, we assign a tensor product

$$H_\gamma = \bigotimes_{j=1}^{n} V',$$

where n is the number of edges in γ. There is a partial ordering on the set of polygons given by inclusion $P_\gamma \subseteq P_{\gamma'}$, which induces the partial ordering $\gamma \leqslant \gamma'$ on frontiers. Clearly the Lie subalgebra

$$ppsl_2(\gamma) \subseteq ppsl_2$$

of piecewise psl_2 maps with breakpoints at the vertices of γ acts on H_γ in the natural way, where psl_2 corresponding to the j^{th} edge acts on the j^{th} factor of H_γ. Then the map (8.1) induces a family of intertwining operators

$$T_\gamma^{\gamma'} : H_\gamma \to H_{\gamma'},$$

so that $T_\gamma^\gamma = 1$ and the consistency condition $T_{\gamma''}^{\gamma} = T_{\gamma''}^{\gamma'} T_{\gamma'}^{\gamma}$ holds whenever $\gamma \leqslant \gamma' \leqslant \gamma''$. The direct limit

$$H = \varinjlim H_\gamma \tag{8.2}$$

yields a representation of $ppsl_2$. It can be made unitary by means of a 1-cocycle determined by the one-dimensional subrepresentation $V_0 \subseteq V$ as in [34] or alternatively using a modification of the construction above based upon the approximation of the representation V' of psl_2 by the representations of the complementary series $V(\lambda)$, for $0 < \lambda < 2$ with $\lambda \neq 1$, so that $V(\lambda) \approx V(2-\lambda)$ with $\lim\limits_{\lambda \to 2} V(\lambda) = V$ and $\lim\limits_{\lambda \to 0} V(\lambda) = V'$; see [34] for details.

Remark 8.1. The partial ordering above on ideal polygons occurring as fundamental domains for punctured surfaces leads one to consider the so-called punctured solenoid $\mathcal{H}$, which is an initial object for the category of punctured surfaces with morphisms given by finite covers branched only over the punctures. The unpunctured version was introduced and studied by Dennis Sullivan in [31]. The decorated Teichmüller space of $\mathcal{H}$ was studied in [28] and parametrized by certain coordinates on the Farey tesselation τ_*, namely, lambda length *functions*, one such continuous and $\mathrm{PSL}_2(\mathbb{Z})$-equivariant function from the profinite completion of $\mathrm{PSL}_2(\mathbb{Z})$ to $\mathbb{R}_{>0}$ for each edge of τ_*. Flip-like generators for the mapping class group of $\mathcal{H}$ are derived in [28], and a complete set of relations in these generators is finally given in [2].

To implement our program, we want to realize H, or heuristically $(V')^{\otimes\infty}$, as an automorphic representation on $\mathrm{PPSL}_2(\mathbb{Z})\backslash\mathrm{PPSL}_2(\mathbb{R})$ of $ppsl_2$. To this end, we notice first that the space of harmonic functions on $\mathrm{PSL}_2(\mathbb{R})$, cf. (B.3), can be identified with the space of functions on the boundary of $\mathrm{PSL}_2(\mathbb{R})$, which is dual to the space of functions of the holographic coordinates $\{(s, \delta)\}$ introduced in Section 2. Furthermore for both spaces, we can also identify the corresponding $\mathrm{PSL}_2(\mathbb{R})$ actions, and therefore, we can realize V' by imposing modular invariance on the space of functions depending on a single pair (s, δ) of holographic coordinates. This realization clearly extends to finite tensor products $(V')^{\otimes n}$ associated to n-gons P_γ. We conjecture that the inductive limit H also admits a realization by the automorphic functions in holographic coordinates, with $\mathrm{PPSL}_2(\mathbb{Z})$ playing the role of the modular group $\mathrm{PSL}_2(\mathbb{Z})$.

On the other hand, the analogy between $\mathrm{PPSL}_2(\mathbb{Z})$ and the mapping class group suggests an extension of the former by an infinite symmetric group, or more generally by an infinite braid group, which is still a discrete subgroup of $\mathrm{Homeo}_+(\mathbb{S}^1)$, cf. [14] and the references therein. The reduction of H by the additional symmetry yields the space Λ, or heuristically $S^\infty V'$, which is naturally identified with the free bsosonic field, one of the simplest CFT_2.

As discussed in Appendix B, the theory of automorphic forms allows the enlargement of various spaces by relaxing the automorphic property to smaller discrete subgroups; for example, the restriction to invariance by the commutant $\mathrm{PSL}_2(\mathbb{Z})' \subseteq \mathrm{PSL}_2(\mathbb{Z})$ enlarges V sixfold additively. Similarly, we expect that replacing $\mathrm{PPSL}_2(\mathbb{Z})$ by $\mathrm{P}(\mathrm{PSL}_2(\mathbb{Z}))'$ will correspondingly yield a multiplicative increase of Λ and thereby allow the construction of a CFT_2 of size comparable to the Monster CFT_2.

Finally we come to the question of how we can effectively capture the Monster using the new universal automorphic theory, and in particular how we can derive the Monstrous Moonshine. At this moment, we do not know the complete answer, but we can begin on the opposite side, which will help to clarify the problem and capture the beast. Namely, we consider all 194 conjugacy classes of the Monster and the Thompson series of the representations of these classes in the the Monster representation of [12]. Then we know from [1] that they are the canonical Hauptmoduln $J_\Gamma(z)$ for some genus-zero discrete subgroups Γ of $\mathrm{PSL}_2(\mathbb{R})$ of Moonshine type, i.e., groups commensurable with $\mathrm{PSL}_2(\mathbb{Z})$ which contain $\Gamma_\infty = \{\pm\left(\begin{smallmatrix}1 & n\\ 0 & 1\end{smallmatrix}\right)\}$. Then one has

$$J_\Gamma(z) = q^{-1} + \sum_{n=1}^{\infty} c_\Gamma(n) q^n,$$

for some integral coefficients $c_\Gamma(n)$. One can also construct the corresponding Eisenstein series using a logarithmic derivative of $J_\Gamma(z)$, or as usual an analytic continuation to $s = 0$ of the series

$$E_2^\Gamma(z,s) = \sum_{(c,d)\in\Gamma/\Gamma_\infty} \frac{(\mathrm{Im}\ z)^s}{(cz+d)^2|cz+d|^{2s}}.$$

As in the classical example $\Gamma = \mathrm{PSL}_2(\mathbb{Z})$, the resulting Eisenstein series after multiplication by dz is Γ-invariant though not holomorphic. Then we can repeat the lift of a Γ-invariant 1-form recalled in Appendix B to the automorphic function

$$f = E_2^\Gamma \rightsquigarrow \phi_f(g) = (ci+d)^{-2} f(g\cdot i),$$

where $g = \left(\begin{smallmatrix}a & b\\ c & d\end{smallmatrix}\right) \in \mathrm{PSL}_2(\mathbb{R})$, and we again obtain an indecomposable representation of $\mathrm{PSL}_2(\mathbb{R})$ that we shall denote V^Γ. In fact, we just get another model of the same indecomposable representation of $\mathrm{PSL}_2(\mathbb{R})$. We can also expect a similar construction of the space of universal automorphic forms for $\mathrm{P}\Gamma$ denoted Λ^Γ. It is natural to conjecture that we find a twisted conformal field theory associated to Λ^Γ and the Monster conjugacy class corresponding to Γ. The comparison of Λ and Λ^Γ should yield the Monster element in this conjugacy class, and they together will allow realization of the Monster group via automorphisms of Λ. At this point, the trap will close upon the Monster, and the Moonshine will follow.

Appendix A. Harmonic analysis

To begin, we express the generators of the Witt algebra in terms of the normalized arithmetic wavelets as computed in Theorem 4.13 of [26] and going back in essence to [20].

Theorem A.1. *For each $n \in \mathbb{Z}$, we have the wavelet expansion*

$$\begin{aligned} L_n = e^{in\theta}\frac{\partial}{\partial\theta} &= (b_0^n + b_{+1}^n e^{i\theta} + b_{-1}^n e^{-i\theta})\frac{\partial}{\partial\theta} \\ &+ \frac{i}{4}\sum_{e\in\tau_*}\left\{n(\xi^n+\eta^n) + \frac{\eta+\xi}{\eta-\xi}\,(\xi^n-\eta^n)\right\}\bar{\vartheta}_e(\theta), \end{aligned}$$

where $e \in \tau_*$ has ideal points $\xi, \eta \in \mathbb{S}^1$ and

$$b_0^n = \begin{cases} +1, n \equiv 0(4); \\ 0, n \equiv 1(4); \\ +1, n \equiv 2(4); \\ 0, n \equiv 3(4); \end{cases} \quad b_{+1}^n = \begin{cases} 0, n \equiv 0(4); \\ +1, n \equiv 1(4); \\ -i, n \equiv 2(4); \\ 0, n \equiv 3(4); \end{cases} \quad b_{-1}^n = \begin{cases} 0, n \equiv 0(4); \\ 0, n \equiv 1(4); \\ +i, n \equiv 2(4); \\ +1, n \equiv 3(4). \end{cases}$$

This is not the simplest expression $e^{in\theta} \doteq \sum_{|e|\in\tau_*} g_n^e \bar{\vartheta}_{|e|}$, rather these particular coefficients g_n^e are specially chosen in Theorem A.1 to guarantee their suitable decay in n, cf. Theorem 6.4 of [27].

The next result, Theorem 4.11 of [26], which goes back to [24], is of basic utility and provides the Fourier expansion of the normalized arithmetic wavelets.

Theorem A.2. *If $A = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in \mathrm{PSL}_2$, then the Fourier expansion $\bar{\vartheta}_A \sim \sum_{n\in\mathbb{Z}} c_n\ e^{in\theta}\frac{\partial}{\partial\theta}$ for $n^2 > 1$ is given by*

$$\begin{aligned} \pi i(n^3-n)\ c_n \ &= \ -[(c-a)^2+(b-d)^2]\left[\frac{(b-d)-i(a-c)}{(b-d)+i(a-c)}\right]^n \\ &+ 2(c^2+d^2)\left[\frac{d-ic}{d+ic}\right]^n \ + \ 2(a^2+b^2)\left[\frac{b-ia}{b+ia}\right]^n \\ &- [(c+a)^2+(b+d)^2]\left[\frac{(b+d)-i(a+c)}{(b+d)+i(a+c)}\right]^n, \end{aligned}$$

where the Fourier modes $c_0, c_{\pm 1}$ *are chosen to guarantee that the expansion is normalized. In particular for the mother wavelet, we have* $\bar{\vartheta} = \vartheta \sim \frac{8}{\pi i} \sum_{n \equiv 2(4)} \frac{1}{n^3 - n}\, e^{in\theta} \frac{\partial}{\partial\theta}$.

Remark A.3. A sketch of the proof is that since $\bar{\vartheta}_A$ is once continuously differentiable, we can twice integrate by parts the standard expression for the Fourier coefficients c_n with $n^2 > 1$ and derive these expressions without difficulty. For $n^2 \leqslant 1$ the corresponding equations give certain constraining equations on the zeroeth Fourier modes, which are crucial for the computation of the Kirillov-Kostant form, cf. Section 6

It is not difficult to compute directly the Fourier expansion of the (unnormalized) hyperfans as follows.

Proposition A.4. *Given* $A = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in \mathrm{PSL}_2$, *let*

$$\zeta_- = \frac{b - ia}{b + ia}, \quad \zeta_+ = \frac{d - ic}{d + ic} \in \mathbb{S}^1.$$

Then the hyperfan ψ_A *has Fourier expansion* $\psi_A \sim \sum c_n\, e^{in\theta}$ *with*

$$\begin{aligned} 2\pi i\; c_n = {} & \zeta_-^n \left[\frac{(d - ic)^2}{2(n+1)} \zeta_- + \frac{(d + ic)^2}{2(n-1)} \zeta_-^{-1} - \frac{c^2 + d^2}{n} \right] \\ & - \zeta_+^n \left[\frac{(d - ic)^2}{2(n+1)} \zeta_+ + \frac{(d + ic)^2}{2(n-1)} \zeta_+^{-1} - \frac{c^2 + d^2}{n} \right], \end{aligned}$$

for $n^2 > 2$, *and*

$$\begin{aligned} 2\pi i\; c_0 = {} & \frac{(d - ic)^2}{2} [\zeta_+^{-1} - \zeta_-^{-1}] - \frac{(d + ic)^2}{2} [\zeta_+ - \zeta_-] \\ & + i(c^2 + d^2)[\theta_+ - \theta_-], \\ 2\pi i\; c_{\pm 1} = {} & \mp \frac{(d \pm ic)^2}{2} [\zeta_+^{\pm 2} - \zeta_-^{\pm 2}] \pm (c^2 + d^2)[\zeta_+^{\pm 1} - \zeta_-^{\pm 1}] \\ & - \frac{i(d \mp ic)^2}{2} [\theta_+ - \theta_-], \end{aligned}$$

where $\theta_\mp = \arctan \zeta_\pm$.

Proof. ψ_A is supported on an interval with respective initial and terminal points given by ζ_-^{-1} and ζ_+^{-1}, and takes there the values

$$A^{-1} \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} A = \begin{pmatrix} cd & d^2 \\ -c^2 & -cd \end{pmatrix}$$

or in other words $\frac{(d-ic)^2}{2} e^{i\theta} + \frac{(d+ic)^2}{2} e^{-i\theta} - (c^2 + d^2)$. The standard expression for Fourier coefficients yields the results. □

Notice that the normalized hyperfans $\bar{\psi}_A$ have the same higher Fourier coefficients as ψ_A since $\psi_A \doteq \bar{\psi}_A$. The small Fourier modes for $\bar{\psi}_A$, and likewise those of $\bar{\theta}_A$, can be computed with some difficulty by calculating the values of these vector fields at $\frac{0}{1}, \frac{1}{1}, \frac{1}{0} \in \mathbb{S}^1$. As we do not require them, we omit the details.

Appendix B. The E_2 automorphic representation

The automorphic form that we have constructed on the universal Teichmüller space has a simple analogue on the hyperbolic plane, namely,

$$\xi(z) = E_2(z)dz,$$

where $E_2(z)$ is an almost holomorphic modular form of weight 2. Since dz transforms with respect to $\mathrm{PSL}_2(\mathbb{R})$ with the factor balancing that of $E_2(z)$, we obtain a $\mathrm{PSL}_2(\mathbb{Z})$-invariant 1-form that can be viewed as the classical counterpart of the automorphic form constructed in Section 7.

To state our results unambiguously, let us recall the following explicit formulae, c.f. [9]. Set

$$\mathbb{E}_2(z) = 1 - 24\sum_{n=1}^{\infty}\sigma(n)q^n,$$

where $\sigma(n)$ is the sum of all the positive divisors of n and we set $q = \exp(2\pi i z)$. Then $\mathbb{E}_2(z)$ is holomorphic but not quite modular invariant since

$$\mathbb{E}_2(-\frac{1}{z}) = z^2\mathbb{E}_2(z) + \frac{12}{2\pi i}z.$$

To get an honest weight 2 form, we need a correction

$$E(z) = \mathbb{E}_2(z) - \frac{3}{\pi\ \mathrm{Im}(z)},$$

but we thereby lose the holomorphicity of $\mathbb{E}_2(z)$, since

$$\frac{d}{d\bar{z}}E(z) = \frac{3i}{2\pi}\frac{1}{(\mathrm{Im}(z))^2}.$$

In the classical theory of automorphic forms, one can lift the holomorphic modular forms from the hyperbolic plane to $\mathrm{PSL}_2(\mathbb{R})$ so that they become the lowest weight vectors of the holomorphic series representations. Specifically for a weight $2k$ holomorphic form $f : \mathcal{U} \to \mathbb{C}$, where $k \geqslant 2$, we define

$$\phi_f(g) = (ci + d)^{-2k} f(g \cdot i),$$

as in [15], where $g = \left(\begin{smallmatrix} 1 & b \\ c & d \end{smallmatrix}\right) \in \mathrm{PSL}_2(\mathbb{R})$. It follows that ϕ_f is invariant under the left action

$$\phi_f(\gamma g) = \phi_f(g), \text{ for } \gamma \in \mathrm{PSL}_2(\mathbb{Z}) \tag{B.1}$$

of $\mathrm{PSL}_2(\mathbb{Z})$. One can then define the action of $\mathrm{PSL}_2(\mathbb{R})$ on a certain space of automorphic functions generated by ϕ_f by the right action

$$(\pi(g)\phi)(h) = \phi(hg), \text{ for } h, g \in \mathrm{PSL}_2(\mathbb{R}),$$

so that ϕ_f becomes the lowest weight vector for the Lie algebra $psl_2(\mathbb{R})$ in the appropriate basis E, F, H.

To state the explicit formulae, we shall rely on explicit calculations from [11]. Let h, e, f be the standard basis of $psl_2(\mathbb{R})$ and consider the Cayley transform of this basis

$$H = \begin{pmatrix} 0 & -1 \\ i & 0 \end{pmatrix}, E = \frac{1}{2}\begin{pmatrix} 1 & i \\ i & -1 \end{pmatrix}, F = \frac{1}{2}\begin{pmatrix} 1 & -i \\ -i & 1 \end{pmatrix}.$$

Using the standard parametrization

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} = \begin{pmatrix} 1 & x \\ 0 & 1 \end{pmatrix}\begin{pmatrix} y^{\frac{1}{2}} & 0 \\ 0 & y^{-\frac{1}{2}} \end{pmatrix}\begin{pmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{pmatrix} \tag{B.2}$$

of $\mathrm{PSL}_2(\mathbb{R})$, one can find an explicit action of the Lie algebra basis as follows

$$\begin{aligned} H &= -\partial_\theta, \\ E &= 2ie^{2i\theta}(y\partial_{\bar{z}} - \frac{1}{4}\partial_\theta), \\ F &= -2ie^{-2i\theta}(y\partial_{\bar{z}} - \frac{1}{4}\partial_\theta). \end{aligned}$$

Thus, one has

$$\begin{aligned} F\phi_f &= 0, \\ H\phi_f &= 2k\phi_f. \end{aligned}$$

In the case that $k = 1$, the first of these two equations no longer holds, and instead one has

$$F\phi_f = \frac{3}{\pi}.$$

It follows that ϕ_f is no longer a highest weight vector, but it also generates a one-dimensional sub-representation. Only after factorization with respect to this sub-representation does one obtain the weight 2 irreducible representation of the holomorphic series, denoted V_+.

Similarly using the complex conjugation, one gets the weight 2 representation of the antiholomorphic series denoted V_-. The one-dimensional sub-representation, denoted V_0, is common to both the weight 2 indecomposable representations, and we get a larger indecomposable representation, denoted V, which has a simple composition series

$$0 \to V_0 \to V \to V_+ \otimes V_- \to 0.$$

In order to characterize the resulting three component representation, one can use the Casimir operator, which in the explicit coordinates (B.2) has the form

$$\Delta = y^2 (\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}) - y \frac{\partial^2}{\partial x \partial \theta}.$$

It annihilates the weight 2 automorphic representation generated by Φ_f and its conjugate, where $f = E_2$, to wit

$$\Delta \phi_{E_2} = 0. \tag{B.3}$$

One can check that this harmonic property (B.3) together with the automorphicity condition (B.1) and the usual growth condition of automorphic functions characterizes the three component representation V that we have obtained by lifting the E_2 modular 1-form. The problem of fundamental importance in our new theory is to construct a representation of the Lie algebra $ppsl_2(\mathbb{R})$ using a lift of our automorphic 1-form in Section 7.

The automorphic representation V that we have constructed is well known in the representation theory of $\mathrm{PSL}_2(\mathbb{R})$ as a limit of complementary series [34]. The representations V_+ and V_- are the spin 1 irreducible representations of the holomorphic and antiholomorphic discrete series. Note that the lift of Eisenstein series E_{2k}, for $k = 2, 3, \ldots$, yields spin k irreducible representations of the same series. The representation V plays a pivotal role and somehow seems to have been missed in the theory of automorphic functions for the pair $\mathrm{PSL}_2(\mathbb{Z}) \subseteq \mathrm{PSL}_2(\mathbb{R})$ Thus it is expected that the counterpart of the representation V in our new theory will play an equally fundamental role, and it is one of our main open problems to construct it explicitly.

One can ask what is an advantage of a realization of this representation as an automorphic representation. One such benefit is that we can naturally increase this representation by relaxing the automorphicity condition (B.1) from the modular group $\mathrm{PSL}_2(\mathbb{Z})$ to various subgroups including its commutant $\mathrm{PSL}_2(\mathbb{Z})'$ considered in Section 1. This immediately yields six copies of the weight 2 representation.

Finally, we note that we could also consider the weight 1 representations which correspond to the limit of the holomorphic discrete series of

$SL_2(\mathbb{R})$. The index of the commutant is $[SL_2(\mathbb{R}) : SL_2(\mathbb{R})'] = 12$ in this case, and we get correspondingly 12 copies upon relaxing the automorphicity condition.

Abstract

In these notes we give an introduction both to Monstrous Moonshine and to the classification of rational conformal field theories, using this as an excuse to explore several related structures and go on a little tour of modern math. We will discuss Lie algebras, modular functions, the finite simple group classification, vertex operator algebras, Fermat's Last Theorem, category theory, (generalised) Kac-Moody algebras, denominator identities, the A-D-E meta-pattern, representations of affine algebras, Galois theory, etc. This work is informal and pedagogical, and aimed mostly at grad students in math or math phys, but I hope that many interested nonexperts will find something of value here — like any good Walt Disney movie I try not to completely ignore the 'grown-ups'. My emphasis is on ideas and motivations, so these notes are intended to complement other papers and books where this material is presented with more technical detail. The level of difficulty varies significantly from topic to topic. The two parts — in fact any of the sections — can be read independently.

Table of Contents

Part 1. The classification of conformal field theories

1.1. Informal motivation 1
1.2. Lie algebras 4
1.3. Representations of finite-dimensional simple Lie algebras 10
1.4. Affine algebras and the Kac-Peterson matrices 13
1.5. The classification of physical invariants 17

Part 1. The classification of conformal field theories

1.1. INFORMAL MOTIVATION

In this section we will sketch a very informal and 'hand-wavy' motivation to what we shall call the classification problem for rational conformal field theory (RCFT). Much of this material is more carefully treated in e.g. [18].

A CFT is a quantum field theory (QFT), usually with a two-dimensional space-time, whose symmetries include the conformal transformations. There are different approaches to CFT — for one of these see [26,27]. Another formulation which has been deeply influential is due to Graeme Segal [52]. It is motivated by string theory and is phrased in an important mathematical language called *category theory*.

A *category* consists of two types of things. One are called *objects*, and the other are called *arrows* (or *morphisms*). An arrow, written $f : A \to B$, has an initial and a final object (A and B respectively). Arrows f, g can be composed to yield a new arrow $f \circ g$, if the final object of g equals the initial object of f. Maps between categories are called *functors* if they take the objects (resp., arrows) of one to the objects (resp., arrows) of the other, and preserve composition.

The only difficulty people can have in understanding categories is in realising that there is no real content to them. It's just a language, highly abstract like the more familiar set theory, but in many contexts (a great example is the theory of knot invariants [58]) one which is both natural and suggestive. It tries to deflect some of our instinctive infatuation with objects (nouns), to the mathematically more fruitful one with structure-preserving maps between objects (verbs). A gentle introduction to the mathematics and philosophy of categories is [43]; we'll give a taste of this shortly.

The standard example of a category is called **Set**, where the 'objects' are sets, and the arrows from A to B are functions $A \to B$. A related example that Segal uses is **Vect**, where the objects are complex vector spaces and the arrows are linear maps. A rather trivial example of a functor $\mathcal{F} : \mathbf{Vect} \to \mathbf{Set}$ sends a vector space V to its underlying set, also called V — i.e. $\mathcal{F}$ simply 'forgets' the vector space structure on V and ignores the fact that the arrows f in **Vect** are linear. The other category Segal uses he calls **C**; its objects are disjoint unions of (parametrised) circles S^1, and the arrows are (conformal equivalence classes of) *cobordisms*, i.e. (Riemann) surfaces whose boundaries are those circles. Composition of arrows in **C** is accomplished by gluing the surfaces along the appropriate boundary circles.

Consider the usual definition of a one-to-one function: $f(x) = f(y)$ only when $x = y$. Category theory replaces this with the following. The arrow $f : A \to B$ is called 'monic' if for any arrow $g : C \to B$, there exists a unique arrow $h : C \to A$ such that $f \circ h = g$. So it's a sort of factorisation property. You can easily verify that in **Set** the notions of 'one-to-one' and 'monic' coincide. What does this redefinition gain us? It certainly doesn't seem any simpler. But it does change the focus from the *argument* of f, to the *global* functional behaviour of f, and a change of perspective can never be bad. And it allows us to transport the idea of one-to-one-ness to arbitrary categories. For instance, in the Riemann surface category **C**, the 'one-to-one functions' are the genus-0 cobordisms.

Or consider the notion of *product*. In category theory, we say that the triple (P, a, b) is a product of objects A, B if $a : P \to A$ and $b : P \to B$ are arrows, and if for any $f : C \to A$, $g : C \to B$, there is a unique arrow $h : C \to P$ such that $f = a \circ h$ and $g = b \circ h$. This notion unifies several constructions (each of which is the 'product' in an appropriately chosen category): Cartesian product of sets; intersection of sets; multiplication of numbers; the logical operator 'and'; direct product; infimum in a partially ordered set; etc. *Sum* can be defined similarly, unifying the constructions of disjoint union, 'or', addition, tensor product, direct sum, supremum, etc.

This generality of course comes with a price: it can wash away all of the endearing special features of a favourite theory or structure. There certainly are contexts where e.g. all human beings should be thought of as equal, but there are other contexts where the given human is none other than your mother and must be treated as such. It turns out that category theory provides a beautiful framework for understanding topological invariants such as the Jones-Reshetikhin-Turaev-Witten knot invariants (see e.g. [58]). And it seems to be a natural language for formulating CFT axiomatically, as we'll now see.

According to Segal, a CFT is a functor $\mathcal{T}$ from **C** to **Vect**, which obeys various properties. The picture comes from string theory: the fundamental object is a 'vibrating' loop; a state is given by a collection of these loops; each classical Feynman path from the initial to the final states is a world-sheet, i.e. a surface Σ whose boundary is all the loops in the initial and final states. QFT assigns a complex number I (the action) to each of these world-sheets, and the quantum amplitude, written $\langle \text{final}|\text{initial}\rangle$, will then be the integral over all worldsheets of $e^{\mathrm{i}I/\hbar}$. (The quantum amplitude is how the theory makes contact with experiment, as it tells us the probability of the given process $|\text{initial}\rangle \mapsto |\text{final}\rangle$ happening.) This is what Segal is trying to capture formally. The vector spaces in **Vect** come in in order to handle uniformly and simultaneously the various 'vibrations' of the strings. In particular there is one basic vector space H (a Hilbert space of quantum states), and the functor will take n copies of S^1 to $H^n = H \otimes \cdots \otimes H$.

The simplest interesting example here is the 'tree-level creation of a string from the vacuum'. In this case the world-sheet looks like a bowl, i.e. *topologically* is a disk D (if we imagine the bowl to be made of rubber, we could grab its rim and stretch it down flat onto the table, so we say a bowl and a disk are topologically equivalent — see also §2.3). Segal's functor gives us a linear map $\mathcal{T}(D) : \mathbb{C} \to H$ (H^0 is just $\mathbb{C}$), which we can think of equivalently as the assignment of the vector $\mathcal{T}(D)(1)$ in H to D. In the case of the standard unit disk (i.e. where the parametrisation of the boundary S^1 is simply $\theta \mapsto e^{2\pi \mathrm{i}\theta}$), this vector is cal0led the *vacuum state* $\Omega = |0\rangle$.

For another example, consider the 'vacuum-to-vacuum expectation value'. The initial and final states (objects) here are both the empty set, so the world-sheets (arrows) are closed Riemann surfaces. As usual in QFT, we can organise these by how many internal 'loops' are involved (this number is called the *genus* of the surface): topologically, 0-loop (i.e. 'tree-level') world-sheets are spheres, 1-loop world-sheets are tori, etc. These closed Riemann surfaces are discussed in more detail in §2.3. The 0-loop contribution isn't very interesting (there is only one conformal equivalence class of spheres), so let us look at the 1-loop contribution. It will be of the form $\int \mathcal{Z}([torus])\, d[torus]$, where $\mathcal{Z}$ is a complex-valued function called the partition function, and $[torus]$ is a conformal equivalence class of tori. In the Segal formalism we recover this in the following way: the functor takes $[torus]$ to a linear function from $H^0 = \mathbb{C}$ to $H^0 = \mathbb{C}$. Any such linear function is simply a 1×1 matrix, i.e. a complex number, which we call $\mathcal{Z}([torus])$.

Now there is a nice parametrisation of conformal equivalence classes of tori, as we will see more explicitly in §2.3. Namely, a representative for each class can be chosen to be of the form $\mathbb{C}/(\mathbb{Z} + \mathbb{Z}\tau)$ where τ is in the upper half plane $\mathcal{H}$. Thus we can write $\mathcal{Z}$ as a function of a complex variable τ. However, different τ correspond to the same equivalence class of tori: the redundancy is exactly captured by the modular group $\mathrm{PSL}_2(\mathbb{Z})$. Namely, τ and $\frac{a\tau+b}{c\tau+d}$ are equivalent, whenever $a, b, c, d \in \mathbb{Z}$ and $ad - bc = 1$. Thus $\mathcal{Z}(\tau) = \mathcal{Z}(\frac{a\tau+b}{c\tau+d})$. In other words, the partition function is modular invariant![1]

There are two sectors in CFT, a holomorphic one and an antiholomorphic one, corresponding to the two directions ('left-' and 'right-moving') of motion on a string, or the two components of the group $\mathrm{Diff}(S^1)$ of diffeomorphisms of the circle. This means that many of the quantities (e.g. the partition function) factorise into parts depending holomorphically and anti-holomorphically on the modular parameters (e.g. τ in genus 1). In a *rational* CFT there are finitely many 'primary fields' $a \in \Phi$ — the precise meaning of this is not important here, but it says that the space of states for the theory decomposes into a finite sum[2] $H = \oplus_{a,b\in\Phi} M_{ab} H_a \otimes \overline{H}_b$, where M_{ab} are nonnegative integers which count the multiplicity of $H_a \otimes \overline{H}_b$ in H. The linear maps $\mathcal{T}(\Sigma) : H^m \to H^n$ in an RCFT will factorise similarly; this 'chiral factorisation' is captured by what Segal calls the 'modular functor' [52]. The partition function becomes

$$\mathcal{Z}(\tau) = \sum_{a,b\in\Phi} M_{ab}\, \chi_a(\tau)\, \chi_b(\tau)^* \tag{1.1.1}$$

for certain holomorphic functions χ_a. One of the primary fields (we'll denote it '0') corresponds to the vacuum Ω, and uniqueness of the vacuum means that $M_{00} = 1$.

H_0 is called a *chiral algebra*; in the language of §2.6, H_0 will be a vertex operator algebra (VOA). Φ parametrises the irreducible H_0-modules and the χ's are their characters; in an RCFT we require this number to be finite. For example, for the Moonshine VOA $V^\natural$ discussed in Part 2, Φ consists of only one element.

The higher-genus behaviour of an RCFT is determined from the lower-genus behaviour, by composition of 'arrows' (i.e. the gluing together of surfaces) in **C**. See Figure 3 of [30] to find how a genus-2 surface is built up from genus-0 ones. In fact, it's generally believed that an RCFT will be uniquely determined by: (i) the choice of chiral algebra; (ii) the partition function (which tells you the spectrum of the theory, i.e. how the two sectors link up); and (iii) the structure constants C_{ab}^c, which in the Segal formalism correspond to the surfaces called 'pairs-of-pants', equivalently disks with two interior disks removed. Our approach will be to start with a chiral algebra, and find all possible partition functions. We will thus ignore the important question of existence and uniqueness of the structure constants, though at least for our chiral algebras, it seems to be generally believed that the structure constants will be unique.

---

[1] In higher-dimensional string theories, a similar argument shows more generally that *automorphic forms* will appear naturally.

[2] It seems though that 'rational' logarithmic CFT is trying to teach us the lesson that this familiar requirement can and should be weakened. See Gaberdiel-Kausch (1999).

Perhaps all chiral algebras come from standard constructions (e.g. orbifolds and the Goddard-Kent-Olive (GKO) coset construction — see e.g. [18]) involving lattices and affine Kac-Moody algebras. For instance a $\mathbb{Z}_2$-orbifold of the VOA of the Leech lattice gives us the Moonshine module $V^\natural$, and the so-called minimal models come from GKO cosets involving $A_1^{(1)}$. This is in line with the spirit of Tannaka-Krein duality (and its generalisations by Deligne and Doplicher-Roberts), which roughly says that if a bunch of things *act like* they're the set of representations of a Lie group, then they *are* the set of representations of a Lie group.

In any case, one of the simplest, best understood, and important classes (called Wess-Zumino-Witten (WZW) models — see for instance [30,59] in this volume) of RCFTs correspond to affine Kac-Moody algebras at a positive integer level k. We will have much more to say later about these algebras, but for now let us remark that Φ here will be the (finite) set P_+^k of integrable level k highest weights λ. Their chiral algebras were constructed by Frenkel and Zhu. The following sections concern the attempt to classify the partition functions corresponding to Kac-Moody algebras — see especially §1.5. I will use this theme as an excuse to describe many other things, e.g. the A-D-E meta-pattern, Lie theory, Galois, fusion rings, ... I dedicate these notes to the profound friendship developing in recent years between mathematics and physics. As Victor Kac said in his 1996 Wigner medal acceptance speech, "Some of the best ideas come to my field from the physicists. And on top of this they award me a medal. One couldn't hope for a better deal."

1.2. LIE ALGEBRAS

Lie algebras (and their nonlinear partners *Lie groups*) appear in numerous places throughout math and mathematical physics. A nice introduction is [9]; Lie theory is presented with more of a physics flavour in [24], as well as [59].

An *algebra* is a vector space with a way to multiply vectors which is compatible with the vector space structure (i.e. the vector-valued product is *bilinear*: $(a\vec{u}+a'\vec{u}')\,(b\vec{v}+b'\vec{v}') = ab\,\vec{u}\vec{v} + ab'\,\vec{u}\vec{v}' + a'b\,\vec{u}'\vec{v} + a'b'\,\vec{u}'\vec{v}'$). For example, the complex numbers $\mathbb{C}$ can be thought of as a 2-dimensional algebra over $\mathbb{R}$ (a basis is 1 and $\mathrm{i} = \sqrt{-1}$; the *scalars* here are real numbers and the *vectors* are complex numbers). The quaternions are 4-dimensional over $\mathbb{R}$ and the octonions are 8-dimensional over $\mathbb{R}$. Incidentally, these are the only finite-dimensional algebras over $\mathbb{R}$ which obey the cancellation law: $\vec{u} \neq 0$ and $\vec{u}\vec{v} = 0$ implies $\vec{v} = 0$ (the reader should try to convince himself why the familiar vector product on $\mathbb{R}^3$ fails the cancellation law). This important little fact makes several unexpected appearances in math. For instance, it is trivially possible to 'comb the hair' on the circle S^1 without 'cheating' (i.e. needing a hair-part or exploiting a bald spot): just comb the hair clockwise for example. However it is not possible to comb the hair on the sphere S^2 (e.g. your own head) without cheating. The only other k-spheres S^k which can be combed (i.e. for which there exist k linearly independent continuous vector fields) are $k = 3$ and 7. This is intimately connected with the existence of $\mathbb{C}$, the quaternions, and octonions (namely,

S^1, S^3, S^7 can be thought of as the length 1 complex numbers, quaternions, and octonions, resp.).

In a *Lie* algebra $\mathfrak{g}$, the product is usually called a 'bracket' and is written $[xy]$. It is required to be 'anti-commutative' and 'anti-associative':

$$[xy] + [yx] = 0 \tag{1.2.1a}$$

$$[x[yz]] + [y[zx]] + [z[xy]] = 0 \tag{1.2.1b}$$

(like most other equalities in math, (1.2.1b) is usually called the *Jacobi identity*). Usually we will consider Lie algebras over $\mathbb{C}$, but sometimes over $\mathbb{R}$. Note that (1.2.1a) says $[xx] = 0$.

One important consequence of bilinearity is that it is enough to know the values of all the brackets $[x_i x_j]$ for $i < j$, for any basis $\{x_1, x_2, \ldots\}$ of $\mathfrak{g}$. (The reader should convince himself of this before proceeding.)

The simplest example of a Lie algebra is $\mathfrak{g} = \mathbb{C}$ (or $\mathfrak{g} = \mathbb{R}$), with the bracket $[xy]$ identically 0. In fact, this is the only 1-dimensional Lie algebra. It is a straightforward exercise for the reader to find all 2- and 3-dimensional Lie algebras (over $\mathbb{C}$) up to isomorphism (i.e. change of basis): there are precisely 2 and 6 of them, respectively (though one of the 6 depends on a complex parameter). Over $\mathbb{R}$, there are 2 and 9 (with 2 depending on real parameters). This exercise cannot be continued much further — e.g. not all 7-dimensional Lie algebras (over $\mathbb{C}$) are known. Nor is it obvious that this would be an interesting or valuable exercise. We should suspect that our definition of Lie algebra is probably a little too general for anything obeying it to be automatically an interesting structure. More often than not, a classification turns out to be a stale and useless list.

Two of the 3-dimensional Lie algebras are important in what follows. One of them is well-known to the reader: consider the vector-product (also called cross-product) in $\mathbb{C}^3$. Taking the standard basis $\{e_1, e_2, e_3\}$ of $\mathbb{C}^3$, the bracket can be defined by the relations

$$[e_1 e_2] = e_3 \ , \qquad [e_1 e_3] = -e_2 \ , \qquad [e_2 e_3] = e_1 \ . \tag{1.2.2a}$$

This Lie algebra, denoted A_1 or $\mathrm{sl}_2(\mathbb{C})$, can be called the 'mother of all (semi-simple) Lie algebras'. A more familiar realisation of A_1 uses a basis $\{e, f, h\}$ with relations

$$[ef] = h \ , \qquad [he] = 2e \ , \qquad [hf] = -2f \ . \tag{1.2.2b}$$

The reader can find the change-of-basis (valid over $\mathbb{C}$ but not $\mathbb{R}$) showing that (1.2.2) define isomorphic *complex* (but not *real*) Lie algebras.

Another important 3-dimensional Lie algebra is called the Heisenberg algebra[3] and is the algebra of the canonical commutation relations in quantum mechanics: choosing a basis x, p, h, it is defined by

$$[xp] = h \ , \qquad [xh] = [ph] = 0 \ . \tag{1.2.3}$$

---

[3] Actually, 'Heisenberg algebra' refers to a family of Lie algebras, with (1.2.3) being the one of lowest dimension.

From our definition, it is far from clear that Lie algebras, as a class, should be natural and worth studying. After all, there are infinitely many possible axiomatic systems: why should the one defining a Lie algebra be anything special *a priori*? Perhaps this could have been anticipated by the following line of reasoning.

Axiom. Groups are important and interesting.
Axiom. Manifolds are important and interesting.

Manifolds are structures where calculus is possible; locally, a manifold looks like a piece of $\mathbb{R}^n$ (or $\mathbb{C}^n$), but these pieces can be bent and stitched together to create more interesting shapes. For instance a circle is a 1-dimensional manifold, while Einstein claimed space-time is a curved 4-dimensional one.

Definition. A Lie group is a manifold with a compatible group structure.

This means that 'multiplication' and 'inverse' are differentiable maps. $\mathbb{R}$ is a Lie group, under addition: obviously, $\mu : \mathbb{R}^2 \to \mathbb{R}$ and $\iota : \mathbb{R} \to \mathbb{R}$ defined by $\mu(a, b) = a + b$ and $\iota(a) = -a$ are both differentiable. (Why isn't $\mathbb{R}$ a Lie group under multiplication?) A circle is also a Lie group: parametrise the points with the angle θ defined mod 2π (or mod 360 if you prefer); the 'product' of the point at angle θ_1 with the point at angle θ_2 will be the point at angle $\theta_1 + \theta_2$. Surprisingly, the only other k-sphere which is a Lie group is S^3 (the product can be defined using quaternions of unit length[4], or using the matrix group $\mathrm{SU}_2(\mathbb{C})$). Many but not all Lie groups can be expressed as matrix groups. Two other examples are GL_n (invertible $n \times n$ matrices) and SL_n (ones with determinant 1).

A consequence of the above axioms is then surely:

Corollary. Lie groups should be important and interesting.

Lie group structure theory can be thought of as a major generalisation of linear algebra. The basic constructions familiar to undergraduates have important analogues valid in many Lie groups. For instance, years ago we were taught to solve linear equations and invert matrices by using elementary row operations to reduce a matrix to row-echelon form. What this says is that any matrix $A \in \mathrm{GL}_n(\mathbb{C})$ can be factorised $A = BPN$, where N is uppertriangular with 1's on the diagonal, P is a permutation matrix, and B is an uppertriangular matrix. This is essentially what is called the Bruhat decomposition of the Lie group $\mathrm{GL}_n(\mathbb{C})$. More generally (where it applies to any 'reductive' Lie group G), P will be an element of the so-called 'Weyl group' of G (of which we'll have much more to say later), and B will be in a 'Borel subgroup'.

Lie groups appear throughout physics. E.g. the orthogonal group $\mathrm{SO}_3(\mathbb{R})$ is the configuration space of a rigid body centred at the origin, while $\mathrm{SU}_2(\mathbb{C})$ is the set of states of an electron at rest. The gauge group of the Standard Model of particle physics is $\mathrm{SU}_3(\mathbb{C}) \times \mathrm{SU}_2(\mathbb{C}) \times \mathrm{U}_1(\mathbb{C})$, while the Lorentz group of special relativity is $\mathrm{SO}_{3,1}(\mathbb{R})$.

There is an important relation between Lie groups and Lie algebras.

Fact. The tangent space of a Lie group is a Lie algebra. Any (finite-dimensional real or complex) Lie algebra is the tangent space to some Lie group.

---

[4] Similarly, the 7-sphere inherits from the octonions a *nonassociative* (hence nongroup) product, compatible with its manifold structure.

More precisely, the tangent space at 1 (i.e. the set of all infinitesimal generators of the Lie group) can be given a natural Lie algebra structure. A Lie algebra, being a linearised Lie group, is much simpler and easier to handle. The Lie algebra preserves the local properties of the Lie group, though it loses global topological properties (like boundedness). A Lie group has a single Lie algebra, but a Lie algebra can correspond to many different Lie groups. The Lie algebra corresponding to both $\mathbb{R}$ and S^1 is $\mathfrak{g} = \mathbb{R}$ with trivial bracket. The Lie algebra corresponding to both $S^3 = \mathrm{SU}_2(\mathbb{C})$ and $\mathrm{SO}_3(\mathbb{R})$ is the cross-product algebra on $\mathbb{R}^3$ (usually called $\mathrm{so}_3(\mathbb{R})$). Given the above fact, a safe guess would be:

Conjecture. Lie algebras are important and interesting.

From this line of reasoning, it should be expected that historically Lie groups arose first. Indeed that is the case: the Norwegian Sophus Lie introduced them in 1873 to try to develop a Galois theory for ordinary differential equations. As the reader may be aware, Galois theory is used for instance to show that not all 5th degree (or higher) polynomials can be explicitly 'solved' using radicals — we will meet Galois theory in §1.8. Lie wanted to study the explicit solvability (integrability) of differential equations, and this led him to develop what we now call Lie theory. The importance of Lie groups however have grown well beyond this initial motivation.

An important class of Lie algebras are the so-called finite-dimensional *simple* ones. Their definition and motivation will be studied in §2.7 below, but in a certain sense they serve as building blocks for all other finite-dimensional Lie algebras.

The classification of simple finite-dimensional Lie algebras over $\mathbb{C}$ is quite important and was accomplished at the turn of the century by Killing and Cartan. There are 4 infinite families A_ℓ ($\ell \geq 1$), B_ℓ ($\ell \geq 3$), C_ℓ ($\ell \geq 2$), and D_ℓ ($\ell \geq 4$), and 5 exceptionals E_6, E_7, E_8, F_4 and G_2. A_ℓ can be thought of[5] as $\mathrm{sl}_{\ell+1}(\mathbb{C})$, the $(\ell+1) \times (\ell+1)$ matrices with trace 0. The orthogonal algebras B_ℓ and D_ℓ can be identified with $\mathrm{so}_{2\ell+1}(\mathbb{C})$ and $\mathrm{so}_{2\ell}(\mathbb{C})$, resp., where $\mathrm{so}_n(\mathbb{C})$ is all $n \times n$ anti-symmetric matrices $A^t = -A$. The symplectic algebra C_ℓ is $\mathrm{sp}_{2\ell}(\mathbb{C})$, i.e. all $2\ell \times 2\ell$ matrices A obeying $A\Omega = -\Omega A^t$, where $\Omega = \begin{pmatrix} 0 & I_\ell \\ -I_\ell & 0 \end{pmatrix}$ and I_ℓ is the identity matrix. The exceptionals can be constructed e.g. using the octonions. In all these cases the bracket is given by the commutator

$$[AB] = [A, B] := AB - BA \tag{1.2.4}$$

(it is a good exercise for the reader to confirm that the commutator satisfies (1.2.1), and that e.g. $\mathrm{sl}_n(\mathbb{C})$ is indeed closed under it). To see that (1.2.2b) truly is $\mathrm{sl}_2(\mathbb{C})$, put

$$e = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad f = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}, \qquad h = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \tag{1.2.5}$$

Incidentally the names A, B, C, D have no significance: since the 4 series start at $\ell = 1, 2, 3, 4$, it seemed natural to call these A, B, C, D, resp. Unfortunately a bit of bad luck happened: B_2 and C_2 are isomorphic and so at random that algebra was placed in the orthogonal series; however affine Dynkin diagrams make it clear that it really is a symplectic algebra which accidentally looks orthogonal; hence in hindsight the names of the B- and C-series really should have been switched.

---

[5] Strictly speaking these are *representations* (see next section).

This classification changes if the *field* — the choice of scalars=numbers — is changed. By a field, we mean we can add, subtract, multiply and divide, such that all the usual properties like commutativity and distributivity are obeyed. Fields will make a few different appearances in these notes. $\mathbb{C}$, $\mathbb{R}$, and $\mathbb{Q}$ are fields, while $\mathbb{Z}$ is not (you can't always divide an integer by e.g. 3, and remain in $\mathbb{Z}$). The integers mod n, which we will write $\mathbb{Z}_n$, are a field iff n is prime (the reader can verify that in e.g. $\mathbb{Z}_4$, it is not possible to divide by the field element $[2] \in \mathbb{Z}_4$ even though $[2] \neq [0]$ there). $\mathbb{C}$ and $\mathbb{R}$ are examples of fields of characteristic 0 — this means that 0 is the only integer k with the property that $kx = 0$ for all x in the field. $\mathbb{Z}_p$ is the simplest example of a field with nonzero characteristic: in $\mathbb{Z}_p$, multiplying by the integer p has the same effect as multiplying by 0, and so we say $\mathbb{Z}_p$ has characteristic p. Strange fields have important applications in e.g. coding theory and, ironically, in number theory itself — see e.g. §1.8.

As always, $\mathbb{C}$ is better behaved than e.g. $\mathbb{R}$ because every polynomial can be factorised over $\mathbb{C}$ (we say $\mathbb{C}$ is *algebraically closed*) — this implies for example that every matrix has an eigenvector over $\mathbb{C}$ but not necessarily over $\mathbb{R}$. Over $\mathbb{R}$, the difference in the simple Lie algebra classification is that each symbol $X_\ell \in \{A_\ell, \dots, G_2\}$ corresponds to a number of inequivalent algebras (over $\mathbb{C}$, each algebra has its own symbol). For example, 'A_1' corresponds to 3 different real simple Lie algebras, namely the matrix algebras $\mathrm{sl}_2(\mathbb{R})$, $\mathrm{sl}_2(\mathbb{C})$ (interpreted as a *real* vector space), and $\mathrm{so}_3(\mathbb{R})$. The simple Lie algebra classification has recently been done in any characteristic $p > 7$. It is surprising but very common that the smaller primes behave very poorly, and the classification for characteristic 2 is probably completely hopeless.

Associated with each simple algebra X_ℓ is a Weyl group, and a (Coxeter-)Dynkin diagram. The Weyl group is a finite reflection group, e.g. for A_ℓ it is the symmetric group $\mathfrak{S}_{\ell+1}$. See Figure 7 of [59] for the Weyl group of A_2. The Dynkin diagram of X_ℓ (see e.g. [24,36,38] or Figure 6 in [59]) is a graph with ℓ nodes, and with possibly some double and triple edges. It says how to construct X_ℓ abstractly using generators and relations — see §2.7. We will keep meeting both throughout these notes.

Another source of Lie algebras are the vector fields $\mathrm{Vect}(M)$ on a manifold M. A vector field v is a choice (in a smooth way) of a tangent vector $v(p) \in T_pM$ at each point of M. It can be thought of as a (1st order) differential operator, acting on functions $f : M \to \mathbb{R}$ (or $f : M \to \mathbb{C}$); at each point $p \in M$ take the directional derivative of f in the direction $v(p)$. For example the vector fields on the circle, $\mathrm{Vect}(S^1)$, can be thought of as anything of the form $g(\theta)\frac{d}{d\theta}$ where $g(\theta)$ can be any function with period 1. We can compose vector fields $u \circ v$, but this will result in a 2nd order differential operator: e.g.

$$(f(\theta)\frac{d}{d\theta}) \circ (g(\theta)\frac{d}{d\theta}) = f(\theta)\, g(\theta)\, \frac{d^2}{d\theta^2} + f(\theta)\, g'(\theta)\, \frac{d}{d\theta}\ .$$

Instead, the natural 'product' of vector fields is given by their commutator $[u, v] = u \circ v - v \circ u$, as it always results in a vector field: e.g.

$$[f(\theta)\frac{d}{d\theta}, g(\theta)\frac{d}{d\theta}] = (f(\theta)\, g'(\theta) - f'(\theta)\, g(\theta))\frac{d}{d\theta}$$

in Vect(S^1). Vect(M) with this bracket is an infinite-dimensional Lie algebra. In the case where M is a Lie group G, the Lie algebra of G can be interpreted as a certain finite-dimensional subalgebra of Vect(G) given by the 'left-invariant vector fields'.

Simple algebras need not be finite-dimensional. An example of an infinite-dimensional one is the *Witt algebra* $\mathcal{W}$, which can be defined (over $\mathbb{C}$) by the basis[6] L_n, $n \in \mathbb{Z}$, and the relations

$$[L_m L_n] = (m-n) L_{m+n} \ . \tag{1.2.6}$$

Using the realisation $L_n = -\mathrm{i}e^{-\mathrm{i}n\theta}\frac{d}{d\theta}$, the Witt algebra can also be interpreted as the polynomial subalgebra of the complexification $\mathbb{C} \otimes \mathrm{Vect}(S^1)$ — i.e. change the scalar field of Vect(S^1) from $\mathbb{R}$ to $\mathbb{C}$. Incidentally, infinite-dimensional Lie algebras need not have a corresponding Lie group: e.g. the real algebra Vect(S^1) is the Lie algebra of the Lie group $\mathrm{Diff}^+(S^1)$ of orientation-preserving diffeomorphisms $S^1 \to S^1$, but $\mathbb{C} \otimes \mathrm{Vect}(S^1)$ has no Lie group. $\mathrm{Diff}^+(S^1)$ plays a large role in CFT, by acting on the objects of Segal's category **C**.

The Witt algebra appears naturally in CFT: e.g. using the realisation $L_n = -z^{n+1}\frac{d}{dz}$ it is the polynomial subalgebra of the Lie algebra Vect($\mathbb{C}/\{0\}$). Very carelessly, Vect($\mathbb{C}/\{0\}$) is often thought of as the infinitesimal conformal transformations on a suitable neighbourhood of 0 (yet clearly L_{-2}, L_{-3}, ... are singular at 0!). Indeed the CFT literature is very sloppy when discussing the conformal group in 2-dimensions. The unfortunate fact is that, contrary to claims, *there is no infinite-dimensional conformal group* for $\mathbb{C} \cong \mathbb{R}^2$. The best we can do is the 3-dimensional group $\mathrm{PSL}_2(\mathbb{C})$ of Möbius transformations $z \mapsto \frac{az+b}{cz+d}$, which are orientation-preserving conformal transformations for the Riemann sphere $\mathbb{C} \cup \{\infty\}$. There seem to be 2 ways out of this rather embarrassing predicament. One is to argue that we are really interested in 'infinitesimal conformal invariance' in some meromorphic sense, so the full Witt algebra can appear. The other way is to argue that it is the conformal group of 'Minkowski space' $\mathbb{R}^{1,1}$ (or better, its compactification $S^1 \times S^1$) rather than $\mathbb{R}^2 \cong \mathbb{C}$ (or its compactification S^2) which is relevant for CFT. That conformal group *is* infinite-dimensional; for $S^1 \times S^1$ it consists of 2 copies of $\mathrm{Diff}^+(S^1) \times \mathrm{Diff}^+(S^1)$. For a more careful treatment of this point, see [51].

For reasons we will discuss in §1.4, we are more interested in the *Virasoro algebra* $\mathcal{V}$ rather than the Witt algebra $\mathcal{W}$. This is a '1-dimensional central extension' of $\mathcal{W}$; as a vector space $\mathcal{V} = \mathcal{W} \oplus \mathbb{C}C$ with relations given by

$$[L_m L_n] = (m-n) L_{m+n} + \delta_{n,-m} \frac{m\,(m^2-1)}{12}\, C \tag{1.2.7a}$$

$$[L_m C] = 0 \ . \tag{1.2.7b}$$

'1-dimensional central extension' means $\mathcal{V}$ has one extra basis vector C, which lies in the *centre* of $\mathcal{V}$ (i.e. $[xC] = 0$ for all $x \in \mathcal{V}$), and sending $C \to 0$ recovers $\mathcal{W}$ (i.e. takes (1.2.7a) to (1.2.6)). A common mistake in the physics literature is to regard C as a number: it is in fact a vector, though in many (but not all) representations it is mapped to a scalar multiple of the identity.

---

[6] In infinite dimensions, to avoid convergence complications, only finite linear combinations of basis vectors are generally permitted. Infinite linear combinations would involve taking some 'completion'.

The reason for the strange-looking (1.2.7a) is that we have little choice: $\mathcal{V}$ is the unique nontrivial 1-dimensional central extension of $\mathcal{W}$. The factor $\frac{1}{12}$ there is conventional but standard, and has to do with 'zeta-function regularisation' in string theory — i.e. the divergent sum $\sum_{n=1}^{\infty} n$ is 'reinterpreted' as $\zeta(-1) = \frac{-1}{12}$, where $\zeta(s) = \sum_{n=1}^{\infty} n^{-s}$ is the Riemann zeta function. Incidentally $\zeta(s)$ can be written as the product $\prod_p (1-p^{-s})^{-1}$ over all primes $p = 2, 3, 5, \ldots$ (try to see why); hence $\zeta(s)$ has a lot to do with primes, in particular their distribution. In fact the most famous unsolved problem in math today is the Riemann conjecture, which says that $\zeta(s) \neq 0$ whenever $\mathrm{Re}(s) \neq \frac{1}{2}$. One researcher recently described this conjecture as saying that the primes have music in them.

In CFT, L_0 is the energy operator. For example the partition function is given by $\mathcal{Z}(\tau) = \mathrm{Tr}_H(q^{L_0-c/24} q^{*\bar{L}_0-c/24})$ and the (normalised) character χ_a equals $\mathrm{Tr}_{H_a}(q^{L_0-c/24})$ for $q = e^{2\pi \mathrm{i}\tau}$. cI is the scalar multiple of the identity to which C gets sent; it has a physical interpretation [18] involving Casimir (vacuum) energy, which depends on space-time topology, and the strange shift by $c/24$ is due to an implicit mapping from the cylinder to the plane.

1.3. REPRESENTATIONS OF FINITE-DIMENSIONAL SIMPLE LIE ALGEBRAS

The representation theory of the simple Lie algebras[7] can perhaps be regarded as an enormous generalisation of trigonometry. For instance the facts that $\frac{\sin(nx)}{\sin(x)}$ can be written as a polynomial in $\cos(x)$ for any $n \in \mathbb{Z}$, and that

$$\frac{\sin(mx)\,\sin(nx)}{\sin(x)} = \sin((m+n)x) + \sin((m+n-2)x) + \cdots + \sin((m-n)x)$$

for any $m, n \in \mathbb{Z}_>$, are both easy special cases of the theory.

The classic example of an algebraic structure are the numbers, and they prejudice us into thinking that commutativity and associativity are the ideal. We have learned over the past couple of centuries that commutativity can often be dropped without losing depth and usefulness, but most interesting structures seem to obey some form of associativity. Moreover, true associativity (as opposed to e.g. anti-associativity) really simplifies the arithmetic. Given the happy 'accident' that the commutator $[x, y] := xy - yx$ in any associative algebra obeys anti-associativity, it would seem to be both tempting and natural to study the ways (if any) in which associative algebras $\mathfrak{A}$ can 'model' or *represent* a given Lie algebra. Precisely, we are looking for a map $\rho : \mathfrak{g} \to \mathfrak{A}$ which preserves the linear structure (i.e. ρ is a linear function), and which sends the bracket $[xy]$ in $\mathfrak{g}$ to the commutator $[\rho(x), \rho(y)]$ in $\mathfrak{A}$.

In practice groups (resp., algebras) often appear as symmetries (resp., infinitesimal generators of symmetries). These symmetries often act linearly. In other words, in practise the preferred associative algebras will usually be matrix algebras, and this is the usual form for a representation and the only kind we will consider. The *dimension* of these representations is the size of the matrices.

---

[7] See e.g. [25] for more details. Historically, representations of Lie algebras were considered even before representations of finite groups.

Finding all possible representations, even for the simple Lie algebras, is probably hopeless. However, it is possible to find all *finite-dimensional* representations of the simple Lie algebras, and the answer is easy to describe. Given a simple Lie algebra X_ℓ, there is a representation L_λ for each ℓ-tuple $\lambda = (\lambda_1, \ldots, \lambda_\ell)$ of nonnegative integers. λ is called a *highest-weight.* Moreover, we can take direct sums $\oplus_i L_{\lambda^{(i)}}$ of finitely many of these representations. The matrices in such a direct sum will be in block form. It turns out that, up to change-of-basis, this exhausts all finite-dimensional representations of X_ℓ.

It is common to replace 'representation ρ of $\mathfrak{g}$' with the equivalent notion of '$\mathfrak{g}$-module M' — i.e. we think of the matrices $\rho(x)$ as linear maps $M \to M$. A $\mathfrak{g}$*-module* is a vector space on which $\mathfrak{g}$ acts (on the left). Instead of considering the matrix $\rho(x)$, we consider 'products' xv (think of this as the matrix $\rho(x)$ times the column vector v) for $v \in M$. This product must be bilinear, and must obey $[xy]v = x(yv) - y(xv)$.

To get an idea of what L_λ looks like, consider A_1. Recall its generators e, f, h and relations (1.2.2b). Choose any $\lambda \in \mathbb{C}$. Define $x_0 \neq 0$ to formally obey $hx_0 = \lambda x_0$ and $ex_0 = 0$. Define inductively $x_{i+1} := fx_i$ for $i = 0, 1, \ldots$. Define M_λ to be the span of all x_i — we will see shortly that they are linearly independent (so M_λ is infinite-dimensional). M_λ is a module of A_1: the calculations $hx_{i+1} = hfx_i = ([hf] + fh)x_i = (-2f + fh)x_i$ and $ex_{i+1} = efx_i = ([ef] + fe)x_i = (h + fe)x_i$ show inductively that $hx_m = (\lambda - 2m)x_m$ and $ex_m = (\lambda - m + 1)m\, x_{m-1}$. From these the reader can show that the x_i are linearly independent. M_λ is called a *Verma module*; λ is called its highest-weight, and x_0 is called a highest-weight vector.

Now specialise to $\lambda = n \in \mathbb{Z}_\geq := \{0, 1, 2, \ldots\}$. Note that $ex_{n+1} = 0$ and $hx_{n+1} = (-n-2)x_{n+1}$. This means that, for these n, M_n contains a *submodule* with highest-weight vector x_{n+1}, isomorphic to M_{-n-2}. x_{n+1} is called a *null vector.* In other words, we could set $x_{n+1} := 0$ and still have an A_1-module. We would then get a *finite-dimensional* module which we'll call $L_n := M_n/M_{-n-2}$ (not to be confused with the Virasoro generator in (1.2.7)). Its basis is $\{x_0, x_1, \ldots, x_n\}$ and so it has dimension $n + 1$.

For example, take $n = 1$. Note that what we get in terms of the basis $\{x_0, x_1\}$ is the familiar representation $\mathrm{sl}_2(\mathbb{C})$ given in (1.2.5).

The situation for the other simple Lie algebras X_ℓ is similar.

It turns out to be hard to compare representations: ρ and ρ' could be equivalent (i.e. differ merely by a change-of-basis) but look very different. Or if we are given a representation, we may want to decompose it into the direct sum of some $L_{\lambda^{(i)}}$. When working with representations, it is often very useful to avoid much of the extraneous basis-dependent detail present in the function ρ. Finite group theory suggests how to do this: we should use *characters.* The character of an A_1-module M is given by Weyl: write M as a direct sum of eigenspaces $M(m)$ of h; then define

$$\mathrm{ch}_M(z) := \sum_m \dim\, M(m)\; e^{mz}\ , \tag{1.3.1}$$

for any $z \in \mathbb{C}$. The m are called *weights* and the $M(m)$ *weight-spaces.* For example, for

L_n the weights are $m = n, n-2, \ldots, -n$, the weight-spaces $L_n(m)$ are $\mathbb{C}\, x_{(n-m)/2}$, and

$$\mathrm{ch}_n(z) = \sum_{i=0}^{n} e^{(n-2i)z} = \frac{\sin((n+1)\, z)}{\sin(z)} \ . \tag{1.3.2}$$

Analogous formulas apply to any algebra X_ℓ: the character will then be a function of an ℓ-dimensional subspace $\mathfrak{h}$ called the *Cartan subalgebra*, spanned by all the h_i (see §2.7), so can be thought of as a complex-valued function of ℓ complex variables. The weights m will lie in the dual space to $\mathfrak{h}$ — i.e. are linear maps $\mathfrak{h} \to \mathbb{C}$ — so will have ℓ components. See for instance Figure 8 in [59]. Incidentally, ℓ is called the *rank* of X_ℓ.

Weyl's definition works: two representations are equivalent iff their characters are identical, and $M = \oplus_i L_{\lambda^{(i)}}$ iff $\mathrm{ch}_M(z) = \sum_i \mathrm{ch}_{\lambda^{(i)}}(z)$. It also is enormously simpler: e.g. the smallest nontrivial representation of E_8 is a map from $\mathbb{C}^{248}$ to the space of 248×248 matrices, while its character is a function $\mathbb{C}^8 \to \mathbb{C}$. But why is Weyl's definition natural? How did he come up with it?

To answer that question, we must remind ourselves of the characters of finite groups[8]. A representation of a finite group G is a structure-preserving map ρ (i.e. a group homomorphism) from G to matrices. The group's product becomes matrix product. In these notes we will be exclusively interested in group representations over $\mathbb{C}$. Two representations ρ, ρ' are called *equivalent* if there exists a matrix (change-of-basis) U such that $\rho'(g) = U\rho(g)U^{-1}$ for all g. The character ch_ρ is the map $G \to \mathbb{C}$ given by the trace: $\mathrm{ch}_\rho(g) = \mathrm{tr}(\rho(g))$. We see that equivalent representations will have the same character, because of the fundamental identity $\mathrm{tr}(AB) = \mathrm{tr}(BA)$. This identity also tells us that the character is a 'class function', i.e. $\mathrm{ch}_\rho(hgh^{-1}) = \mathrm{tr}(\rho(h)\, \rho(g)\, \rho(h)^{-1}) = \mathrm{ch}_\rho(g)$ so ch_ρ is constant on each 'conjugacy class'. Group characters are also enormously simpler than representations: e.g. the smallest nontrivial representation of the Monster $\mathbb{M}$ (see Part 2) consists of almost 10^{54} matrices, each of size 196883×196883, while its character consists of 194 complex numbers. Incidentally, finite group representations behave analogously to the representations of X_ℓ: the role of the modules L_λ is played by the irreducible representations ρ_i, and any finite-dimensional representation of G can be decomposed uniquely into a direct sum of various ρ_i. The difference is that there are only finitely many ρ_i — their number equals the number of conjugacy classes of G.

We can use this group intuition here. In particular, given any Lie algebra X_ℓ and representation ρ, we can think of the map $e^x \mapsto e^{\rho(x)}$ as a representation of a Lie group $G(X_\ell)$ corresponding to X_ℓ (the exponential e^A of a matrix is defined by the usual power series; it will always converge). The trace of the matrix $e^{\rho(x)}$ will be the *group* character value at $e^x \in G(X_\ell)$, so we'll define it to be the *algebra* character value at $x \in X_\ell$. Again, it suffices to consider only representatives of each conjugacy class of $G(X_\ell)$, because the character will be a class function. Now, almost every matrix is diagonalisable (since almost any $n \times n$ matrix has n distinct eigenvalues), and so it would seem we aren't losing much by restricting $x \in X_\ell$ to *diagonalisable* matrices. Hence we may take our conjugacy class representatives to be *diagonal* matrices $x \in X_\ell$, i.e. (for $X_\ell = A_1$) to $x = zh$ for $z \in \mathbb{C}$ (h is diagonal in the x_i basis of L_λ). So the algebra character can be chosen to be a function of z. Finally, the trace of $e^{\rho(x)} = e^{z\rho(h)}$ will be given by (1.3.1). This completes the motivation for Weyl's character formula.

---

[8] Surprisingly, what we now call the characters of group representations were invented almost a decade before group representations were.

There is one other important observation we can make. Different diagonal matrices can belong to the same conjugacy class. For instance,

$$\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} a & 0 \\ 0 & b \end{pmatrix} \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}^{-1} = \begin{pmatrix} b & 0 \\ 0 & a \end{pmatrix} ,$$

so e^{zh} and e^{-zh} lie in the same $G(A_1) = \mathrm{SL}_2(\mathbb{C})$ conjugacy class. Hence $\mathrm{ch}_M(z) = \mathrm{ch}_M(-z)$. This symmetry $z \mapsto -z$ belongs to the *Weyl group* for A_1. Each X_ℓ has similar symmetries, and the Weyl group plays an important role in the whole theory, sort of analogous to the modular group for modular functions we'll discuss in §2.3.

Weyl found a generalisation of the right-side of (1.3.2), valid for all X_ℓ. The character of L_λ can be written as a fraction (2.8.1): the numerator will be a alternating sum over the Weyl group, and the denominator will be a product over 'positive roots'. This formula and its generalisations have profound consequences, as we'll see in §2.8.

Incidentally, the trigonometric identities given at the beginning of this section are the tensor product formula of representations (interpreted as the product and sum of characters), and the fact that an arbitrary character can be written as a polynomial in the fundamental characters, both specialised to A_1 (see (1.3.2) for the A_1 characters).

1.4. AFFINE ALGEBRAS AND THE KAC-PETERSON MATRICES

The theory of nontwisted affine Kac-Moody algebras (usually called *affine algebras* or *current algebras*) is extremely analogous to that of the finite-dimensional simple Lie algebras. Nothing infinite-dimensional tries harder to be finite-dimensional than affine algebras. Standard references for the following material are [38,41,24].

Let X_ℓ be any simple finite-dimensional Lie algebra. The affine algebra $X_\ell^{(1)}$ is essentially the *loop algebra* $\mathcal{L}(X_\ell)$, defined to be all possible 'Laurent polynomials' $\sum_{n\in\mathbb{Z}} a_n t^n$ where each $a_n \in X_\ell$ and all but finitely many $a_n = 0$. t here is an indeterminant. The bracket in $\mathcal{L}(X_\ell)$ is the obvious one: e.g. $[at^n, bt^m] = [ab]t^{n+m}$. Geometrically, $\mathcal{L}(X_\ell)$ is the Lie algebra of polynomial maps $S^1 \to X_\ell$ — hence the name (for that realisation, think of $t = e^{2\pi i\theta}$). Hence there are many generalisations of the loop algebra (e.g. any manifold in place of S^1 will do), closely related ones called *toroidal algebras* being the Lie algebra of maps $S^1 \times \cdots \times S^1 \to X_\ell$. But the loop algebra is simplest and best understood, and the only one we'll consider. Note that $\mathcal{L}(X_\ell)$ is infinite-dimensional. Its Lie groups are the *loop groups*, consisting of all loops $S^1 \to G(X_\ell)$ in a Lie group for X_ℓ.

We saw S^1 before, in the discussion of the Witt algebra. Thus the Virasoro and affine algebras should be related. In fact, the Virasoro algebra acts on the affine algebras as 'derivations', and this connection plays an important technical role in the theory.

$X_\ell^{(1)}$ is in the same relation to the loop algebra, that the Virasoro $\mathcal{V}$ is to the Witt $\mathcal{W}$. Namely, it is its (unique nontrivial 1-dimensional) central extension — see e.g. (7.7.1) of [38] for the analogue of (1.2.7a) here. In addition, for more technical reasons, a further (noncentral) 1-dimensional extension is usually made: the derivation $t\frac{d}{dt}$ is included (see footnote 33). $X_\ell^{(1)}$ is the simplest of the infinite-dimensional Kac-Moody algebras. The superscript '(1)' denotes the fact that the loop algebra was twisted by an order-1 automorphism — i.e. that it is untwisted. It is called 'affine' because of its Weyl group, as we shall see.

Central extensions are a common theme in today's infinite-dimensional Lie theory[9]. Their *raison d'être* is always the same: a richer supply of representations. For example, $\mathcal{W}$ has several representations, but no nontrivial one is an 'irreducible unitary positive-energy representation' — the kind of greatest interest in math phys. On the other hand, its central extension $\mathcal{V}$ has a rich supply of those representations (e.g. there's one for each choice of $c > 1, h > 0$, namely the Verma module $V_{c,h}$ corresponding to $L_0x_0 = hx_0, Cx_0 = cx_0$). At the level of groups, central extensions allow *projective* representations (i.e. representations up to a scalar factor) to become true representations. Projective representations (hence central extensions) appear naturally in QFT because a quantum state vector $|v\rangle$ is physically indistinguishable from any nonzero scalar multiple $\alpha|v\rangle$.

All of the quantities associated to X_ℓ have an analogue here: Dynkin diagram, Weyl group, weights,... For instance, the affine Dynkin diagram is obtained from the Dynkin diagram for X_ℓ by adding one node. See for example Figure 9 of [59]. The extra node is always labelled by a '0'. The Cartan subalgebra $\mathfrak{h}$ here will be $(\ell+2)$-dimensional. Many of these details will be discussed in more detail in §2.7 below.

The construction of $X_\ell^{(1)}$ is so trivial that it seems surprising anything interesting and new can happen here. But a certain 'miracle' happens...

No interesting representation of $X_\ell^{(1)}$ is finite-dimensional. The analogue for $X_\ell^{(1)}$ of the finite-dimensional representations of X_ℓ are called the *integrable highest-weight representations*, and will be denoted L_λ. The *highest-weight* λ here will be an $(\ell+1)$-tuple $(\lambda_0, \lambda_1, \dots, \lambda_\ell)$, $\lambda_i \in \mathbb{Z}_\geq$ (strictly speaking, it will be an $(\ell+2)$-tuple, but the extra component is not important and is usually ignored). As for X_ℓ, the highest-weights can be thought of as the assignment of a nonnegative integer to each node of the Dynkin diagram. The construction of L_λ is as in the finite-dimensional case. They are called *integrable* because they are precisely those highest-weight representations which can be 'integrated' to a projective representation of the corresponding loop group, and hence a representation of a central extension of the loop group.

We define the character χ_λ as in (1.3.1), though now the weights m will be $(\ell+2)$-tuples, and there will be infinitely many of them. χ_λ will be a complex-valued function of $\ell+2$ complex variables $(\vec{z}, \tau, u)$ (see (1.4.1a) below). It can be written as an alternating sum over the Weyl group W, over a 'nice' denominator. The difference here is that W is now infinite.

Perhaps most of the interest in affine algebras can be traced to the 'miracle' that their Weyl groups are a semidirect product $Q^\vee \rtimes \overline{W}$ of translations in a lattice $\mathbb{Q}^\vee$ (the ℓ-dimensional 'co-root lattice' of X_ℓ — see §1.6) with the (finite) Weyl group $\overline{W}$ of X_ℓ.

---

[9] Incidentally the *finite-dimensional* simple Lie algebras do not have nontrivial central extensions.

See Figure 10 of [59] for the Weyl group of $A_2^{(1)}$. 'Semidirect product'[10] means that any element of W can be written uniquely as (t, w) for some translation t and some $w \in \overline{W}$, and $(t, w) \circ (t', w') = (\text{stuff}, w \circ w')$.

One thing this implies is that χ_λ will be of the form 'theta function'/denominator. Theta functions are classically-studied modular forms (we will discuss these terms in §2.3), and thus the modular group $\mathrm{SL}_2(\mathbb{Z})$ will make an appearance! To make this more precise, consider the highest-weight $\lambda = (\lambda_0, \lambda_1)$ of $A_1^{(1)}$, and write $k = \lambda_0 + \lambda_1$. Then

$$\chi_\lambda = \frac{\Theta^{(k+2)}_{\lambda_1+1} - \Theta^{(k+2)}_{-\lambda_1-1}}{\Theta^{(2)}_1 - \Theta^{(2)}_{-1}} \tag{1.4.1a}$$

where these functions all depend on 3 complex variables z, τ, u, and

$$\Theta^{(n)}_m(z, \tau, u) := e^{-2\pi i n u} \sum_{\ell \in \mathbb{Z} + \frac{m}{2n}} \exp[\pi i n \tau \ell^2 - 2\sqrt{2}\pi i n \ell z] \ . \tag{1.4.1b}$$

In (1.4.1a) we can see the alternating sum over the Weyl group of A_1 in the numerator (and denominator, since we've used the $A_1^{(1)}$ denominator identity in writing (1.4.1a)). For general $X_\ell^{(1)}$, the denominator will always be independent of λ, and the theta function (1.4.1b) will become a multidimensional one involving a sum over $Q^\vee$ shifted by some weight and appropriately rescaled. The (co-)root lattice of A_1 is $\sqrt{2}\mathbb{Z}$. The key variable in (1.4.1a) is the modular one τ, which will lie in the upper half complex plane $\mathcal{H}$ (in order to have convergence). In the applications to CFT, the other variables are often set to 0.

The number k introduced in (1.4.1a) plays an important role in the general theory. In the representation L_λ, the central term C will get sent to some multiple of the identity — the multiplier is labelled k and is called the *level* of the representation. For any $X_\ell^{(1)}$ there is a simple formula expressing the level k in terms of the highest-weight λ; e.g. for $A_\ell^{(1)}$ and $C_\ell^{(1)}$ it is given by $k = \lambda_0 + \lambda_1 + \cdots + \lambda_\ell$. Write P_+^k for the (finite) set of level k highest-weights (so the size of P_+^k for $A_\ell^{(1)}$ is $\binom{k+\ell}{\ell}$). An important weight in P_+^k is $(k, 0, \ldots, 0)$. We will denote this '0'. In RCFT it corresponds to the vacuum.

The modular group $\mathrm{SL}_2(\mathbb{Z})$ acts on the Cartan subalgebra $\mathfrak{h}$ of $X_\ell^{(1)}$ in the following way:

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} (\vec{z}, \tau, u) = (\frac{\vec{z}}{c\tau + d}, \frac{a\tau + b}{c\tau + d}, u - \frac{c\,\vec{z}\cdot\vec{z}}{2(c\tau + d)})$$

Under this action, the characters χ_λ also transform nicely: in particular we find for any level k weight λ

$$\chi_\lambda(\frac{\vec{z}}{\tau}, \frac{-1}{\tau}, u - \frac{\vec{z}\cdot\vec{z}}{2\tau}) = \sum_{\mu \in P_+^k} S_{\lambda\mu}\, \chi_\mu(\vec{z}, \tau, u) \tag{1.4.2a}$$

$$\chi_\lambda(\vec{z}, \tau + 1, u) = \sum_{\mu \in P_+^k} T_{\lambda\mu}\, \chi_\mu(\vec{z}, \tau, u) \tag{1.4.2b}$$

---

[10] This is also discussed briefly in section 2.2.

where S and T are complex matrices called the *Kac-Peterson matrices*. S will always be symmetric and unitary, and has many remarkable properties as we shall see. Its entries are related to Lie group characters at elements of finite order (see (1.4.5) below). T is diagonal and unitary; its entries are related to the eigenvalues of the quadratic Casimir.

For example, consider $A_1^{(1)}$ at level k. Then S and T will be $(k+1)\times(k+1)$ matrices given by

$$S_{\lambda\mu}=\sqrt{\frac{2}{k+2}}\,\sin(\pi\,\frac{(\lambda_1+1)(\mu_1+1)}{k+2})\ ,\qquad T_{\lambda\mu}=\exp[\pi\mathrm{i}\,\frac{(\lambda_1+1)^2}{2(k+2)}-\frac{\pi\mathrm{i}}{4}]\,\delta_{\lambda,\mu}\ . \tag{1.4.3}$$

One important place S appears is the famous *Verlinde formula*

$$N_{\lambda\mu}^{\nu}=\sum_{\kappa\in P_+^k}\frac{S_{\lambda\kappa}\,S_{\mu\kappa}\,S_{\nu\kappa}^*}{S_{0,\kappa}} \tag{1.4.4}$$

for the fusion coefficients $N_{\lambda\mu}^{\nu}$ of the corresponding RCFT. We will investigate some consequences of this formula in a later section. The fusion coefficients for the affine algebras are well-understood; see e.g. Section 4 of [59] for their interpretation (usually called the Kac-Walton formula) as 'folded tensor product coefficients'.

We will see in §1.7 that symmetries of the extended Dynkin diagram have consequences for S and T (simple-currents, charge-conjugation). There is a 'Galois action' on S which we will discuss in §1.8. There is a strange property of S and T called *rank-level duality* (see e.g. [45]): the matrices for $A_\ell^{(1)}$ at level k are closely related to those of $A_{k-1}^{(1)}$ at level $\ell+1$, and similar statements hold for $B_\ell^{(1)}$, $C_\ell^{(1)}$ and $D_\ell^{(1)}$. Another reason S is mathematically interesting is the formula

$$\frac{S_{\lambda\mu}}{S_{0\mu}}=\mathrm{ch}_{\bar\lambda}(-2\pi\mathrm{i}\,\frac{\overline{\mu+\rho}}{k+h^\vee})\ . \tag{1.4.5}$$

The right-side is a character of X_ℓ, and $\bar\lambda=(\lambda_1,\dots,\lambda_\ell)$ means ignore the extended node. ρ is the 'Weyl vector' $(1,1,\dots,1)$ and $h^\vee$ is called the *dual Coxeter number* and is the level of ρ. For $A_\ell^{(1)}$, $h^\vee=\ell+1$. Of course the right-side can also be regarded as a character for a Lie group associated to X_ℓ, in which case the argument would have to be exponentiated and would correspond to an element of finite order in the group. These numbers (1.4.5) have been studied by many people (most extensively by Pianzola) and have some nice properties. For instance Moody-Patera (1984) have argued that exploiting them leads to some quick algorithms for computing e.g. tensor product coefficients. Kac [37] found a curious application for them: a Lie theoretic proof of 'quadratic reciprocity'!

Quadratic reciprocity is one of the gems of classical number theory. It tells us that the equations

$$\begin{aligned}x^2&\equiv a\ (\mathrm{mod}\ b)\\ y^2&\equiv b\ (\mathrm{mod}\ a)\end{aligned}$$

are related; more precisely, for fixed a and b (for simplicity take them to both be primes $\neq 2$) the questions of whether there is a solution x to the first equation and a solution y to the second, are related. They will both have the same yes or no answer, unless $a \equiv b \equiv 3 \pmod 4$, in which case they will have opposite answers. E.g. take $a = 23$ and $b = 3$, then we know the first equation does not have a solution (since $a \equiv 2 \pmod 3$ and $x^2 \equiv 2$ doesn't have a solution mod 3), and hence the second equation must have a solution (indeed, $y = 7$ works). There are now many proofs for quadratic reciprocity, and Kac used Lie characters at elements of finite order to find another one.

What is interesting here is that Kac's proof uses only certain special weights for A_ℓ. The natural question is: is it possible to find any generalisations of quadratic reciprocity using other weights and algebras? Many generalisations of quadratic reciprocity are known; will generalising Kac's argument recover them, or will they perhaps yield new reciprocity laws? It seems no one knows.

The relation (1.4.5) is important because it connects finite-dimensional Lie data with infinite-dimensional Lie data. The 'conceptual arrow' can be exploited both ways: in the generalisations of the arguments of §1.9 to other algebras, (1.4.5) allows us to use our extensive knowledge of finite-dimensional algebras to squeeze out some information in the affine setting; but also it is possible to use the richer symmetries of the affine data to see 'hidden' symmetries in finite-dimensional data. For example it can be used (Gannon-Walton 1995) to find a sort of Galois symmetry of dominant weight multiplicities in X_ℓ, which would be difficult or impossible to anticipate without (1.4.5).

1.5. The classification of physical invariants

We are interested in the following classification problem. Choose any affine algebra $X_\ell^{(1)}$ and level $k \in \mathbb{Z}_\geq$. Find all matrices $M = (M_{\lambda\mu})_{\lambda,\mu \in P_+^k}$ such that

(P1) $MS = SM$ and $MT = TM$, where S, T are the Kac-Peterson matrices (1.4.2);
(P2) each entry $M_{\lambda\mu} \in \mathbb{Z}_\geq$;
(P3) $M_{00} = 1$.

Any such M, or equivalently the corresponding partition function $\mathcal{Z} = \sum_{\lambda,\mu} M_{\lambda\mu}\chi_\lambda\chi_\mu^*$, is called a *physical invariant*.

The first and most important classification of physical invariants was the Cappelli-Itzykson-Zuber A-D-E classification for $A_1^{(1)}$ at all levels k [8]. We will give their result shortly. This implies for instance the minimal model RCFT classification, as well as the $N = 1$ super(symmetric)conformal minimal models. The other classifications of comparable magnitude are $A_2^{(1)}$ for all k; $A_\ell^{(1)}$, $B_\ell^{(1)}$ and $D_\ell^{(1)}$ for all $k \leq 3$; $(A_1 \oplus A_1)^{(1)}$ for all levels (k_1, k_2); and $(u(1) \oplus \cdots \oplus u(1))^{(1)}$ for all (matrix-valued) levels k. See e.g. [29] for references. The most difficult of these classifications is for $A_2^{(1)}$, done by Gannon (1994).

In other words, very little in this direction has been accomplished in the 15 or so years this problem has existed. But this is not really a good measure of progress. The effort instead has been directed primarily towards the full classification; most of these partial results are merely easy spin-offs from that more serious and ambitious assault.

The proof in [8] was very complicated and followed the following lines. First, an explicit basis was found for the vector space (called the 'commutant') of all matrices obeying (P1). Then (P2) and (P3) were imposed. Unfortunately their proof was long and formidable. Others tried to apply their approach to $A_2^{(1)}$, but without success. The eventual proof for $A_2^{(1)}$ was completely independent of the [8] argument, and exploited more of the structure implicit in the problem. As the $A_2^{(1)}$ argument became more refined, it became the model for the general assault. In §1.9 we sketch this new approach.

From this more general perspective, of these completed classifications only the level 2 $B_\ell^{(1)}$ and $D_\ell^{(1)}$ ones will have any lasting value (the orthogonal algebras at level 2 behave very peculiarly, possess large numbers of exceptional physical invariants, and must be treated separately). The others behave more generically and will fall out as special cases once the more general classifications are concluded. Other classifications which should be straightforward with our present understanding are $C_2^{(1)}$ at all k; $G_2^{(1)}$ at all k; and $B_\ell^{(1)}$ and $D_\ell^{(1)}$ at $k = 4$. The $C_2^{(1)}$ should be easiest and would imply the $C_\ell^{(1)}$ level 2, as well as the $B_\ell^{(1)}$ and $D_\ell^{(1)}$ level 5, classifications. A very safe conjecture is that the only *exceptional* physical invariants (we define this term in §1.7) for $C_2^{(1)}$ occur at $k = 3, 7, 8, 12$ — this is known to be true for all $k \leq 500$. $G_2^{(1)}$ would be more difficult but also much more valuable; its only known exceptionals occur at $k = 3, 4$, and these are the only exceptionals for $k \leq 500$, and a very safe conjecture is that there are no other $G_2^{(1)}$ exceptionals. $B_\ell^{(1)}$ and $D_\ell^{(1)}$ at level 4 will also be more difficult, but also would be valuable; less is understood about its physical invariants and there is a good chance new exceptionals exist there.

The most surprising thing about the known physical invariant classifications is that there so few surprises: almost every physical invariant is 'generic'. We will see that the symmetries of the extended Dynkin diagram give rise to general families of physical invariants. We will call any physical invariants which do not arise in these generic ways (i.e. using what are called simple-currents or conjugations), *exceptional*. Many exceptionals have been found, and now we are almost at the point where we can safely conjecture the complete list of physical invariants for $X_\ell^{(1)}$ at any k, for X_ℓ a simple algebra.

Unfortunately the classification for semi-simple algebras $X_{\ell_1} \oplus \cdots \oplus X_{\ell_s}$ does not reduce to the one for simple ones. In fact, *any explicit classification of the physical invariants for $X^{(1)}$, for all semi-simple X, would easily be one of the greatest accomplishments in the history of math,* for it would include as a small part such monumental things as an explicit classification of all positive-definite integral lattices. Thus we unfortunately cannot expect an *explicit* classification for the *semi*-simple algebras.

To make this discussion more concrete and explicit, consider $A_1^{(1)}$. For convenience drop λ_0, so $P_+^k = \{0, 1, \ldots, k\}$. Write J for the permutation (called a simple-current) $Ja := k - a$. Then the complete list of physical invariants for $A_1^{(1)}$ is

$$\mathcal{A}_{k+1} = \sum_{a=0}^{k} |\chi_a|^2 \ , \qquad \text{for all } k \geq 1$$

$$\mathcal{D}_{\frac{k}{2}+2} = \sum_{a=0}^{k} \chi_a \, \chi_{J^a a}^* \ , \qquad \text{whenever } \frac{k}{2} \text{ is odd}$$

$$\begin{aligned}
\mathcal{D}_{\frac{k}{2}+2} &= |\chi_0+\chi_{J0}|^2+|\chi_2+\chi_{J2}|^2+\cdots+2|\chi_{\frac{k}{2}}|^2\ , && \text{whenever } \frac{k}{2} \text{ is even}\\
\mathcal{E}_6 &= |\chi_0+\chi_6|^2+|\chi_3+\chi_7|^2+|\chi_4+\chi_{10}|^2\ , && \text{for } k=10\\
\mathcal{E}_7 &= |\chi_0+\chi_{16}|^2+|\chi_4+\chi_{12}|^2+|\chi_6+\chi_{10}|^2\\
&\quad +\chi_8\,(\chi_2+\chi_{14})^*+(\chi_2+\chi_{14})\,\chi_8^*+|\chi_8|^2\ , && \text{for } k=16\\
\mathcal{E}_8 &= |\chi_0+\chi_{10}+\chi_{18}+\chi_{28}|^2+|\chi_6+\chi_{12}+\chi_{16}+\chi_{22}|^2\ , && \text{for } k=28\ .
\end{aligned}$$

The physical invariants $\mathcal{A}_n$ and $\mathcal{D}_n$ are generic, corresponding respectively to the order 1 (i.e. identity) and order 2 (i.e. the simple-current J) Dynkin diagram symmetries, as we shall see in §1.7. Physically, they are the partition functions of WZW models on $\mathrm{SU}_2(\mathbb{C})$ and $\mathrm{SO}_3(\mathbb{R})$ group manifolds, resp. The exceptionals $\mathcal{E}_6$ and $\mathcal{E}_8$ are best interpreted as due to the $C_{2,1}\supset A_{1,10}$ and $G_{2,1}\supset A_{1,28}$ conformal embeddings (see §1.7; standard notation is to write '$X_{\ell,k}$' for '$X_\ell^{(1)}$ and level k'). The $\mathcal{E}_7$ exceptional is harder to interpret, but can be thought of as the first in an infinite series of exceptionals involving rank-level duality and D_4 triality.

Around Christmas 1985, Zuber wrote Kac about the $A_1^{(1)}$ physical invariant problem, and mentioned the physical invariants he and Itzykson knew at that point (what we now call $\mathcal{A}_\star$ and $\mathcal{D}_{even}$). A few weeks later, Kac wrote back saying he found one more invariant, and jokingly pointed out that it must be indeed quite exceptional as the exponents of E_6 appeared in it. "I must confess that I didn't pay much attention to that last remark (I hardly knew what Coxeter exponents were, at the time!)" [63]. By spring 1986, Cappelli arrived in Paris and got things moving again; together Cappelli-Itzykson-Zuber found $\mathcal{E}_7$, $\mathcal{D}_{odd}$, and then $\mathcal{E}_8$, and struggled to find more. "And it is only in August [1986], during a conversation with Pasquier, in which he was showing me his construction of lattice models based on Dynkin diagrams, that I suddenly remembered this cryptic but crucial! observation of Victor, rushed to the library to find a list of the exponents of the other algebras... and found with the delight that you can imagine that they were matching our list" [63]. Thus the A-D-E pattern to these physical invariants was discovered.

1.6. THE A-D-E META-PATTERN

Before we discuss *meta-patterns* in math, let's introduce the notion of *lattice*[11], a simple geometric structure we'll keep returning to in these notes. The standard reference for lattice theory is [13].

Consider the real vector space $\mathbb{R}^{m,n}$: its vectors look like $\vec{x}=(\vec{x}_+;\vec{x}_-)$ where $\vec{x}_+$ and $\vec{x}_-$ are m- and n-component vectors respectively, and dot products are given by $\vec{x}\cdot\vec{y}=\vec{x}_+\cdot\vec{y}_+-\vec{x}_-\cdot\vec{y}_-$. The dot products $\vec{x}_\pm\cdot\vec{y}_\pm$ are given by the usual product and sum of components. For example, the familiar Euclidean (positive-definite) space is $\mathbb{R}^n=\mathbb{R}^{n,0}$, while Minkowski space is $\mathbb{R}^{3,1}$.

---

[11] There are many words in math which have several incompatible meanings. For example, there are *vector* fields and *number* fields, and modular *forms* and modular *representations*. 'Lattice' is another of these words. Aside from the geometric meaning we will use, it also refers to a 'partially ordered set'.

Now choose any basis $B = \{\vec{x}_1, \ldots, \vec{x}_{m+n}\}$ in $\mathbb{R}^{m,n}$. So $\mathbb{R}^{m,n} = \mathbb{R}\vec{x}_1 + \cdots + \mathbb{R}\vec{x}_{m+n}$. Define the set $\Lambda(B) := \mathbb{Z}\vec{x}_1 + \cdots + \mathbb{Z}\vec{x}_{m+n}$. This is a *lattice*, and all lattices can be formed in this way[12]. So a lattice is discrete and is closed under sums and integer multiples. For example, $\mathbb{Z}^{m,n}$ is a lattice (take the standard basis in $\mathbb{R}^{m,n}$). A more interesting lattice is the hexagonal lattice (also called A_2), given by the basis $B = \{(\frac{\sqrt{2}}{2}, \frac{\sqrt{6}}{2}), (\sqrt{2}, 0)\}$ of $\mathbb{R}^2$ — try to plot several points. If you wanted to slide a bunch of coins on a table together as tightly as possible, their centres would form this hexagonal lattice. Another important lattice is $II_{1,1} \subset \mathbb{R}^{1,1}$, given by $B = \{(\frac{1}{\sqrt{2}}; \frac{1}{\sqrt{2}}), (\frac{1}{\sqrt{2}}; \frac{-1}{\sqrt{2}})\}$; equivalently it can be thought of as the set of all pairs $(a, b) \in \mathbb{Z}^2$ with dot product

$$(a, b) \cdot (c, d) = ad + bc\ . \tag{1.6.1}$$

It is important to note that different choices of basis may or may not result in a different lattice. For a trivial example, consider $B = \{1\}$ and $B' = \{-1\}$ in $\mathbb{R} = \mathbb{R}^{1,0}$: they both give the lattice $\mathbb{Z} = \mathbb{Z}^{1,0}$. Two lattices are called *equivalent* if they only differ by a change-of-basis. E.g. $B = \{(\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}), (\frac{1}{\sqrt{2}}, \frac{-1}{\sqrt{2}})\}$ in $\mathbb{R}^2$ yields a lattice equivalent to $\mathbb{Z}^2$.

The *dimension* of the lattice is $m + n$. The lattice is called *positive-definite* if it lies in some $\mathbb{R}^m$ (i.e. $n = 0$). The lattice is called *integral* if all dot products $\vec{x} \cdot \vec{y}$ are integers, for $\vec{x}, \vec{y} \in \Lambda$. A lattice Λ is called *even* if it is integral and in addition all norms $\vec{x} \cdot \vec{x}$ are *even* integers. For example, $\mathbb{Z}^{m,n}$ is integral but not even, while A_2 and $II_{1,1}$ are even. The *dual* Λ^* of a lattice Λ consists of all vectors $\vec{x} \in \mathbb{R}^{m,n}$ such that $\vec{x} \cdot \Lambda \subset \mathbb{Z}$. So a lattice is integral iff $\Lambda \subseteq \Lambda^*$. A lattice is called *self-dual* if $\Lambda = \Lambda^*$. $\mathbb{Z}^{m,n}$ and $II_{1,1}$ are self-dual but A_2 is not.

There are lots of ‘meta-patterns’ in math, i.e. collections of seemingly different problems which have similar answers. Once one of these meta-patterns is identified it is always helpful to understand what is responsible for it. For example, while I was writing up my PhD thesis I noticed in several places the numbers 1, 2, 3, 4, and 6. For instance $\cos(2\pi r) \in \mathbb{Q}$ for $r \in \mathbb{Q}$ iff the denominator of r is 1, 2, 3, 4, or 6. This pattern was easy to explain: they are precisely those positive integers n with Euler totient $\phi(n) \leq 2$, i.e. there are at most 2 positive numbers less than n coprime[13] to n. The other incidences of these numbers can usually be reduced to this $\phi(n) \leq 2$ property (e.g. the dimension of the number field $\mathbb{Q}[\cos(2\pi\frac{a}{b})]$ (see §1.8) considered as a vector space over $\mathbb{Q}$ will be $\phi(b)/2$).

A more interesting meta-pattern involves the number 24 and its divisors. One sees 24 wherever modular forms naturally appear. For instance, we see it in the critical dimensions in string theory: 24 + 2 and 8 + 2. Another example: the dimensions of even self-dual positive-definite lattices must be a multiple of 8 (e.g. the E_8 root lattice defined shortly has dimension 8, while the Leech lattice discussed in §2.4 has dimension 24). The meta-pattern 24 is also understood: the fundamental problem for which it is the answer is the following one. Fix n, and consider the congruence $x^2 \equiv 1 \pmod{n}$. Certainly in order to have a chance of satisfying this, x and n must be coprime. The extreme situation is when *every* number x coprime to n satisfies this congruence:

---

[12] In most presentations a lattice is permitted to have smaller dimension than its ambient space, however that freedom gains no real generality.

[13] We say m,n are *coprime* if any prime p which divides m does not divide n, and vice versa.

$$\gcd(x,n)=1 \qquad \Longleftrightarrow \qquad x^2 \equiv 1 \pmod{n}\ . \tag{1.6.2}$$

The reader can try to verify the following simple fact: n obeys this extreme situation (1.6.2) iff n divides 24.

What does this congruence property have to do with these other occurrences of 24? Let Λ be an even self-dual positive-definite lattice of dimension n. Then an elementary argument shows that there will exist an n-tuple $\vec{a}=(a_1,\ldots,a_n)$ of odd integers with the property that 8 must divide $\vec{a}\cdot\vec{a}=\sum_i a_i^2$. But $a_i^2 \equiv 1 \pmod 8$, and so we get $8|n$.

A much deeper and still not-completely-understood meta-pattern is called A-D-E (see [1] for a discussion and examples). The name comes from the so-called *simply-laced algebras*, i.e. the simple finite-dimensional Lie algebras whose Dynkin diagrams — see Figure 6 in [59] — contain only single edges (i.e. no arrows). These are the $A_\star$- and $D_\star$-series, along with the E_6, E_7 and E_8 exceptionals. The claim is that many other problems, which don't seem to have anything directly in common with simple Lie algebras, have a solution which falls into this A-D-E pattern (for an object to be meaningfully labelled X_ℓ, some of the data associated to the algebra X_ℓ should reappear in some form in that object). Let's look at some examples.

Consider even positive-definite lattices Λ. The smallest possible nonzero norm in Λ will be 2, and the vectors of norm 2 are special and are called *roots*. The reason they are special is that reflecting through them will always be an automorphism of Λ. That is, the reflection $\vec{u}\mapsto\vec{u}-2\frac{\vec{u}\cdot\vec{\alpha}}{\vec{\alpha}\cdot\vec{\alpha}}\,\vec{\alpha}$ through $\vec{\alpha}\neq\vec{0}$ won't in general map Λ to itself, unless $\vec{\alpha}$ is a root of Λ. It is important in lattice theory to know the lattices which are spanned by their roots; it turns out these are precisely the orthogonal direct sums of lattices called A_n, D_n, and E_6, E_7 and E_8. They carry those names for a number of reasons. For example, the lattice called X_n will have a basis $\{\vec{\alpha}_1,\ldots,\vec{\alpha}_n\}$ with the property that the matrix $A_{ij}:=\vec{\alpha}_i\cdot\vec{\alpha}_j$ is the Cartan matrix (see §2.7) for the Lie algebra X_n! Also, the reflection group generated by reflections in the roots of the lattice X_n will be isomorphic to the Weyl group of the Lie algebra X_n. Finally, to any simple Lie algebra there is canonically associated a lattice called the root lattice; for the simply-laced algebras, these will equal the corresponding lattice of the same name. Incidentally, the root lattices for the non-simply-laced simple algebras will (up to rescalings) be direct sums of the simply-laced root lattices.

We have already met the A_2 lattice: it is the densest packing of circles in the plane. It has long been believed that the obvious pyramidal way to pack oranges is also the densest possible way — the centres of the oranges form the A_3 root lattice. A controversial proof for this famous conjecture has been offered by W.-Y. Hsiang in 1991; in 1998 a new proof by Hale *et al* has been proposed. The densest known packings in dimensions 4,5,6,7,8 are D_4, D_5, E_6, E_7, E_8, resp. E_8 is the smallest even self-dual positive-definite lattice.

A famous A-D-E example is called the McKay[14] correspondence. Consider any finite subgroup G of the Lie group $\mathrm{SU}_2(\mathbb{C})$ (i.e. the 2×2 unitary matrices with determinant 1). For example, there is the cyclic group $\mathbb{Z}_n$ of n elements generated by the matrix

$$M_n=\begin{pmatrix}\exp[2\pi\mathrm{i}/n] & 0\\ 0 & \exp[-2\pi\mathrm{i}/n]\end{pmatrix}$$

---

[14] He is the same John McKay we will celebrate in section 2.1.

Let R_i be the irreducible representations of G. For instance, for $\mathbb{Z}_n$, there are precisely n of these, all 1-dimensional, given by sending the generator M_n to $\exp[2k\pi\mathrm{i}/n]$ for each $k = 1, 2, \ldots, n$. Now consider the tensor product $G \otimes R_i$, where we interpret $G \subset \mathrm{SU}_2(\mathbb{C})$ here as a 2-dimensional representation. We can decompose that product into a direct sum $\oplus_j m_{ij} R_j$ of irreducibles (the m_{ij} here are multiplicities). Now create a graph with one node for each R_i, and with the ith and jth nodes ($i \neq j$) connected with precisely m_{ij} directed edges $i \to j$. If $m_{ij} = m_{ji}$, we agree to erase the double arrows from the m_{ij} edges. Then McKay observed that the graph of any G will be a distinct extended Dynkin diagram of A-D-E type! For instance, the cyclic group with n elements corresponds to the extended graph of A_{n-1}.

How was McKay led to his remarkable correspondence? He knew that the sum of the 'marks' $a_i = 1, 2, 3, 4, 5, 6, 4, 2, 3$ associated to each node of the extended E_8 Dynkin diagram equaled 30, the Coxeter number of E_8. So what did their *squares* add to? 120, which he recognised as the cardinality of one of the exceptional finite subgroups of $\mathrm{SU}_2(\mathbb{C})$, and that got him thinking...

Another famous example of A-D-E, due to Arnol'd, are the 'simple critical points' of smooth complex-valued functions f, on e.g. $\mathbb{C}^3$. For example, both $x^2 + y^2 + z^{n+1}$ and $x^2 + y^3 + z^5$ have singularities at $(0, 0, 0)$ (i.e. their first partial derivatives all vanish there), and they are assigned to A_n and E_8, respectively. The $\mathrm{SU}_2(\mathbb{C})$ subgroups can be related to singularities as follows. The group $\mathrm{SU}_2(\mathbb{C})$ acts on $\mathbb{C}^2$ in the obvious way (matrix multiplication). If G is a discrete subgroup, then consider the (ring of) polynomials in 2 variables w_1, w_2 invariant under G. It turns out it will have 3 generators $x(w_1, w_2)$, $y(w_1, w_2)$, $z(w_1, w_2)$, which are connected by 1 polynomial relation (syzygy). For instance, take G to be the cyclic group $\mathbb{Z}_n$, then we're interested in polynomials $p(w_1, w_2)$ invariant under $w_1 \mapsto \exp[2\pi\mathrm{i}/n]w_1$, $w_2 \mapsto \exp[-2\pi\mathrm{i}/n]w_2$. Any such invariant $p(w_1, w_2)$ is clearly generated by (i.e. can be written as a polynomial in) $w_1 w_2$, w_1^n and w_2^n. Choosing instead the generators $x = \frac{w_1^n - w_2^n}{2}$, $y = \mathrm{i}\,\frac{w_1^n + w_2^n}{2}$, $z = w_1 w_2$, we get the syzygy $z^n = -(x^2 + y^2)$. For any G, generators x, y, z can always be found so that the syzygy will be one of the polynomials associated to a simple singularity, and in fact will give the equation of the algebraic surface $\mathbb{C}^2/G$ as a 2-dimensional complex surface in $\mathbb{C}^3$ (e.g. the complex surfaces $\mathbb{C}^2/\mathbb{Z}_n$ and $\{(x, y, z) \in \mathbb{C}^3 \,|\, x^2 + y^2 + z^n = 0\}$ are equivalent).

Arguably the first A-D-E classification goes back to Theaetetus, around 400 B.C. He classified the regular solids. For instance the tetrahedron can be associated to E_6 while the cube is matched with E_7. This A-D-E is only partial, as there are no regular solids assigned to the A-series, and to get the D-series one must look at 'degenerate regular solids'.

The closest thing to an explanation of the A-D-E meta-pattern would seem to be the notion of 'additive assignments' on graphs (which is a picturesque way of describing the corresponding eigenvalue problem). Consider any graph $\mathcal{G}$ with undirected edges, and none of the edges run from a node to itself. We can also assume without loss of generality that $\mathcal{G}$ is connected. Assign a positive number a_i to each node. If this assignment has the property that for each i, $2a_i = \sum a_j$ where the sum is over all nodes j adjacent to i (counting multiplicities of edges), then we call it 'additive'. For instance, for the graph ○═○, the assignment $a_1 = 1 = a_2$ is additive, but the assignment $a_1 = 1, a_2 = 2$ is not. The question is, which graphs have an additive assignment? The answer is: precisely the extended Dynkin diagrams of A-D-E type! And their additive assignments are unique (up to constant proportionality) and are given by the *marks* a_i of the algebra (see e.g. the Table on p.54 of [38]). For example the extended A_n graph consists of $n+1$ nodes arranged in a circle, and its marks a_i all equal 1.

What do additive assignments have to do with the other A-D-E classifications? Consider a finite subgroup G of $\mathrm{SU}_2(\mathbb{C})$. Take the dimension of the equation $G \otimes R_i = \oplus_j m_{ij} R_j$: we get $2d_i = \sum_j m_{ij} d_j$ where $d_j = \dim(R_j)$. Hence the dimensions of the irreducible representations define an additive assignment for each of McKay's graphs, and hence those graphs must be of A-D-E type (provided we know $m_{ij} = m_{ji}$).

As Cappelli-Itzykson-Zuber observed, the physical invariants for $A_1^{(1)}$ also realise the A-D-E pattern, in the following sense. The *Coxeter number* h of the name $\mathcal{X}_\ell$ (i.e. the sum $\sum_i a_i$ of the marks) equals $k+2$, and the *exponents* m_i of X_ℓ equal those $a \in P_+^k$ for which $M_{aa} \neq 0$ (for the simply-laced algebras, the m_i are defined by writing the eigenvalues of the corresponding Cartan matrix (see §2.7) as $4\sin^2(\frac{\pi m_i}{2h})$ — the m_i are integers and the smallest is always 1). Probably what first led Kac to his observation about the E_6 exponents was that $k+2$ (this is how k enters most formulas) for his exceptional equalled the Coxeter number 12 for E_6. More recently, the operator algebraists Ocneanu [48] and independently Böckenhauer-Evans [4] found an A-D-E interpretation for the off-diagonal entries M_{ab} of the $A_1^{(1)}$ physical invariants, using subfactor theory.

We are not claiming that this $A_1^{(1)}$ classification is 'equivalent' to any other A-D-E one — that would miss the point of meta-patterns. What we really want to do is to identify some critical combinatorial part of an $A_1^{(1)}$ proof with critical parts in other A-D-E classifications — this is what we did with the other meta-patterns. A considerably simplified proof of the $A_1^{(1)}$ classification is now available [29], so hopefully this task will now be easier.

There has been some progress at understanding this $A_1^{(1)}$ A-D-E. Nahm [46] constructed the invariant $\mathcal{X}_\ell$ in terms of the compact simply-connected Lie group of type X_ℓ, and in this way could interpret the $k+2=h$ and $M_{m_i m_i} \neq 0$ coincidences. A very general explanation for A-D-E has been suggested by Ocneanu [48] using his theory of path algebras on graphs; although his work has never been published, others are now rediscovering (and publishing!) similar work (see e.g. [4]). Nevertheless, the A-D-E in CFT remains almost as mysterious now as it did a dozen years ago — for example it still isn't clear how it directly relates to additive assignments.

There are 4 other claims for A-D-E classifications of families of RCFT physical invariants, and all of them inherit their (approximate) A-D-E pattern from the more fundamental $A_1^{(1)}$ one. One is the $c<1$ minimal models, also proven in [8], and another is the $N=1$ superconformal minimal models, proved by Cappelli (1987). In both cases the physical invariants are parametrised by pairs of A-D-E diagrams. The list of known $c=1$ RCFTs also looks like A-D-E (two series parametrised by $\mathbb{Q}_+$, and three exceptionals), but the completeness of that list has never been rigourously established.

The fourth classification often quoted as A-D-E, is the $N=2$ superconformal minimal models. Their classification was done by Gannon (1997). The connection here with A-D-E turns out to be rather weak: e.g. 20, 30, and 24 distinct invariants would have an equal right to be called $\mathcal{E}_6$, $\mathcal{E}_7$, and $\mathcal{E}_8$ respectively. It would appear that the frequent claims that the $N=2$ minimal models fall into an A-D-E pattern are rather dubious.

Hanany-He [35] suggest that the $A_1^{(1)}$ A-D-E pattern can be related to subgroups $G \subset \mathrm{SU}_2(\mathbb{C})$ by orbifolding 4-dimensional $N=4$ supersymmetric gauge theory by G, resulting in an $N=2$ superCFT whose 'matter matrix' can be read off from the Dynkin diagram corresponding to G. The same game can be played with finite subgroups of $\mathrm{SU}_3(\mathbb{C})$, resulting in $N=1$ superCFTs whose matter matrices correspond to graphs very reminiscent of the 'fusion graphs' of Di Francesco-Petkova-Zuber (see e.g. [62]) corresponding to $A_2^{(1)}$ physical invariants. [35] use this to conjecture a McKay-type correspondence between singularities of type $\mathbb{C}^n/G$, for $G \subset \mathrm{SU}_n(\mathbb{C})$, and the physical invariants of $A_{n-1}^{(1)}$. This in their view would be the form A-D-E takes for higher rank physical invariants. Their actual conjecture though is still somewhat too vague.

For a final example of meta-pattern, consider 'modular function' (see §2.3). After all, they appear in a surprising variety of places and disguises. Maybe we shouldn't regard their ubiquity as fortuitous, instead perhaps there's a deeper common 'situation' which is the source for that ubiquity. Just as 'symmetry' yields 'group', or 'rain-followed-by-heat' breeds mosquitos. Math is not above metaphysics; like any area it grows by asking questions, and changing your perspective — even to a metaphysical one — should suggest new questions.

1.7. SIMPLE-CURRENTS AND CHARGE-CONJUGATION

The key properties[15] of the matrix S are that it's unitary and symmetric (so M in §1.5 equals SMS^*),

$$S_{0\mu} > 0 \text{ for all } \mu \in P_+^k \ , \tag{1.7.1}$$

and that the numbers $N_{\lambda\mu}^{\nu}$ defined by Verlinde's formula (1.4.4) are nonnegative integers. These are obeyed by the matrix S in any (unitary) RCFT. From these basic properties, we will obtain here some elementary consequences which have important applications.

But first, let's make an observation which isn't difficult to prove, but doesn't appear to be generally known.

Verlinde's formula looks strange, but it is quite generic,

and we can see it throughout math and mathematical physics. Consider the following.

Let $\mathfrak{A}$ be a commutative associative algebra, over $\mathbb{R}$ say. Suppose $\mathfrak{A}$ has a finite basis Φ (over $\mathbb{R}$) containing the unit 1. Define the 'structure constants' $N_{ab}^c \in \mathbb{R}$, for $a,b,c \in \Phi$, by $ab = \sum_{c\in\Phi} N_{ab}^c c$. Suppose there is an algebra homomorphism $*$ (so $*$ is linear, and $(xy)^* = x^*y^*$) which permutes the basis vectors (so $\Phi^* = \Phi$), and we have the relation $N_{ab}^1 = \delta_{b,a^*}$. We call any such algebra $\mathfrak{A}$ a *fusion algebra.* Then any fusion algebra will necessarily have a unitary matrix S with $S_{1a} > 0$ and with the structure constants given by Verlinde's formula. Algebraically, the relation $S = S^t$ holds if $\mathfrak{A}$ is 'self-dual' in a certain natural sense.

---

[15] A good exercise for the reader is to prove that if S is unitary and symmetric, and obeys (1.7.1), then there will be at most finitely many physical invariants M for that S,T.

Define the 'fusion matrices' N_λ by $(N_\lambda)_{\mu\nu} = N_{\lambda\mu}^{\nu}$. Then Verlinde's formula says that the μth column $S_{\uparrow\mu}$ of S is an eigenvector of each fusion matrix N_λ, with eigenvalue $\frac{S_{\lambda\mu}}{S_{0\mu}}$.

Useful Fact. If v is a simultaneous eigenvector of each fusion matrix N_λ, then there exists a constant $c \in \mathbb{C}$ and a $\lambda \in P_+^k$ such that $v = c\, S_{\uparrow\lambda}$.

For one consequence, take the complex conjugate of the eigenvector equation $N_\lambda\, S_{\uparrow\mu} = \frac{S_{\lambda\mu}}{S_{0\mu}}\, S_{\uparrow\mu}$: we get that the vector $S_{\uparrow\mu}^*$ is a simultaneous eigenvector of all N_λ, and hence must equal $c\, S_{\uparrow\gamma}$ for some number c and weight $\gamma \in P_+^k$, both depending on μ. Write $\gamma = C\mu$; then C defines a permutation of P_+^k. The reader can verify that unitarity of S forces $|c| = 1$, while (1.7.1) forces $c > 0$. Thus $c = 1$ and we obtain the formula

$$S_{\lambda\mu}^* = S_{\lambda,C\mu} = S_{C\lambda,\mu}\ . \tag{1.7.2}$$

Also, unitarity and symmetry of S forces $C = S^2$, while conjugating twice shows $C^2 = id$. C is an important matrix in RCFT, and is called *charge-conjugation*. When $C = id.$, then the matrix S is real.

Note that (1.7.1) now implies $C0 = 0$. Also $CT = TC$. Hence $M = C$ will always define a physical invariant, and if M is any other physical invariant, the matrix product $MC = CM$ will define another physical invariant. Also, $N_{C\lambda,C\mu}^{C\nu} = N_{\lambda\mu}^{\nu}$ and $(N_\lambda)^t = CN_\lambda = N_\lambda C = N_{C\lambda}$.

For the WZW (=affine) case, C has a special meaning: $C\lambda$ is the highest-weight 'contragredient' to λ. C corresponds to an order 2 (or 1) symmetry of the (unextended) Dynkin diagram. For example, for $A_\ell^{(1)}$, we have $C(\lambda_0, \lambda_1, \ldots, \lambda_{\ell-1}, \lambda_\ell) = (\lambda_0, \lambda_\ell, \lambda_{\ell-1}, \ldots, \lambda_1)$. For $A_1^{(1)}$ then, $C = id.$, which can also be read off from (1.4.3).

The algebras $D_{even}^{(1)}$ all have at least one nontrivial symmetry of the (unextended) Dynkin diagram which isn't the charge-conjugation. The most interesting example is $D_4^{(1)}$, which has 5 of these. By a *conjugation*, we will mean any symmetry of the unextended Dynkin diagram.

To go much further, we need a fascinating tool called *Perron-Frobenius theory* — a collection of results concerning the eigenvalues and eigenvectors of nonnegative matrices (i.e. matrices in which every entry is a nonnegative real number). Whenever you have such matrices in your problem, and it is natural to multiply them, then there is a good chance Perron-Frobenius theory will tell you something interesting. The basic result here is that if A is a nonnegative matrix, then there will be a nonnegative eigenvector $x \geq 0$ with eigenvalue $\rho \geq 0$, such that if λ is any other eigenvalue of A, then $|\lambda| \leq \rho$. There are lots of other results (see e.g. [44]), e.g. ρ must be at least as large as any diagonal entry of A, and there must be a row-sum of A no bigger than ρ, and another row-sum no smaller than ρ.

For instance, consider

$$A = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}\ , \qquad B = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}\ .$$

Perron-Frobenius eigenvectors for A and B are $\begin{pmatrix}1\\1\\1\end{pmatrix}$ and $\begin{pmatrix}2\\1\\1\end{pmatrix}$, with eigenvalues 3 and 2 resp. The other eigenvalue of A is 0 (multiplicity 2), while those of B are 0 and -1.

Fusion matrices N_λ are nonnegative, and it is indeed natural to multiply them:

$$N_\lambda N_\mu = \sum_{\nu\in P_+^k} N_{\lambda\mu}^\nu N_\nu \ .$$

So we can expect Perron-Frobenius to tell us something interesting. This is the case, and we obtain the curious-looking inequalities

$$S_{\lambda 0}\, S_{0\mu} \geq |S_{\lambda\mu}|\, S_{00} \ . \tag{1.7.3}$$

Squaring both sides, summing over μ and using unitarity, we get that $S_{\lambda 0} \geq S_{00}$. In other words, the ratio $\frac{S_{\lambda 0}}{S_{00}}$, called the *quantum-dimension* of λ, will necessarily be ≥ 1.

The term 'quantum-dimension' comes from quantum groups, where $\frac{S_{\lambda 0}}{S_{00}}$ is the quantum-dimension of the module labelled by λ of the quantum group $U_q(X_\ell)$.

The borderline case then [16] is when a quantum-dimension *equals* 1. Any such weight is called a *simple-current*. The theory of simple-currents was developed most extensively by Schellekens and collaborators (see e.g. [50]). The simple-currents for the affine algebras were classified by J. Fuchs (1991), and the result is that (with one unimportant exception: $E_8^{(1)}$ at level 2) they all correspond to symmetries of the extended Dynkin diagrams. In particular, applying any such symmetry to the vacuum $0 = (k, 0, \ldots, 0)$ gives the list of simple-currents. For instance, the $\ell + 1$ weights of the form $(0, \ldots, k, \ldots, 0)$ (k in the ith spot) are the simple-currents for $A_\ell^{(1)}$. There are 2 simple-currents for $B_\ell^{(1)}$, $C_\ell^{(1)}$ and $E_7^{(1)}$, 3 for $E_6^{(1)}$, and 4 for $D_\ell^{(1)}$. Simple-currents play a large role in RCFT, as we shall see.

Let j be any simple-current. Then (1.7.3) becomes $S_{0\mu} \geq |S_{j\mu}|$ for all μ, so unitarity forces $S_{0\mu} = |S_{j\mu}|$, that is

$$S_{j\mu} = \exp[2\pi \mathrm{i}\, Q_j(\mu)]\, S_{0\mu} \qquad \forall \mu \in P_+^k \tag{1.7.4}$$

for some rational numbers $0 \leq Q_j(\mu) < 1$. Hence by diagonalising, we get $N_j N_{Cj} = I$. But the inverse of a nonnegative matrix A is itself nonnegative, only if A is a 'generalised permutation matrix', i.e. a permutation matrix except the 1's can be replaced by any positive numbers. But N_j and N_{Cj} are also integral, and so they must in fact be permutation matrices. Write $(N_j)_{\lambda\mu} = \delta_{\mu,J\lambda}$ for some permutation J of P_+^k. So $j = J0$. Then

$$\delta_{\lambda,\mu} = N_{j,\lambda}^{J\mu} = \sum_\nu \exp[2\pi \mathrm{i}\, Q_j(\nu)]\, S_{\lambda\nu}\, S_{J\mu,\nu}^* \ ,$$

---

[16] This seems to be a standard trick in math: when some sort of bound is established, look at the extremal cases which realise that bound. If your bound is a good one, it should be possible to say something about those extremal cases, and having something to say is always of paramount importance. This trick is used for instance in the definition of 24 last section, and the definition of normal subgroup in section 2.2.

so taking absolute values and using the triangle inequality and unitarity of S, we find that (1.7.4) generalises:

$$S_{J\lambda,\mu} = \exp[2\pi\mathrm{i}\, Q_j(\mu)]\, S_{\lambda\mu}\ . \tag{1.7.5}$$

The simple-currents form a finite abelian group, corresponding to the composition of the permutations J. For any simple-currents J, J', we get the symmetry $N_{J\lambda,J'\mu}^{\nu} = N_{\lambda\mu}^{JJ'\nu}$. The $\mathbb{Q}/\mathbb{Z}$-valued functions Q_j define gradings on the fusion rings, and conversely any grading corresponds to a simple-current in this way.

For example, the simple-current $j = (0, k)$ of $A_1^{(1)}$ at level k corresponds to $Q_j(\lambda) = \lambda_1/2$ and the permutation $J\lambda = (\lambda_1, \lambda_0)$. We can see this directly from (1.4.3). For $A_2^{(1)}$ level k, there are 2 nontrivial simple-currents, $(0, k, 0)$ and $(0, 0, k)$. The first of these corresponds to triality $Q(\lambda) = (\lambda_1 + 2\lambda_2)/3$ and $\lambda \mapsto (\lambda_2, \lambda_0, \lambda_1)$, while the second to $(2\lambda_1 + \lambda_2)/3$ and $\lambda \mapsto (\lambda_1, \lambda_2, \lambda_0)$. Similar statements hold for all affine algebras: e.g. for $B_\ell^{(1)}$ level k, the nontrivial simple-current has $Q_j(\lambda) = \lambda_\ell/2$ and $J\lambda = (\lambda_1, \lambda_0, \lambda_2, \ldots, \lambda_\ell)$.

One of the applications of simple-currents is that physical invariants can be built from them in generic ways. These physical invariants all obey the selection rule

$$M_{\lambda\mu} \neq 0 \quad \Longrightarrow \quad \mu = J\lambda \quad \text{for some simple}-\text{current } J = J(\lambda, \mu)\ . \tag{1.7.6}$$

We will call any such physical invariant M a *simple-current invariant.* A special case is the $\mathcal{D}_{\frac{k}{2}+2}$ physical invariant for $A_1^{(1)}$ at even level k. Up to a fairly mild assumption, all simple-current invariants have been classified for any RCFT by Schellekens and collaborators; given that assumption, they can all be constructed by generic methods. The basic construction is due to Bernard [3], though it has been generalised by others. In the WZW case, all simple-current invariants (except some for $D_\ell^{(1)}$) correspond to strings on nonsimply-connected Lie groups.

By a *generic physical invariant* of $X_\ell^{(1)}$ we mean one of the form $M = C'M'C''$ where C', C'' are (charge-)conjugations, and M' is a simple-current invariant. In other words, M is constructed in generic ways from symmetries of the extended Dynkin diagram of X_ℓ. Any other M are called *exceptional.*

All known results point to the validity of the following guess:

Conjecture. Choose a simple algebra X_ℓ. Then for all sufficiently large k, all physical invariants of $X_\ell^{(1)}$ at level k will be generic.

In other words, any given $X_\ell^{(1)}$ will have only finitely many exceptionals. For instance, for $A_1^{(1)}$ and $A_2^{(1)}$ at any $k > 28$ and $k > 21$ resp., all physical invariants are generic. For $C_2^{(1)}$ and $G_2^{(1)}$, $k > 12$ and $k > 4$ resp. should work.

The richest source of exceptionals are *conformal embeddings.* In some cases the affine representations L_λ for some algebra $X_\ell^{(1)}$ (necessarily at level 1) can be decomposed into *finite* direct sums of representations of some affine subalgebra $Y_m^{(1)}$ (at some level k). In this case, a physical invariant for $X_\ell^{(1)}$ level 1 will yield a physical invariant for $Y_m^{(1)}$ level k, obtained by replacing every $X_\ell^{(1)}$ level 1 character χ_λ by the appropriate finite sum of

$Y_m^{(1)}$ level k characters. An example will demonstrate this simple idea: $A_1^{(1)}$ level 28 is a conformal subalgebra of $G_2^{(1)}$ level 1, and we have the character decompositions

$$\begin{aligned}\chi_{(1,0,0)} &= \chi'_{(28,0)} + \chi'_{(18,10)} + \chi'_{(10,18)} + \chi'_{(0,28)} \\ \chi_{(0,0,1)} &= \chi'_{(22,6)} + \chi'_{(16,12)} + \chi'_{(12,16)} + \chi'_{(6,22)} \ .\end{aligned}$$

Thus the unique level 1 $G_2^{(1)}$ physical invariant $|\chi_0|^2 + |\chi_{(0,0,1)}|^2$ yields what we call the $\mathcal{E}_8$ physical invariant of $A_1^{(1)}$. All level 1 physical invariants are known, as are all conformal embeddings and the corresponding character decompositions (branching rules).

1.8. Galois Theory

Evariste Galois was a brilliantly original French mathematician. Born shortly before Napoleon's ill-fated invasion of Russia, he died shortly before the ill-fated 1832 uprising in Paris. His last words: "Don't cry, I need all my courage to die at 20".

Galois grew up in a time and place confused and excited by revolution. He was known to say "if I were only sure that a body would be enough to incite the people to revolt, I would offer mine". On May 2 1832, after frustration over failure in love and failure to convince the Paris math establishment of the depth of his ideas, he made his decision. A duel was arranged with a friend, but only his friend's gun would be loaded. Galois died the day after a bullet perforated his intestine. At his funeral it was discovered that a famous general had also just died, and the revolutionaries decided to use the general's death rather than Galois' as a pretext for an armed uprising. A few days later the streets of Paris were blocked by barricades, but not because of Galois' sacrifice: his death had been pointless [56].

Galois theory in its most general form is the study of relations between objects defined implicitly by some conditions. For example, the objects could be the solutions to a given differential equation. In the incarnation of Galois we are interested in here, the objects are numbers, namely the zeros of certain polynomials. We will sketch this theory below, but see e.g. the article by Stark in [60] for more details.

Gauss seems to have been the first to show that 'weird' (complex) numbers could tell us about the integers. For instance, suppose we are interested in the equation $n = a^2 + b^2$. Consider $5 = 2^2 + 1^2$. We can write this as $5 = (2 + \mathrm{i})(2 - \mathrm{i})$, so we are led to consider complex numbers of the form $a + b\mathrm{i}$, for $a, b \in \mathbb{Z}$. These are now called 'Gaussian integers'. Suppose we know the following theorem:

Fact. Let $p \in \mathbb{Z}$ be any prime number. Then p factorises over the Gaussian integers iff $p = 2$ or $p \equiv 1 \pmod 4$.

By 'factorise' there, we mean $p = zw$ where neither z nor w is a 'unit': ± 1, $\pm \mathrm{i}$.

Now suppose p is a prime, $= 2$ or $\equiv 1 \pmod 4$, and we write $p = (a + b\mathrm{i})(c + d\mathrm{i})$. Then $p^2 = (a^2 + b^2)(c^2 + d^2)$, so $a^2 + b^2 = c^2 + d^2 = p$. Conversely, suppose $p = a^2 + b^2$, then $p = (a + b\mathrm{i})(a - b\mathrm{i})$. Thus:

Consequence. [17] Let $p \in \mathbb{Z}$ be any prime number. Then $p = a^2 + b^2$ for $a, b \in \mathbb{Z}$ iff $p = 2$ or $p \equiv 1 \pmod 4$.

Now we can answer the question: can a given n be written as a sum of 2 squares $n = a^2 + b^2$? Write out the prime decomposition $n = \prod p^{a_p}$. Then $n = a^2 + b^2$ has a solution iff a_p is *even* for every $p \equiv 3 \pmod 4$. For instance $60 = 2^2 \cdot 3^1 \cdot 5^1$ cannot be written as the sum of 2 squares, but $90 = 2^1 \cdot 3^2 \cdot 5^1$ can. We can also find (and count) all solutions: e.g. $90 = 2 \cdot 3^2 \cdot 5 = \{(1+\mathrm{i})3(1+2\mathrm{i})\}\{(1-\mathrm{i})3(1-2\mathrm{i})\}$, giving $90 = (-3)^2 + 9^2$.

This problem should give the reader a small appreciation for the power of using nonintegers to study integers. Nonintegers often lurk in the shadows, secretly watching their more arrogant brethren the integers strut. One of the consequences of their presence can be the existence of certain 'Galois' symmetries. Such happens in RCFT, as we will show below.

Look at complex conjugation: $(wz)^* = w^* z^*$ and $(w + z)^* = w^* + z^*$. Also, $r^* = r$ for any $r \in \mathbb{R}$. So we can say that $*$ is a structure-preserving map $\mathbb{C} \to \mathbb{C}$ (called an *automorphism* of $\mathbb{C}$) fixing the reals. We will write this $* \in \mathrm{Gal}(\mathbb{C}/\mathbb{R})$. '$\mathrm{Gal}(\mathbb{C}/\mathbb{R})$' is the Galois group of $\mathbb{C}$ over $\mathbb{R}$; it turns out to contain only $*$ and the identity.

A way of thinking about the automorphism $*$ is that it says that, as far as the real numbers are concerned, i and $-$i are identical twins.

Let $\mathbb{F}$ be any *field* containing $\mathbb{Q}$ (we defined 'field' in §1.2). The *Galois group* $\mathrm{Gal}(\mathbb{F}/\mathbb{Q})$ then will be the set of all automorphisms=symmetries of $\mathbb{F}$ which fix all rationals.

For example, take $\mathbb{F}$ to be the set of all numbers of the form $a + b\sqrt{5}$, where $a, b \in \mathbb{Q}$. Then $\mathbb{F}$ will be a field, which is commonly denoted $\mathbb{Q}[\sqrt{5}]$ because it is generated by $\mathbb{Q}$ and $\sqrt{5}$. Let's try to find its Galois group. Let $\sigma \in \mathrm{Gal}(\mathbb{F}/\mathbb{Q})$. Then $\sigma(a + b\sqrt{5}) = \sigma(a) + \sigma(b)\sigma(\sqrt{5}) = a + b\sigma(\sqrt{5})$, so once we know what σ does to $\sqrt{5}$, we know everything about σ. But $5 = \sigma(5) = \sigma(\sqrt{5}^2) = (\sigma(\sqrt{5}))^2$, so $\sigma(\sqrt{5}) = \pm\sqrt{5}$ and there are precisely 2 possible Galois automorphisms here (one is the identity). As far as $\mathbb{Q}$ is concerned, $\pm\sqrt{5}$ are interchangeable: it cannot see the difference.

For a more important example, consider the *cyclotomic field* $\mathbb{F} = \mathbb{Q}[\xi_n]$, where $\xi_n := \exp[2\pi\mathrm{i}/n]$ is an nth root of 1. So $\mathbb{Q}[\xi_n]$ consists of all complex numbers which can be expressed as polynomials $a_m\xi_n^m + a_{m-1}\xi_n^{m-1} + \cdots + a_0$ in ξ_n with rational coefficients a_i. Once again, to find the Galois group $\mathrm{Gal}(\mathbb{Q}[\xi_n]/\mathbb{Q})$, it is enough to see what an automorphism σ does to the generator ξ_n. Since $\xi_n^n = 1$, we see that it must send it to another nth root of 1, ξ_n^ℓ say; in fact it is easy to see that $\sigma(\xi_n)$ must be another 'primitive' nth root of 1, i.e. ℓ must be coprime to n. So $\mathrm{Gal}(\mathbb{Q}[\xi_n]/\mathbb{Q})$ will be isomorphic to the multiplicative group $\mathbb{Z}_n^\times$ of numbers between 1 and n coprime to n. The rationals can't see any difference between the primitive nth roots of 1 — for instance $\mathbb{Q}$ can't tell that $\xi_n^{\pm 1}$ are 'closer to 1' than the other primitive roots. So any $\sigma \in \mathrm{Gal}(\mathbb{Q}[\xi_n]/\mathbb{Q})$ will correspond to some $\ell \in \mathbb{Z}_n^\times$, and to see what σ does to some $z \in \mathbb{Q}[\xi_n]$ what we do is write z as a polynomial in ξ_n and then replace each occurrence of ξ_n with ξ_n^ℓ. For example,

$$\sigma\big(\cos(2\pi a/n)\big) = \sigma\left(\frac{\xi_n^a + \xi_n^{-a}}{2}\right) = \frac{\xi_n^{a\ell} + \xi_n^{-a\ell}}{2} = \cos(2\pi a\ell/n) \ .$$

---

[17] This result was first stated by Fermat in one of his infamous margin notes (another is discussed in Section 2.3), and was finally proved a century later by Euler. A remarkable 1-line proof was found by Zagier [61].

So to summarise, Galois automorphisms are a massive generalisation of the idea of complex conjugation. If in your problem complex conjugation seems interesting, then there is a good chance more general Galois automorphisms will play an interesting role. This is what happens in RCFT, as we now show.

Fact. [14] Suppose S is unitary and symmetric and each $S_{0a} > 0$.

(a) If in addition the numbers N_{ab}^c given by Verlinde's formula (1.4.4) are rational, then the entries S_{ab} of S must lie in a cyclotomic field.

(b) The numbers N_{ab}^c will be rational iff for any $\sigma \in \mathrm{Gal}(\mathbb{Q}[S]/\mathbb{Q})$, there is a permutation $a \mapsto a^\sigma$, and a choice of signs $\epsilon_\sigma(a) \in \{\pm 1\}$, such that

$$\sigma(S_{ab}) = \epsilon_\sigma(a)\, S_{a^\sigma,b} = \epsilon_\sigma(b)\, S_{a,b^\sigma} \ . \tag{1.8.1}$$

'$\mathbb{Q}[S]$' in part (b) denotes the field generated by $\mathbb{Q}$ and all matrix entries S_{ab}. The argument follows the one given for the charge-conjugation C at the beginning of the last section. The kinds of complex numbers which lie in cyclotomic fields are $\sin(\pi r)$, $\cos(\pi r)$, $\sqrt{r}$ and $r\mathrm{i}$ for any $r \in \mathbb{Q}$. Almost all complex numbers fail to lie in any cyclotomic field: e.g. generic cube roots, 4th roots, ..., of rationals, as well as transcendental numbers like e, π and e^π.

Of course the affine algebras satisfy the conditions of the Fact, as does more generally the modular matrix S for any unitary RCFT, and so these will possess the Galois action. For the affine algebras this action has a geometric interpretation in terms of multiplying weights by an integer ℓ and applying Weyl group elements — see [14] for a description.

This Fact is useful in both directions: as a way of testing whether a conjectured matrix S has a chance of producing the integral fusions we want it to yield; and more importantly as a source of a symmetry of the RCFT which generalises charge-conjugation. Any statement about charge-conjugation seems to have an analogue for any of these Galois symmetries, although it is usually more complicated.

As an example, consider $A_1^{(1)}$: (1.4.3) shows explicitly that $S_{\lambda\mu}$ lies in the cyclotomic field $\mathbb{Q}[\xi_{4(k+2)}]$. Write $\{x\}$ for the number congruent to x mod $2(k+2)$ satisfying $0 \le \{x\} < 2(k+2)$. Choose any Galois automorphism σ, and let $\ell \in \mathbb{Z}_{4(k+2)}^\times$ be the corresponding integer. Then if $\{\ell(a+1)\} < k+2$, we will have $a^\sigma = \{\ell(a+1)\}-1$, while if $\{\ell(a+1)\} > k+2$, we'll have $a^\sigma = 2(k+2) - \{\ell(a+1)\} - 1$. The sign $\epsilon_\sigma(a)$ will depend on a contribution from $\sqrt{\frac{2}{k+2}}$ (which for most purposes can be ignored), as well as the sign $+1$ or -1, resp., depending on whether or not $\{\ell(a+1)\} < k+2$.

Consider specifically $k = 10$, and the Galois automorphism σ_5 corresponding to $\ell = 5$. Then the permutation is $0 \leftrightarrow (6,4)$, $(9,1) \leftrightarrow (1,9)$, $(8,2) \leftrightarrow (2,8)$, $(4,6) \leftrightarrow (0,10)$, while $(7,3)$ and (5,5) are fixed.

This Galois symmetry has been used to find certain exceptional physical invariants, but its greatest use so far is as a powerful selection rule we will describe next section.

In this final section we include some of the basic tools belonging to the 'modern' classifications of physical invariants, and we give a flavour of their proofs. We will state them for the $A_1^{(1)}$ level k problem given above, but everything generalises without effort. See [29] and references therein for more details. Recall the matrices S, T in (1.4.3).

First note that commutation of M with T implies the selection rule

$$M_{\lambda\mu} \neq 0 \quad \Longrightarrow \quad (\lambda_1+1)^2 \equiv (\mu_1+1)^2 \pmod{4(k+2)} \ . \tag{1.9.1}$$

It is much harder to squeeze information out of the commutation with S, but the resulting information turns out surprisingly to be much more useful. In fact, commutation with S is almost incompatible with the constraint $M_{\lambda\mu} \in \mathbb{Z}_{\geq}$.

Note that the vacuum $0 \in P_+^k$ is both physically and mathematically special; our strategy will be to find all possible 0th rows and columns of M, and then for each of these possibilities to find the remaining entries of M.

The easiest result follows by evaluating $MS = SM$ at $(0, \lambda)$ for any $\lambda \in P_+^k$:

$$\sum_{\mu \in P_+^k} M_{0\mu}\, S_{\mu\lambda} \geq 0 \ , \tag{1.9.2}$$

with equality iff the λth column of M is identically 0. (1.9.2) has two uses: it severely constrains the values of $M_{0\mu}$ (similarly $M_{\mu 0}$), and it says precisely which columns (and rows) are nonzero.

Next, let's apply the triangle inequality to sums involving (1.7.5). Choose any $i, j \in \{0, 1\}$. Then

$$M_{J^i 0, J^j 0} = \sum_{\lambda,\mu} (-1)^{\lambda_1 i}\, S_{0\lambda}\, M_{\lambda\mu}\, (-1)^{\mu_1 j}\, S_{0\mu} \ .$$

Taking absolute values, we obtain

$$M_{J^i 0, J^j 0} \leq \sum_{\lambda,\mu} S_{0\lambda}\, M_{\lambda\mu}\, S_{0\mu} = M_{00} = 1 \ .$$

Thus $M_{J^i 0, J^j 0}$ can equal only 0 or 1. If it equals 1, then we obtain the selection rule:

$$\lambda_1 i \equiv \mu_1 j \pmod 2 \text{ whenever } M_{\lambda\mu} \neq 0 \ ;$$

this implies the symmetry $M_{J^i\lambda, J^j\mu} = M_{\lambda\mu}$ for all $\lambda, \mu \in P_+^k$. We can see both of these in the list of physical invariants for $A_1^{(1)}$ level k. This explains a lot of the properties of those invariants. For instance, try to use this selection rule to explain why no χ_{odd} appears in the exceptional called $\mathcal{E}_8$.

Our M is nonnegative, and although multiplying M's may not give us back a physical invariant, it will give us a matrix commuting with S and T. In other words, the commutant is much more than merely a vector space, it is in fact an algebra. Thus we should expect Perron-Frobenius to tell us something here. A first application is the following.

Suppose $M_{\lambda 0}=\delta_{\lambda,0}$ — i.e. the 0th column of M is all zeros except for $M_{00}=1$. Then Perron-Frobenius implies (with a little work) that M will be a permutation matrix — i.e. there is some permutation π of P_+^k such that $M_{\lambda\mu}=\delta_{\mu,\pi\lambda}$, and $S_{\pi\lambda,\pi\mu}=S_{\lambda\mu}$. This nice fact applies directly to the $\mathcal{A}_\star$ and $\mathcal{D}_{odd}$ physical invariants of $A_1^{(1)}$.

This is proved by studying the powers $(M^t\,M)^L$ as L goes to infinity: its diagonal entries will grow exponentially with L, unless there is at most one nonzero entry on each row of M, and that entry equals 1.

More careful reasoning along those lines tells us about the other generic situation here. Namely, suppose $M_{\lambda 0}\neq 0$ only for $\lambda=0$ and $\lambda=J0$, and similarly for $M_{0\lambda}$ — i.e. the 0th row and column of M are all zeros except for $M_{J^i0,J^j0}=1$. Then the λth row (or column) of M will be identically 0 iff λ_1 is odd. Moreover, let λ,μ be any non-fixed-points of J, and suppose $M_{\lambda\mu}\neq 0$. Then

$$M_{\lambda\nu}=\begin{cases}1 & \text{if } \nu=\mu \text{ or } \nu=J\mu\\ 0 & \text{otherwise}\end{cases}$$

with a similar formula for $M_{\nu\mu}$. This applies to the $\mathcal{D}_{even}$ and $\mathcal{E}_7$ invariants of $A_1^{(1)}$.

Our final ingredient is the Galois symmetry (1.8.1) obeyed by S. Choose any Galois automorphism σ. It will correspond to some integer ℓ coprime to $2(k+2)$. From (1.8.1) and $M=SMS^*$ we get, for all λ,μ, the important relation

$$M_{\lambda\mu}=\epsilon_\sigma(\lambda)\,\epsilon_\sigma(\mu)\,M_{\lambda^\sigma,\mu^\sigma}\ . \tag{1.9.3}$$

From (1.9.3) and the positivity of M, we obtain the powerful *Galois selection rule*

$$M_{\lambda\mu}\neq 0 \quad\Longrightarrow\quad \epsilon_\sigma(\lambda)=\epsilon_\sigma(\mu)\ . \tag{1.9.4}$$

Next let us quickly sketch how these tools are used to obtain the $A_1^{(1)}$ classification. For details the reader should consult [29].

The first step will be to find all possible values of λ such that $M_{0\lambda}\neq 0$ or $M_{\lambda 0}\neq 0$. These λ are severely constrained. We know two generic possibilities: $\lambda_1=0$ (good for all k), and $\lambda=J0$ (good when $\frac{k}{2}$ is even). We now ask the question, what other possibilities for λ are there? Our goal is to prove (1.9.7). Assume $\lambda\neq 0,J0$, and write $a=\lambda_1+1$ and $n=k+2$.

There are only two constraints on λ which we will need. One is (1.9.1):

$$(a-1)\,(a+1)\equiv 0 \pmod{4n}\ . \tag{1.9.5}$$

More useful is the Galois selection rule (1.9.4), which we can write as $\sin(\pi\ell\frac{a}{n})\sin(\pi\ell\frac{1}{n})>0$, for all those ℓ. But a product of sines can be rewritten as a difference of cosines, so

$$\cos(\pi\,\ell\,\frac{a-1}{n})>\cos(\pi\,\ell\,\frac{a+1}{n})\ . \tag{1.9.6}$$

(1.9.6) is strong and easy to solve; the reader should try to find her own argument.

What we get is that, provided $n \neq 12, 30$, M obeys the strong condition

$$M_{\lambda 0} \neq 0 \text{ or } M_{0\lambda} \neq 0 \qquad \Longrightarrow \qquad \lambda \in \{0, J0\} \ . \tag{1.9.7}$$

Consider first **case 1**: $M_{\lambda 0} = \delta_{\lambda,0}$. From above, we know $M_{\lambda\mu} = \delta_{\mu,\pi\lambda}$ for some permutation π of P_+^k obeying $S_{\lambda\mu} = S_{\pi\lambda,\pi\mu}$. We know $\pi 0 = 0$; put $\mu := \pi(k-1,1)$. Then $\sin(\pi\frac{2}{n}) = \sin(\pi\frac{\mu_1+1}{n})$, and so we get either $\mu = (k-1,1)$ or $\mu = J(k-1,1)$. By T-invariance (1.9.1), the second possibility can only occur if $4 \equiv (n-2)^2 \pmod{4n}$, i.e. 4 divides n. But for those n, $\mathcal{D}_{\frac{n}{2}+1}$ is also a permutation matrix, so replacing M if necessary with the matrix product $M\,\mathcal{D}_{\frac{n}{2}+1}$, we can always require $\mu = (k-1,1)$, i.e. π also fixes $(k-1,1)$. It is now easy to show π must fix any λ, i.e. that M is the identity matrix $\mathcal{A}_{n-1}$.

The other possibility, **case 2**, is that both $M_{0,J0} \neq 0$ and $M_{J0,0} \neq 0$. (1.9.1) says $1 \equiv (n-1)^2 \pmod{4n}$, i.e. $\frac{n}{2}$ is odd. The argument here is similar to that of **case 1**, but with $(k-2,2)$ playing the role of $(k-1,1)$. We can show that $M_{(k-2,2),(k-2,2)} \neq 0$, except possibly for $k = 16$, where we find the exceptional $\mathcal{E}_7$. Otherwise we get $M = \mathcal{D}_{\frac{n}{2}+1}$.

For more general $X_\ell^{(1)}$ level k, the approach is

(i) to look at all the constraints on the $\lambda \in P_+^k$ for which $M_{0\lambda} \neq 0$ or $M_{\lambda 0} \neq 0$. Most important here are $TM = MT$ (which will always be some sort of norm selection rule) and the Galois selection rule (1.9.4). Generically, what we will find is that such a λ must equal $J0$ for some simple-current J, as in (1.9.7) for $A_1^{(1)}$.

(ii) Solve this generic case (in the $A_1^{(1)}$ classification, these were the physical invariants $\mathcal{A}_\star$, $\mathcal{D}_\star$ and $\mathcal{E}_7$).

(iii) Solve the nongeneric case. The worst of these are the orthogonal algebras at $k = 2$, as well as the places where conformal embeddings (see §1.7) occur.

(ii) has recently been completed for all simple X_ℓ, as has the $k = 2$ part of (iii). (i) is the main remaining task in the physical invariant classification for simple X_ℓ.

A natural question to ask is whether A-D-E has been observed in e.g. the $A_2^{(1)}$ classification. The answer is no, although the fusion graph theory of Di Francesco-Petkova-Zuber [62] is an attempt to assign to these physical invariants graphs reminiscent of the A-D-E Dynkin diagrams. Also, there is related work trying to understand the $A_2^{(1)}$ classification in terms of subgroups of $\mathrm{SU}_3(\mathbb{C})$ (as opposed to $\mathrm{SU}_2(\mathbb{C})$ for $A_1^{(1)}$) — see e.g. [35]. Finding the $A_3^{(1)}$, $A_4^{(1)}$,... classifications would permit the clarification and testing of this vaguely conjectured relation between the $A_n^{(1)}$ physical invariants, and singularities $\mathbb{C}^{n+1}/G$ for G a finite subgroup of $\mathrm{SU}_{n+1}(\mathbb{C})$.

However, a few years ago Philippe Ruelle was walking in a library in Dublin. He spotted a yellow book in the math section, called *Complex Multiplication* by Lang. A strange title for a book by Lang! After all, there can't be all that much even Lang could really say about complex multiplication! Ruelle flipped it to a random page, which turned out to be p.26. On there he found what we would call the Galois selection rule for $A_2^{(1)}$, analysed and solved for the cases where $k+3$ is coprime to 6. Lang however didn't know about physical invariants; he was reporting on work by Koblitz and Rohrlich on decomposing the Jacobians of the Fermat curve $x^n + y^n = z^n$ into their prime pieces, called 'simple factors' in algebraic geometry. n here corresponds to $k+3$. Similarly, Itzykson discovered traces of the $A_2^{(1)}$ exceptionals — these occur when $k+3 = 8, 12, 24$ — in the Jacobian of $x^{24} + y^{24} = z^{24}$. See [2] for further observations along these lines. These 'coincidences' are still far from understood. Nor is it known if, more generally, the $A_\ell^{(1)}$ level k classification will somehow be related to the hypersurface $x_1^n + \cdots + x_\ell^n = z^n$, for $n = k + \ell + 1$.

The $(u(1) \oplus \cdots \oplus u(1))^{(1)}$ classification has connections to rational points on Grassmannians. The Grassmannian is (essentially) the moduli space for the Narain compactifications of the (classical) lattice string. It would be very interesting to interpret other large families of physical invariants as special points on other moduli spaces.

These new connections relating various physical invariant classifications to other areas of math seem to indicate that although the physical invariant classifications are difficult, they could be well worth the effort and be of interest outside RCFT. Once the physical invariant lists are obtained, we will still have the fascinating task of explaining and developing all these mysterious connections. These thoughts keep me going!

Another motivation for completing these lists comes from their relation to subfactor theory in von Neumann algebras[18]. These algebras (see e.g. [22]) can be thought of as symmetries of a (generally infinite) group. Their building blocks are called *factors*. Jones initiated the combinatorial study of *subfactors* N of M (i.e. inclusions $N \subseteq M$ where M, N are factors), relating it to e.g. knots, and for this won a Fields medal in 1990. Jones assigned to each subfactor $N \subseteq M$ a numerical invariant called an 'index', a sort of (generally irrational) ratio of dimensions. Graphs (called principal and dual principal) are also associated to subfactors. A much more refined subfactor invariant, called a 'paragroup', has been introduced by Ocneanu. It is essentially equivalent to a (2+1)-dimensional topological field theory. Moreover, any RCFT can be assigned a paragroup, and any paragroup (via a process called asymptotic inclusion which is akin to Drinfeld's quantum doubling of Hopf algebras) yields an RCFT. See [22] for details.

Böckenhauer-Evans [4] have recently developed this much further, and have clarified the fusion graph ↔ physical invariant relation. The fusion graphs will correspond to subfactor principal graphs. In the work of Di Francesco-Petkova-Zuber, that relation seems to be only empirical (i.e. nonconceptual).

Subfactor theory together with singularity theory is our best hope at present for understanding and generalising the A-D-E meta-pattern.

---

[18] For reasons of necessity, in the following discussion I'll take more liberties than usual in the presentation.

Part 2. Monstrous Moonshine

2.1. INTRODUCTION

In 1978, John McKay made a very curious observation. One of the well-known[19] functions of classical number theory is the j-function[20], given by

$$\begin{aligned} j(\tau) :=& \frac{(1+240\sum_{n=1}^{\infty}\sigma_3(n)\,q^n)^3}{q\prod_{n=1}^{\infty}(1-q^n)^{24}} = \frac{\Theta_{E_8}(\tau)^3}{\eta(\tau)^{24}} \\ =& q^{-1}+744+196\,884\,q+21\,493\,760\,q^2+864\,299\,970\,q^3+\cdots \end{aligned} \tag{2.1.1}$$

Here as elsewhere in this paper, $q=\exp[2\pi\mathrm{i}\,\tau]$. Also, $\sigma_3(n)=\sum_{d|n}d^3$, Θ_{E_8} is the theta function of the E_8 root lattice, and η is the Dedekind eta. What is important here are the values of the first few coefficients. What McKay noticed was that $196\,884\approx 196\,883$. Closer inspection shows $21\,493\,760\approx 21\,296\,876$, and $864\,299\,970\approx 842\,609\,326$. In fact,

$$196\,884 = 196\,883+1 \tag{2.1.2a}$$

$$21\,493\,760 = 21\,296\,876+196\,883+1 \tag{2.1.2b}$$

$$864\,299\,970 = 842\,609\,326+21\,296\,876+2\cdot 196\,883+2\cdot 1 \tag{2.1.2c}$$

The numbers on the right-side are the dimensions of the smallest irreducible representations of the Monster finite simple group $\mathbb{M}$ (in 1978 it still wasn't certain that $\mathbb{M}$ even existed so back then these numbers were merely conjectural). The same game could be played with other coefficients of the j-function. With numbers so large, it seemed to him doubtful that this numerology was merely a coincidence. On the other hand, it was hard to imagine any deep conceptual connection between the Monster and the j-function: they seem completely unrelated.

In November 1978 he mailed the 'McKay equation' (2.1.2a) to John Thompson. At first Thompson dismissed this as nonsense, but after checking the next few coefficients he became convinced. He then added a vital piece to the puzzle. It should be well-known that when one sees a nonnegative integer, it often helps to try to interpret it as the dimension of some vector space. Essentially, that is what McKay was proposing here. (2.1.2) are really hinting that there is a 'graded' representation V of $\mathbb{M}$:

$$V = V_{-1}\oplus V_1\oplus V_2\oplus V_3\oplus\cdots$$

where $V_{-1}=\rho_0$, $V_1=\rho_1\oplus\rho_0$, $V_2=\rho_2\oplus\rho_1\oplus\rho_0$, $V_3=\rho_3\oplus\rho_2\oplus\rho_1\oplus\rho_1\oplus\rho_0\oplus\rho_0$, etc, where ρ_i are the irreducible representations of $\mathbb{M}$ (ordered by dimension), and that

$$j(\tau)-744 = \dim_q(V) := \dim(V_{-1})\,q^{-1}+\sum_{i=1}^{\infty}\dim(V_i)\,q^i\ , \tag{2.1.3}$$

---

[19] 'Well-known' is math euphemism for 'a basic result of which until recently we were utterly ignorant.' As Conway later said, "the j-function was 'well-known' to other people, but not 'well-known' to me."

[20] This and other technical terms used in this introduction will be carefully explained in the following subsections. This section is merely offered as a quick overview.

the graded dimension of V.

Thompson suggested that we twist $\dim_q(V)$, i.e. that more generally we consider the series (now called the *McKay-Thompson series*)

$$T_g(\tau) := \mathrm{ch}_{V,q}(g) = \mathrm{ch}_{V_{-1}}(g)\, q^{-1} + \sum_{i=1}^{\infty} \mathrm{ch}_{V_i}(g)\, q^i \ , \tag{2.1.4}$$

for each element $g \in \mathbb{M}$. The point is that, for any group representation ρ, the character value $\mathrm{ch}_\rho(id.)$ equals the dimension of ρ, and so $T_{id.}(\tau) = j(\tau) - 744$ and we recover (2.1.2) as special cases. But there are many other possible choices of $g \in \mathbb{M}$. Thompson couldn't guess what these functions T_g would be, but he suggested that they too might be interesting. This is a nice thought: when we see a positive integer, we should try to interpret it as a dimension of a vector space; if there is a symmetry present, then it may act on the vector space — i.e. our vector space may carry a representation of that symmetry group — in which case we can apply the Thompson trick and see what if any significance the other character values have in our context.

Conway and Norton [12] did precisely what Thompson asked. Conway called it "one of the most exciting moments in my life" [11] when he opened Jacobi's foundational (but 150 year old!) book on elliptic and modular functions and found that the first few terms of the McKay-Thompson series agreed perfectly with the first few terms of certain special functions, namely the Hauptmoduls of various genus 0 modular groups. Monstrous Moonshine was officially born.

The word 'moonshine' here is English slang for 'unsubstantial or unreal'. It was chosen by Conway to convey as well the feeling that things here are dimly lit, and that Conway-Norton were 'distilling information illegally' from the Monster character table.

In fact the first incarnation of Moonshine goes back to Andrew Ogg in 1975. He was in France describing his result that the primes p for which the group $\Gamma_0(p)+$ has genus 0, are $\{2, 3, 5, 11, 13, 17, 19, 23, 29, 31, 41, 47, 59, 71\}$. $\Gamma_0(p)+$ is the group generated by $\begin{pmatrix} 0 & 1 \\ -p & 0 \end{pmatrix}$ and $\Gamma_0(p)$, and is the normaliser of $\Gamma_0(p)$ in $\mathrm{SL}_2(\mathbb{R})$ (this sentence will make a little more sense after §2.3, but it isn't important here to understand it). He also attended a lecture by Jacques Tits, who was describing a newly conjectured simple group. When Tits wrote down the prime decomposition of the order of that group (see (2.2.1) below), Ogg noticed its prime factors precisely equalled his list of primes. Presumably as a joke, he offered a bottle of Jack Daniels' whisky to the first person to explain the coincidence.

The next step was accomplished by Griess in 1980, with the construction of the Monster[21] $\mathbb{M}$, and with it the proof that the conjectured character table for $\mathbb{M}$ was correct. Griess did this by explicitly constructing the 196883-dimensional representation ρ_1; it turns out to have a (commutative nonassociative) algebra structure, now called the *Griess algebra*. Though this paper was clearly important, the construction was artificial and 100 pages long: since the Monster is presumably a natural mathematical object (see §2.2), an elegant construction for it should exist. This was ultimately accomplished in the mid 1980s with the construction by Frenkel-Lepowsky-Meurman [23] of the Moonshine module

---

[21] Griess also came up with the symbol for the Monster; Conway came up with the name.

$V^\natural$ and its interpretation by Borcherds as a *vertex operator algebra*. The Griess algebra appears naturally in $V^\natural$, as we shall see. $V^\natural$ does indeed seem to be a 'natural' mathematical structure, and $\mathbb{M}$ is its automorphism group: in fact $V^\natural$ is the graded representation V of $\mathbb{M}$ conjectured by McKay and Thompson.

Connections with physics (CFT) go back to Dixon-Ginsparg-Harvey [19] in 1988, in a paper titled "Beauty and the beast: Superconformal symmetry in a Monster module". The Moonshine module $V^\natural$ can be interpreted as the string theory for a $\mathbb{Z}_2$-orbifold of free bosons compactified on the torus $\mathbb{R}^{24}/\Lambda_{24}$ (Λ_{24} is the Leech lattice). Many aspects of Moonshine make complete sense within CFT, but some (e.g. the genus zero property) remain more obscure. (Though in 1987 Moore speculated that the 0-genus of $\Gamma_0(a)+$ could be related to the vanishing of the cosmological constant in certain string theories related to $\mathbb{M}$, and Tuite [57] related genus-zero with the conjectured uniqueness of $V^\natural$.) Nevertheless this helps make the words of Dyson ring prophetic: "I have a sneaking hope, a hope unsupported by any facts or any evidence, that sometime in the twenty-first century physicists will stumble upon the Monster group, built in some unsuspected way into the structure of the universe" [21].

Finally, in 1992 Borcherds [5] completed the proof of the Conway-Norton conjectures by showing $V^\natural$ is the desired representation V. The full conceptual relationship between the Monster and the Hauptmoduls (like j) seems to remain 'dimly lit', although much progress has been realised. This is a subject where it is much easier to conjecture than to prove, and we are still awash in unresolved conjectures.

McKay also noticed in 1978 that similar coincidences hold if $\mathbb{M}$ and $j(\tau)$ are replaced with the Lie group $E_8(\mathbb{C})$ and $(qj(q))^{\frac{1}{3}} = 1 + 248q + \cdots$. This turns out to be much easier to explain, and in 1980 both Kac and Lepowsky remarked that the unique level 1 highest-weight representation of the affine algebra $E_8^{(1)}$ has graded dimension $(qj(q))^{\frac{1}{3}}$.

Moonshiners have a little chip on their shoulders. Modern math, they say, tends to be a little too infatuated with the pursuit of generalisations for generalisations' sake. Surely a noble goal for math is to find interesting and fundamentally new theorems. It can be argued that both history and common-sense suggest that to this end it is most profitable to look simultaneously at both exceptional structures and generic structures, to understand the special features of the former in the context of the latter, and to be led in this way to a new generation of exceptional and generic structures. Moonshiners would sympathise with those biologists who study the duck-billed platypus and lungfish rather than hide them in the closet as monsters: BECAUSE they appear to be unique, those animals presumably have much to teach us about our general understanding of evolution, etc.

It often seems to people that Moonshine can't be very deep: the Conway-Norton conjectures seem to be so finite[22] and specialised. There only are 171 distinct McKay-Thompson series T_g in Monstrous Moonshine, after all. The whole point though is to try to understand *why* the Monster and the Hauptmoduls are so related, and then to try to extend and apply this understanding to other contexts. Moonshine is still young, and our understanding remains incomplete. But already math has benefitted: e.g. we now have a natural definition of $\mathbb{M}$ (as the automorphism group of $V^\natural$), and Moonshine helped lead us to the rich structures of generalised Kac-Moody algebras and vertex operator algebras.

---

[22] Indeed the Moonshine conjectures *are* finite (it is enough to check the first 1200 coefficients), and a slightly weaker form was quickly proved on a computer by Atkin, Fong and Smith [54]. However this sort of argument adds no light to Moonshine, and tells us nothing of V except that it exists.

We will see that Moonshine involves the interplay between *exceptional structures* such as the number 24, the Leech lattice Λ_{24}, the Monster group $\mathbb{M}$, and the Moonshine module $V^\natural$, and *generic structures* such as modular functions, vertex operator algebras, generalised Kac-Moody algebras, and conformal field theories. The following sections will introduce the reader to many of these structures, as we use Moonshine as another happy excuse to take a second little tour through modern mathematics.

2.2. INGREDIENT #1: FINITE SIMPLE GROUPS AND THE MONSTER

A readable introduction to the basics of finite group representation theory is [25]. The finite simple groups are described in [33]; see also [11]. Group representations were introduced in §1.3.

A *normal* subgroup H of a group is one obeying $gHg^{-1} = H$ for all $g \in G$. These are important because the set G/H of 'cosets' gH has a natural group structure precisely when H is normal. Every group has two trivial normal subgroups: itself and $\{1\}$. If these are the only normal subgroups, the group is called *simple*. It is conventional to regard the trivial group $\{1\}$ as not simple (just as 1 is conventionally regarded as not prime). An alternate definition of a (finite) simple group G is that if $\varphi : G \to H$ is any group homomorphism (i.e. structure-preserving map: $\varphi(gg') = \varphi(g)\varphi(g')$), then φ is either constant (i.e. $\varphi(G) = \{1\}$), or φ is one-to-one.

The importance of simple groups is provided by the *Jordan-Hölder Theorem*. By a 'composition series' for a group G, we mean a nested sequence

$$G = H_0 \supset H_1 \supset H_2 \supset \cdots \supset H_k \supset H_{k+1} = \{1\}$$

of groups such that H_i is normal in H_{i-1}, and H_{i-1}/H_i (called a 'composition factor') is simple. Any finite group G has at least one composition series. If $H'_0 \supset \cdots \supset H'_{\ell+1} = \{1\}$ is a second composition series for G, then Jordan-Hölder says that $k = \ell$ and, up to a reordering π, the simple groups H_{i-1}/H_i and $H'_{\pi j-1}/H'_{\pi j}$ are isomorphic.

For example, the cyclic group $\mathbb{Z}_n$ of order(=size) n — you can think of it as the integers modulo n under addition — is simple iff n is prime. Consider the group $\mathbb{Z}_{12} = \langle 1 \rangle$. Two composition series are

$$\mathbb{Z}_{12} \supset \langle 2 \rangle \supset \langle 4 \rangle \supset \langle 0 \rangle$$
$$\mathbb{Z}_{12} \supset \langle 3 \rangle \supset \langle 6 \rangle \supset \langle 0 \rangle$$

corresponding to composition factors $\mathbb{Z}_2$, $\mathbb{Z}_2$, $\mathbb{Z}_3$, and $\mathbb{Z}_3$, $\mathbb{Z}_2$, $\mathbb{Z}_2$. Of course this is consistent with Jordan-Hölder. This is reminiscent of the fact that $2 \cdot 2 \cdot 3 = 3 \cdot 2 \cdot 2$ are both prime factorisations of 12.

There is some value to regarding finite groups as a massive generalisation of the notion of number. The number n can be identified with the cyclic group $\mathbb{Z}_n$. The divisor of a number corresponds to a normal subgroup, so a prime number corresponds to a simple group. The Jordan-Hölder Theorem generalises the uniqueness of prime factorisations. That you can build up any number by multiplying primes, is generalised to building up a group by semi-direct products (more generally, by group extensions): if H is a normal subgroup of G, then G will be an extension of H by the quotient group G/H.

Note however that $\mathbb{Z}_6 \times \mathbb{Z}_2$ and $\mathfrak{S}_3 \times \mathbb{Z}_2$ — both different from $\mathbb{Z}_{12}$ — will also have $\mathbb{Z}_2, \mathbb{Z}_2, \mathbb{Z}_3$ as composition factors: unlike for numbers, 'multiplication' here does not give a unique answer. The semidirect product $\mathbb{Z}_2 \rtimes \mathbb{Z}_2$ can equal either $\mathbb{Z}_4$ or $\mathbb{Z}_2 \times \mathbb{Z}_2$, depending on how the product is taken. More precisely, the notation $G \rtimes G'$ means a group where every element can be written uniquely as a pair (g, g'), for $g \in G$ and $g' \in G'$, and where the group operation is $(g, g')(h, h') = (\text{stuff}, gh)$.

Thus simple groups have an importance for group theory approximating what primes have for number theory. One of the greatest accomplishments of twentieth century math is surely the classification of the finite simple groups. (On the other hand, group extensions turn out to be technically quite difficult and leads one into group cohomology.) This work, completed in the early 1980s (although gaps are continually being discovered and filled in the arguments), runs to approximately 15 000 journal pages, spread over 500 individual papers, and is the work of a whole generation of group theorists. A modern revision is currently underway (see e.g. [34]) to simplify the proof and find and fill all gaps, but the final proof is still expected to be around 4000 pages long. The resulting list is:

- the cyclic groups $\mathbb{Z}_p$ (p a prime);
- the alternating groups $\mathfrak{A}_n$ for $n \geq 5$;
- 16 families of Lie type;
- 26 sporadics.

We've already met the cyclic groups. The alternating group $\mathfrak{A}_n$ consists of the even permutations in the symmetric group $\mathfrak{S}_n$, and so has order(=size) $\frac{1}{2}\,n!$. The groups of Lie type are essentially Lie groups defined over finite fields[23] $\mathbb{F}_q$ (such as $\mathbb{Z}_p$), sometimes 'twisted' in certain senses. The simplest example is $\mathrm{PSL}_n(\mathbb{F}_q)$, which consists of the $n \times n$ matrices with entries in $\mathbb{F}_q$, with determinant 1, quotiented out by the centre of $\mathrm{SL}_n(\mathbb{F}_q)$ (namely the scalar matrices $\mathrm{diag}(a, a, \ldots, a)$ for $a^n = 1$) (except for $\mathrm{PSL}_2(\mathbb{Z}_2)$ and $\mathrm{PSL}_2(\mathbb{Z}_3)$, which aren't simple).

Note that the determinant $|\rho(g)|$ for any representation ρ of any (noncyclic) simple group must be 1, otherwise we would violate the homomorphism definition of simple group (try to see why). Also, the centre of any (noncyclic) simple group must be trivial (why?). The smallest noncyclic simple group is $\mathfrak{A}_5$, with order 60.[24] It is the same as (isomorphic to) $\mathrm{PSL}_2(\mathbb{Z}_5)$ and $\mathrm{PSL}_2(\mathbb{F}_4)$, and can also be expressed as the group of all rotations (reflections have determinant -1 and so cannot belong to any simple group) of $\mathbb{R}^3$ that bring a regular icosahedron back to itself.

---

[23] There is a finite field with q elements, iff q is a power of a prime. For each such q, there is only 1 field of that size. The field with prime p elements is the integers taken mod p.

[24] This implies, incidentally, that if G and H are any two groups with the same order below 60, then they will have the same composition factors.

The smallest sporadic group is the Mathieu group M_{11}, order 7920, discovered in 1861[25]. The largest is the Monster $\mathbb{M}$, conjectured by Fischer and Griess in 1973 and finally proved to exist by Griess in 1980. Its order is[26]

$$\|\mathbb{M}\| = 2^{46} \cdot 3^{20} \cdot 5^{9} \cdot 7^{6} \cdot 11^{2} \cdot 13^{3} \cdot 17 \cdot 19 \cdot 23 \cdot 29 \cdot 31 \cdot 41 \cdot 47 \cdot 59 \cdot 71 \approx 8 \times 10^{53} \ . \quad (2.2.1)$$

20 of the 26 sporadics are involved in (i.e. are quotients of subgroups of) the Monster. Some relations among $\mathbb{M}$, the Leech lattice Λ_{24} and the largest Mathieu group M_{24} are given in Chapters 10 and 29 of [13].

Moonshine hints at a tantalising connection between the classification of finite simple groups, and the classification of RCFTs discussed in Part 1. Speculates [23] (page xli): "One can certainly hope for a uniform description of the finite simple groups as automorphism groups of certain vertex operator algebras — or conformal quantum field theories. If such a quantum field theory could somehow be attached a priori to a finite simple group, the classification of such theories, a problem of great current interest among string theorists, might some day be part of a new approach to the classification of the finite simple groups. On the other hand, can the known classification of the finite simple groups help in the classification of conformal field theories?"

2.3. INGREDIENT #2: MODULAR FUNCTIONS AND HAUPTMODULS

A readable introduction to some of the topics discussed in this section is [16,42,60].

We know from complex analysis that the group $\mathrm{SL}_2(\mathbb{R})$ of 2×2 matrices with real entries and determinant 1, acts on the upper-half plane $\mathcal{H} = \{\tau \in \mathbb{C} \,|\, \mathrm{Im}(\tau) > 0\}$ by fractional linear (or *Möbius*) transformations:

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} \cdot \tau := \frac{a\tau + b}{c\tau + d} \ . \quad (2.3.1)$$

For example the matrix $S := \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ corresponds to the function $\tau \mapsto -1/\tau$, while the matrix $T := \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ corresponds to the translation $\tau \mapsto \tau + 1$. Since $\pm \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ correspond to the same Möbius transformation, strictly speaking our group here is $\mathrm{PSL}_2(\mathbb{R}) = \mathrm{SL}_2(\mathbb{R})/\{\pm I\}$.

The only reason this action (2.3.1) of the 2×2 matrices on complex numbers (or more precisely the Riemann sphere $\mathbb{C} \cup \{\infty\}$) might not look strange to us, is because familiarity breeds numbness. What we really have is a natural action of $n \times n$ matrices on $\mathbb{C}^n$, and this induces their action on $\mathbb{C}^{n-1}$ (together with a codimension-2 set of 'points at infinity') by interpreting $\mathbb{C}^n$ as projective coordinates for $\mathbb{C}^{n-1}$. Specialising to $n = 2$ gives us (2.3.1). In projective geometry, 'parallel lines' intersect at ∞. Projective coordinates allow one to treat 'finite' and 'infinite' points on an equal footing.

---

[25] Although his arguments apparently weren't very convincing. In fact some people, including the Jordan of Jordan-Hölder fame, argued in later papers that the largest of Mathieu's sporadic groups couldn't exist.

[26] The inquisitive reader, hungry for more 'coincidences', may have noticed that 196883 and 21296876 — see (2.1.2) — exactly divide the order of the Monster. Indeed this will hold for any finite group: the dimensions of the irreducible representations of a finite group will always divide its order.

Consider $\Gamma := \mathrm{SL}_2(\mathbb{Z})$, the subgroup of $\mathrm{SL}_2(\mathbb{R})$ consisting of the matrices with integer entries. It can be shown that it is generated by S and T (in other words, every matrix $\alpha \in \Gamma$ can be expressed as a monomial in S and T). For reasons that will be clear shortly, consider the extended upper-half plane $\overline{\mathcal{H}} := \mathcal{H} \cup \{\mathrm{i}\infty\} \cup \mathbb{Q}$ — the extra points $\{\mathrm{i}\infty\} \cup \mathbb{Q}$ are called *cusps*. Γ acts on $\overline{\mathcal{H}}$ (e.g. S interchanges 0 and $\mathrm{i}\infty$). By a *modular function* for Γ, we mean a meromorphic function $f : \overline{\mathcal{H}} \to \mathbb{C}$, symmetric with respect to Γ: i.e. $f(\alpha(\tau)) = f(\tau)$ for all $\alpha \in \Gamma$. Note that we require f to be meromorphic at the cusps (e.g. polynomials are meromorphic at $\mathrm{i}\infty$, but e^z is not).

It is not obvious why modular functions should be interesting, but in fact they are one of the most fundamental notions in modern number theory (see the last paragraph of §1.6). For example, consider the question of writing numbers as sums of squares. We can write $5 = 1^2 + (-2)^2 = (-1)^2 + 1^2 + 0^2 + 1^2 + (-1)^2$, to give a couple of trivial examples. Let $N_n(k)$ be the number of ways we can write the integer n as a sum of k squares, counting order and signs. For example $N_5(1) = 0$ (since 5 is not a perfect square), $N_5(2) = 8$ (since $5 = (\pm 1)^2 + (\pm 2)^2 = (\pm 2)^2 + (\pm 1)^2$), $N_5(3) = 24$, etc. Their generating functions are:[27]

$$\sum_{n=0}^{\infty} N_n(k)\, q^n = (\theta_3(q))^k \ ,$$

where

$$\theta_3(q) = 1 + 2q + 2q^4 + \cdots = \sum_{n \in \mathbb{Z}} q^{n^2}$$

is called a *theta function*. It turns out that θ_3 transforms nicely with respect to Γ, once we make the change-of-variables $q = \exp[\pi \mathrm{i} \tau]$. This takes work to show. For example, θ_3 is clearly invariant under the action of $\begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}$, and a little work (from e.g. Poisson summation) shows that $\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ takes $\theta_3(\tau)$ to $\sqrt{\frac{\tau}{\mathrm{i}}}\,\theta_3(\tau)$. θ_3 is not precisely a modular function (it is a 'modular form of weight $\frac{1}{2}$' for $\Gamma_0(4)$), but this simple example illustrates the point that Γ (and related groups) appear throughout number theory. More on this shortly.

That important change-of-variables $q = \exp[\pi \mathrm{i} \tau]$ was introduced by Jacobi early last century, in his analysis of 'elliptic integrals'. The theory is beautiful and poorly remembered today, which is very disappointing considering how much of modern math was touched by it. I strongly recommend the book [10], written over a century ago; the style and motivation of math in our century is different from that in Jacobi's, and we've lost a little in motivation what we've gained in power. I'll briefly sketch Jacobi's theory.

---

[27] A fundamental principle in math is: whenever you have a subscript with an infinite range, make a power series (called a *generating function*) out of it.

Just as we could develop a theory of 'circular functions' (i.e. sine etc.) starting from the integral $s(a) = \int_0^a \frac{dx}{\sqrt{1-x^2}}$, so can we develop a theory of 'elliptic functions' starting from the 'elliptic integral' $F(k,a) = \int_0^a \frac{dx}{\sqrt{(1-x^2)(1-k^2x^2)}}$. Inverting $s(a)$ gives a function both more useful and with nicer properties than $s(a)$: we call it $\sin(u)$. Similarly, for any k the elliptic function $\mathrm{sn}(k,u)$ is defined by $u = F(k, \mathrm{sn}(k,u))$. Just as we can define a numerical constant π by $\sin(\frac{1}{2}\pi) = 1$ (i.e. $\frac{1}{2}\pi = \int_0^1 \frac{dx}{\sqrt{1-x^2}}$), we get a function $K(k) = \int_0^1 \frac{dx}{\sqrt{(1-x^2)(1-k^2x^2)}}$. Just as $\sin(u)$ has period $4(\frac{1}{2}\pi)$, so has sn u-period $4K(k)$. sn also turns out to have u-period $4\mathrm{i}\,K(k')$ where $k' = \sqrt{1-k^2}$ — today we take this as the starting point and define an elliptic function to be doubly periodic (see [42] or Cohen in [60]).

The theta functions aren't elliptic functions, but they are closely related, and e.g. sn can be written as a quotient of them. In Jacobi's language, we have

$$\theta_3(\frac{\mathrm{i}\,K(k')}{K(k)}) = \sqrt{\frac{2K(k)}{\pi}}\ .$$

The 'modular transformation' $\tau \mapsto \frac{-1}{\tau}$ corresponds to interchanging the 'modulus' k with the 'complementary modulus' k', and thus is completely natural in Jacobi's theory. The important formula $\theta_3(\frac{-1}{\tau}) = \sqrt{\frac{\tau}{\mathrm{i}}}\,\theta_3(\tau)$ is trivial here.

A certain interpretation of modular functions also indicates their usefulness, and played an important role in Part 1. A *torus* is something that looks like the surface of a bagel, at least as far as its topology is concerned. For example, the Cartesian product $S^1 \times S^1$ of circles is a torus (think of one circle being the contact-circle of the bagel with the table on which it rests, then from each point on that horizontal circle imagine placing a vertical circle perpendicular to it, like a rib; together all these ribs fill out the bagel's surface). A more sophisticated example of a torus is an elliptic curve (a complex curve of the form $y^2 = ax^3 + bx^2 + cx + d$ and a special point on it playing the role of 0). A final example is the quotient $\mathbb{C}/\Lambda$ of the complex plane $\mathbb{C}$ with a 2-dimensional lattice Λ (we saw lattices in §1.6; Λ here will be a discrete doubly-periodic set of points in $\mathbb{C}$, containing 0). It turns out that certain equivalence classes of tori (e.g. with respect to conformal or complex-analytic equivalence) always contain a representative torus of the form $\mathbb{C}/\Lambda$, where Λ consists of all points $\mathbb{Z} + \mathbb{Z}\,\tau$, for some $\tau \in \mathcal{H}$. (Incidentally, the cusps correspond to degenerate tori.) In other words, these equivalence classes are parametrized by complex numbers τ in $\mathcal{H}$. So if we have a complex-valued function F on the set of all tori, which is e.g. conformally invariant (an example is the genus-one partition function $\mathcal{Z}$ in conformal field theories — see §1.1), then we can consider F as a well-defined function $F : \mathcal{H} \to \mathbb{C}$. However, it turns out that different points τ in $\mathcal{H}$ correspond to the same equivalence class of tori: e.g. the lattice for τ is the same as that for $\tau + 1$, and these are a rescaling of that for $-1/\tau$. Thus $F(\tau) = F(\tau+1) = F(-1/\tau)$, because $\tau, \tau+1, -1/\tau$ all represent equivalent tori. Since $\tau \mapsto \tau + 1$ and $\tau \mapsto -1/\tau$ generate $\mathrm{PSL}_2(\mathbb{Z})$, what in fact we find is that F has Γ as its group of symmetries. One often says that Γ is the 'modular group of the torus', and that the orbit space $\Gamma\backslash\mathcal{H}$ is the 'moduli space' of (conformal equivalence classes of) tori. $\mathcal{H}$ is called its 'Teichmüller space' or 'universal cover'. This is exactly analogous to $S^1 = \mathbb{R}/\mathbb{Z}$: $\mathbb{R}$ is its universal cover and $\mathbb{Z}$ is its 'modular group' (or 'mapping class group'). Another example: the Teichmüller space for (conformal equivalence classes of) 'pair-of-pants', or equivalently a disc minus two open interior disks, is $\mathbb{R}^3$ (an ordered triple), while its modular group is the symmetric group $\mathfrak{S}_3$ and its moduli space consists of unordered triples. Incidentally, we write $\Gamma\backslash\mathcal{H}$ instead of $\mathcal{H}/\Gamma$ because the group Γ acts on $\mathcal{H}$ 'on the left'. A good introduction to the geometry here is [55].

In any case, a surprising number of innocent-looking questions in number theory can be dragged (usually with effort) into the richly developed realm of elliptic curves and modular functions, and it is there they are often solved. For instance, we all know the ancient Greeks were interested in Pythagorean triples: find all integer solutions a, b, c to $a^2 + b^2 = c^2$, i.e. find all integer (or if you prefer, rational) right-angle triangles. They solved this by elementary means: choose any integers (or rationals) x, y and put $u = \frac{x^2-y^2}{x^2+y^2}$, $v = \frac{2xy}{x^2+y^2}$; then $u^2 + v^2 = 1$ and (multiplying by the denominator) this gives all Pythagorean triples.

There are two ways of extending this problem. One is to ask which $n \in \mathbb{Z}$ can arise as areas of these rational right-angle triangles. It turns out $n = 5$ is the smallest one: $a = \frac{3}{2}$, $b = \frac{20}{3}$, $c = \frac{41}{6}$ works ($5 = \frac{1}{2}(\frac{3}{2})(\frac{20}{3})$ and $(\frac{3}{2})^2 + (\frac{20}{3})^2 = (\frac{41}{6})^2$). This is a hard problem — just try to show $n = 1$ cannot work. $n = 157$ turns out to work: the simplest triangle has a and b as quotients of integers of size around 10^{25}, and c as the quotient of integers around 10^{47}. Although this problem was studied by the ancient Greeks and also by the Arabs in the 10th century, it was finally cracked in the 1980s. It was solved by first translating it into the question of whether the elliptic curve $y^2 = x^3 - n^2x$ has infinitely-many rational points, and then applying all the rich 20th century machinery to answering that question.

The other continuation of the Pythagorean triples question is more famous: find all integer solutions to $a^n + b^n = c^n$ (or equivalently all rational solutions to $a^n + b^n = 1$). 350 years ago Fermat wrote in the margin of the book he was reading (the book was describing the Greek solution to Pythagorean triples) that he had found a "truly marvelous" proof that for $n > 2$ there are no nontrivial solutions, but that the margin was too narrow to contain it. This result came to be known as 'Fermat's Last Theorem'[28] and despite considerable effort no one has succeeded in rediscovering his proof. Most people today believe that Fermat soon realised his 'proof' wasn't valid, otherwise he would have alluded to it in later letters. In any case, a very long and complicated proof was finally achieved in the 1990s: the 'Taniyama conjecture' says that a certain function associated to any elliptic curve over $\mathbb{Q}$ will be modular; if $a^n + b^n = c^n$ for some $n > 2$, then the elliptic curve $y^2 = x^3 + (a^n - b^n)x^2 - a^nb^n$ will violate the Taniyama conjecture; finally Wiles proved the Taniyama conjecture is true.

To most mathematicians, the 'area-n problem' and 'Fermat's Last Theorem' are interesting only because they can be related to elliptic curves and modular forms — it's easy to ask hard questions in math, but most questions tend to be stale. Number theory is infatuated with modular stuff because (in increasing order of significance) (a) it's exceedingly rich, with lots of connections to other areas of math and math phys; (b) it's a battleground on which many innocent-looking but hard-to-crack problems can be slain; and (c) last generation's number theorists also worked on modular stuff.

---

[28] It was called his 'Last Theorem' because it was the last of his 48 margin notes to be proved by other mathematicians — another one is discussed in Section 1.8. The story of Fermat's Last Theorem is a fascinating one, but alas this footnote is too small to do it credit. See for instance the excellent book [53].

In any case, modular functions turn out to be important for math (and mathematical physics) even though they may at first glance look artificial. Poincaré explained how to study them. He said to look at the orbits of $\overline{\mathcal{H}}$ with respect to Γ. For example, one orbit, hence one point in $\Gamma\backslash\overline{\mathcal{H}}$, contains all cusps. We write this as $\Gamma\backslash\overline{\mathcal{H}}$, and give it the natural topological structure (i.e. 2 points $[\tau], [\tau'] \in \Gamma\backslash\overline{\mathcal{H}}$ are considered 'close' if the 2 sets $\Gamma\tau, \Gamma\tau'$ nearly overlap). Note first that by applying T repeatedly, every point in $\mathcal{H}$ corresponds to a point in the vertical strip $-\frac{1}{2} \leq \mathrm{Re}(\tau) \leq \frac{1}{2}$ — in fact to a unique point in that strip, if we avoid the two edges. S is an inversion through the unit circle, so it permits us to restrict to those points in the vertical strip which are distance at least 1 from the origin. The resulting region R is called a fundamental region for Γ. Apart from the boundary of R, every Γ-orbit will intersect R in one and only one point.

What should we do about the boundary? Well, the edge $\mathrm{Re}(\tau) = -\frac{1}{2}$ gets mapped by T to the edge $\mathrm{Re}(\tau) = \frac{1}{2}$, so we should identify (=glue together) these. The result is a cylinder running off to infinity, with a strange lip at the bottom. S tells us how we should close that lip: identify $\mathrm{i}e^{\mathrm{i}\theta}$ and $\mathrm{i}e^{-\mathrm{i}\theta}$. This seals the bottom of the cylinder, so we get an infinitely tall cup with a strangely puckered base. In fact the top of this cup is also capped off, by the cusp $\mathrm{i}\infty$. So what we have (topologically speaking) is a *sphere.* It does not look like a smooth sphere, but in fact it inherits the smoothness of $\mathcal{H}$.

Incidentally, topological manifolds of dimension ≤ 3 always have a unique compatible smooth structure. 'Topological structure' means you can speak of continuity or closeness, 'smooth structure' means you can also do calculus. On the other hand, $\mathbb{R}^4$ has infinitely many smooth structures compatible with its topological structure; mysteriously, all other Euclidean spaces $\mathbb{R}^n$ have a unique smooth structure! Thus both mathematics and physics single out 4-space. Coincidence???

So anyways, what this construction of $\Gamma\backslash\overline{\mathcal{H}}$ means is that a modular function can be reinterpreted as a meromorphic complex-valued function on this sphere. This is very useful, because our undergraduate complex variables class taught us all about meromorphic complex-valued functions f on the Riemann sphere $\mathbb{C} \cup \infty$. There are many meromorphic functions on $\mathbb{C}$, but to also be meromorphic at ∞ forces f to be *rational*, i.e. $f(w) = \frac{\text{some polynomial } P(w)}{\text{some polynomial } Q(w)}$, where w is the complex parameter on the Riemann sphere. So our modular function $f(\tau)$ will simply be some rational function P/Q evaluated at the change-of-variables function $w = c(\tau)$ which maps us from our sphere $\Gamma\backslash\overline{\mathcal{H}}$ to the Riemann sphere. There are many different choices for this function $c(\tau)$, but the standard one is $c(\tau) = j(\tau)$, the j-function of (2.1.1)[29]. Thus, any modular function can be written as a rational function $f(\tau) = P(j(\tau))/Q(j(\tau))$ in the j-function. Conversely, any such function will be modular.

This is analogous to saying that any function $g(x)$ periodic under $x \mapsto x + 1$ can be thought of as a function on the unit circle $S^1 \subset \mathbb{C}$ evaluated at the change-of-variables function $x \mapsto e^{2\pi \mathrm{i}x}$, and hence has a Fourier expansion $\sum_n g_n \exp[2\pi \mathrm{i}nx]$.

---

[29] Historically, j was the standard choice, but in Moonshine the preferred choice would be the function $J = j - 744$ with zero constant term.

We can generalise this argument. Consider a subgroup G of $\mathrm{SL}_2(\mathbb{R})$ which is both not too big, and not too small. 'Not too big' means it should be *discrete*, i.e. the matrices in G can only get so close to the identity matrix $\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$. To make sure G is 'not too small', it is enough to require that G contains some subgroup of the form

$$\Gamma_0(N) := \{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}_2(\mathbb{Z}) \,|\, c \equiv 0 \pmod{N} \} \ , \tag{2.3.2a}$$

i.e. G must contain all matrices in Γ whose bottom-left entry is a multiple of N. So G must contain T, for example. We will also be interested only in those G which obey

$$\begin{pmatrix} 1 & t \\ 0 & 1 \end{pmatrix} \in G \ \Rightarrow \ t \in \mathbb{Z} \tag{2.3.2b}$$

i.e. the only translations in G are by integers. We will call a function $f : \overline{\mathcal{H}} \to \mathbb{C}$ a *modular function for* G if it is meromorphic (including at the cusps $\mathbb{Q} \cup \{\mathrm{i}\infty\}$), and if also f is symmetric with respect to G: $f \circ \alpha = f$ for all $\alpha \in G$. This implies we will be able to expand f as a Laurent series in q. We analyse this as before: look at the orbit space $\Sigma = G\backslash\overline{\mathcal{H}}$; because G is not too big, Σ will be a (Riemann) surface; because G is not too small, Σ will be compact.

The compact Riemann surfaces have been classified (up to homeomorphism — i.e. considering only topology as relevant), and are characterised by a number called the *genus*. Genus 0 is a sphere, genus 1 is a torus, genus 2 is like two tori resting side-by-side, etc. For example, the surface of a wine glass, or a fork, is topologically a sphere, while a coffee cup and a key will (usually) be tori. Eye glasses with the lenses popped out is a 2-torus, while a ladder with n rungs on it has genus $n-1$.

We will call G 'genus g' if its surface Σ has genus g. For example, $G = \Gamma_0(2)$ and $G = \Gamma_0(25)$ are both genus 0, while $\Gamma_0(50)$ is genus 2 and $\Gamma_0(24)$ is genus 3. Once again, we are interested here in the genus 0 case. As before, this means that there is a change-of-variables function we'll denote J_G which has the property that it's a modular function for G, and all other modular functions for G can be written as a rational function in it. Because of (2.3.2), we can choose J_G to look like

$$J_G(\tau) = q^{-1} + a_1(G)\, q + a_2(G)\, q^2 + \cdots$$

So J_G plays exactly the same role for G that $J := j - 744$ plays for Γ. J_G is called the Hauptmodul for G. (Incidentally for genus > 0, two generators, not one, are needed.)

For example, $\Gamma_0(2)$, $\Gamma_0(13)$ and $\Gamma_0(25)$ are all genus 0, with Hauptmoduls

$$J_2(\tau) = q^{-1} + 276\, q - 2048\, q^2 + 11202\, q^3 - 49152\, q^4 + 184024\, q^5 + \cdots \tag{2.3.3}$$

$$J_{13}(\tau) = q^{-1} - q + 2\, q^2 + q^3 + 2\, q^4 - 2\, q^5 - 2\, q^7 - 2\, q^8 + q^9 + \cdots \tag{2.3.4}$$

$$J_{25}(\tau) = q^{-1} - q + q^4 + q^6 - q^{11} - q^{14} + q^{21} + \cdots \tag{2.3.5}$$

The smaller the modular group, the smaller the coefficients of the Hauptmodul. In this sense, the j-function is optimally bad among the Hauptmoduls: e.g. for it $a_{23} \approx 10^{25}$.

An obvious question is, how many genus 0 groups (equivalently, how many Hauptmoduls) are there? It turns out that $\Gamma_0(p)$ is genus 0, for a prime p, iff $p-1$ divides 24. Thompson in 1980 proved that for any g, there are only finitely many genus g groups obeying our two conditions (2.3.2). In particular this means there are only finitely many Hauptmoduls. Over 600 Hauptmoduls with integer coefficients $a_i(G)$ are presently known.

2.4. THE MONSTROUS MOONSHINE CONJECTURES

We are now ready to make precise the main conjecture of Conway and Norton [12]. (We should emphasise though that there have been several other conjectures, some of which turned out to be partially wrong.)

They conjectured that for each element g of the Monster $\mathbb{M}$, there is a Hauptmodul

$$J_g(\tau) = q^{-1} + \sum_{n=1}^{\infty} a_n(g)\, q^n \tag{2.4.1}$$

for a genus 0 group G_g such that each coefficient $a_n(g)$ is an integer, and for each n the map $g \mapsto a_n(g)$ is a character of $\mathbb{M}$. They also conjectured that G_g contains $\Gamma_0(N)$ as a normal subgroup, for some N depending on the order of g.

Another way of saying this is that there exists an infinite-dimensional graded representation $V = V_{-1} \oplus \bigoplus_{n=1}^{\infty} V_n$ of $\mathbb{M}$ such that the McKay-Thompson series $T_g(\tau)$ in (2.1.4) is a Hauptmodul.

There are around 8×10^{53} elements to the Monster, so naively we may expect around 8×10^{53} different Hauptmoduls $J_g = T_g$. However the character of a representation evaluated at g and at hgh^{-1} will always be the same, so $J_g = J_{hgh^{-1}}$. Hence the relevant quantity is the number of conjugacy classes, which for $\mathbb{M}$ is only 194. Moreover, a character evaluated at g^{-1} will always be the complex conjugate of its value at g, but here all character values $\chi_{V_n}(g)$ are integers (according to the conjecture). Thus $J_g = J_{g^{-1}}$. The total number of distinct Hauptmoduls J_g arising in Monstrous Moonshine turns out to be only 171.

For example, if we choose g to be the identity, we recover $T_{id.} = J$. It turns out that there are precisely 2 different conjugacy classes of order 2 elements, one of them giving the Hauptmodul J_2 in (2.3.3). Similarly for 13, but J_{25} doesn't correspond to any conjugacy class of $\mathbb{M}$.

Moonshine provides an explanation for a forgotten mystery of classical mathematics: why are the coefficients of the j-function *positive* integers? On the other hand, that they are *integers* has long been important to number theory (complex multiplication, class field theory — see e.g. [16]).

There are lots of other less important conjectures. One which played a role in ultimately proving the main conjecture involves the *replication formulae*. Conway-Norton want to think of the Hauptmoduls J_g as being intimately connected with $\mathbb{M}$; if so, then the group structure of $\mathbb{M}$ should somehow directly relate different J_g. In particular, consider the power map $g \mapsto g^p$. Now, it was well-known that $j(\tau)$ has the property that $j(p\tau) + j(\frac{\tau}{p}) + j(\frac{\tau+1}{p}) + \cdots + j(\frac{\tau+p-1}{p})$ equals a polynomial in j, for any prime p (*sketch* *of proof:* it's a modular function for Γ, and hence equals a rational function of j; since its only poles will be at the cusps, the denominator polynomial must be trivial). Hence the same will hold for J. Explicitly we get

$$J(2\tau) + J(\frac{\tau}{2}) + J(\frac{\tau+1}{2}) = J^2(\tau) - 2a_1 \tag{2.4.2a}$$

$$J(3\tau) + J(\frac{\tau}{3}) + J(\frac{\tau+1}{3}) + J(\frac{\tau+2}{3}) = J^3(\tau) - 3a_1 J(\tau) - 3a_2 \tag{2.4.2b}$$

where $J(\tau) = \sum_k a_k q^k$. Slightly more complicated formulas hold in fact for any composite n. Conway and Norton conjectured that these formulas have an analogue for the Moonshine functions J_g in (2.4.1). In particular, (2.4.2) become for any $g \in \mathbb{M}$

$$J_{g^2}(2\tau) + J_g(\frac{\tau}{2}) + J_g(\frac{\tau+1}{2}) = J_g^2(\tau) - 2a_1(g) \tag{2.4.3a}$$

$$J_{g^3}(3\tau) + J_g(\frac{\tau}{3}) + J_g(\frac{\tau+1}{3}) + J_g(\frac{\tau+2}{3}) = J_g^3(\tau) - 3a_1(g)\, J_g(\tau) - 3a_2(g). \tag{2.4.3b}$$

These are examples of the replication formulae.

'Replication' concerns the power map $g \mapsto g^n$ in $\mathbb{M}$. Can Moonshine see more of the group structure of $\mathbb{M}$? A step in this direction was made by Norton [47], who associated a Hauptmodul to commuting elements g, h in $\mathbb{M}$. Physically [19], this corresponds to orbifold traces, i.e. the $V^\natural$ RCFT with boundary conditions twisted by g and h in the 'time' and 'space' directions. Still, we would like to see more of $\mathbb{M}$ in Moonshine.

An important part of the Monstrous Moonshine conjectures came a few years after [12]. Frenkel-Lepowsky-Meurman [23] constructed a graded infinite-dimensional representation $V^\natural$ of $\mathbb{M}$ and conjectured (correctly) that it is the representation in (2.1.4). $V^\natural$ has a very rich algebraic structure, which will be discussed in §2.6.

A major claim of [23] was that $V^\natural$ is a 'natural' structure (hence their notation). To see what they mean by that, it's best to view another simpler example of a natural construction: that of the *Leech lattice* Λ_{24}. Recall the discussion of (root) lattices in §1.6.

Λ_{24} is one of the most interesting lattices, and is related to Moonshine. It can be defined using 'laminated lattices'. Start with the 0-dimensional lattice $\Lambda_0 = \{0\}$, which consists of just a single point. Use it to construct a 1-dimensional lattice, with minimal (nonzero) norm 4, built out of infinitely many copies of Λ_0 laid side by side. The result of course is simply the even integers $2\mathbb{Z}$, which we will call here Λ_1. Now construct a 2-dimensional lattice, of minimum norm 4, built out of infinitely many copies of Λ_1 laid next to each other. There are lots of ways to do this, but choose the densest lattice possible. The result is unique: it is the hexagonal lattice A_2 scaled by a factor of $\sqrt{2}$: call it Λ_2. Continue in this way: Λ_3, Λ_4, Λ_5, Λ_6, Λ_7, and Λ_8 will be the root lattices A_3, D_4, D_5, E_6, E_7 and E_8, respectively, all scaled by $\sqrt{2}$. See [13] chapter 6 for a more complete treatment of laminated lattices.

The 24th repetition of this construction yields the Leech lattice. It is the unique 24-dimensional self-dual lattice with no norm-2 vectors, and provides among other things the densest known packing of 23-dimensional spheres in $\mathbb{R}^{24}$. Many of its properties are discussed throughout [13]. So lamination provides us with a sort of no-input construction of the Leech lattice, and a good example of the mathematical meaning of 'natural'. After dimension 24, it seems chaos results from the lamination procedure (there are 23 different 25-dimensional lattices that have an equal right to be called Λ_{25}, and over 75 000 are expected for Λ_{26}).

It is natural to ask about Moonshine for other groups. There is a partial Moonshine for the Mathieu groups M_{24} and M_{12} (which have about 2×10^8 and 10^5 elements resp.), the automorphism group .0 of Λ_{24} (which has about 8×10^{18} elements), and a few others — see e.g. [49]. These groups are either simple or almost simple (e.g. .0 is the direct product of $\mathbb{Z}_2$ with the simple group .1). More generally, there will be some sort of Moonshine for any group which is the automorphism group of a vertex operator algebra; the finite simple groups of Lie type should be automorphism groups of VOAs closely related to the affine algebras except defined over fields like $\mathbb{Z}_p$.

There is a geometric side to Moonshine, associated to names like Lian-Yau and Hirzebruch. In particular, Hirzebruch's 'prize question' asks for the construction of a 24-dimensional manifold on which $\mathbb{M}$ acts, whose twisted elliptic genus are the McKay-Thompson series. This is still open.

It should be emphasised that Monstrous Moonshine is a completely unexpected connection between finite groups and modular functions. Although there has been enormous progress in our understanding of this connection (so much so, that Richard Borcherds won the 1998 Fields medal for his work on this), there still is mystery at its heart. In particular, that $\mathbb{M}$ is associated with *modular functions* can be explained mathematically by it being the automorphism group of the Moonshine VOA $V^\natural$, and physically by the associated RCFT, but what is so special about $\mathbb{M}$ that these modular functions should be genus 0? We will come back to this in §2.9.

2.5. Formal Power Series

Vertex (operator) algebras (VOAs) are a mathematically precise formulation of the notion of *W-algebra* or *chiral algebra*[30] which is so central to conformal field theory (see §1.1). VOAs were first defined by Borcherds, and their theory has since been developed by a number of people (Frenkel, Lepowsky, Meurman, Zhu, Dong, Li, Mason, Huang, ...). Because our primary motivation here is Moonshine, I will only focus on one aspect of their theory (the connection with Lie algebras). Useful to consult while reading this review are the notes [27] — they take a more analytic approach to many of the things we discuss, and their approach (namely that of CFT) motivates beautifully much of VOA theory.

In quantum field theory the basic object is the quantum field, which roughly speaking is a choice of operator $\hat{A}(x)$ at each space-time point x. 'Operator' means something that 'operates on' functions or vectors. E.g. an indefinite integral is an operator, as is a derivative. The operators in the QFT act on the space spanned by the states $|\star\rangle$, and together form an infinite-dimensional vector space (e.g. a C^* algebra) — this infinite-dimensionality of QFT is a major source of its mathematical difficulties, and QFT still has not been put on completely satisfactory mathematical grounds.

---

[30] An alternate (and much more complicated) mathematical formulation of chiral algebra is due to Beilinson and Drinfeld, and belongs to algebraic geometry. See [28] for a good — but still difficult — review.

But another difficulty is that the quantum field $\hat{A}$ really isn't an operator-valued *function* of space-time. 'Function' is too narrow a concept. For example, one of the most familiar 'functions' in quantum mechanics is the Dirac delta $\delta(x)$. You see it for example in the canonical commutation relations: e.g. for a scalar field $\hat{\varphi}$, we have $[\hat{\varphi}(\vec{x},t), \frac{\partial}{\partial t}\hat{\varphi}(\vec{y},t)] = \mathrm{i}\hbar\delta^3(\vec{x}-\vec{y})$. $\delta(x)$ has the property that for any other smooth function f,

$$\int_{-1}^{1} f(y)\,\delta(y)\,\mathrm{d}y = f(0)\ , \qquad \int_{-1}^{1} f(y)\,\delta'(y)\,\mathrm{d}y = f'(0)\ ,$$

etc. The problem is that $\delta(x)$ isn't a function — no function could possibly have those properties.

One way to make sense of 'functions' like the Dirac delta and its derivatives is distribution theory. Although it was first informally used in physics, it was rigourously developed around 1950 by Laurent Schwartz, and uses the idea of test functions. See e.g. [15].

What I will describe now is an alternate approach, *algebraic* as opposed to *analytic*. These two approaches are not equivalent: you can do some things in one approach which you can't do in the other. But the algebraic approach is considerably simpler technically — no calculus or convergence to worry about — and it is remarkable how much can still be captured. This approach is the starting point for the VOA story described next section, and was first created around 1980 by Garland and Date-Kashiwara-Miwa. Keep in mind that what we are trying to capture is an operator-valued 'function' on space-time. Space-time in CFT is 2-dimensional, and so we can think of it (at least locally) as being on the complex plane $\mathbb{C}$ (more precisely, we will usually associate the space-time point (x,t) with the complex number $z = e^{t+\mathrm{i}x}$). Good introductions to the material in this section are [23,39,31].

Let W be any vector space. We are most interested in it being an infinite-dimensional space of matrices (i.e. operators on an infinite-dimensional space), but forget that for now. Define $W[[z,z^{-1}]]$ to be the set of all formal series $\sum_{n=-\infty}^{\infty} w_n z^n$, where the coefficients w_n lie in our space W. We don't ask here whether a given series converges or diverges — z is merely a formal variable. We will also be interested in $W[z,z^{-1}]$ (Laurent polynomials). We can add these formal series in the usual way, and multiply them by numbers (scalars) in the usual way.

Remember our ultimate aim here: we want to capture quantum fields. So we want our formal series to be operator-valued. The way to accomplish this is to choose W to be a vector space of operators, or matrices if you prefer. A fancy way to say this is '$W = \mathrm{End}(V)$', which means the things in W operate on vectors in V. If we take $V = \mathbb{C}^m$, then we can think of W as being the space of all $m\times m$ complex matrices. We are ultimately interested in the case $m=\infty$, but we won't lose much now by taking $m=1$, which would mean formal power series with numerical coefficients.

Because our coefficients w_n are operators, we can multiply our formal series. We define multiplication in the usual way. For example, consider $W = V = \mathbb{C}$, and take $c(z) = z^{21} - 5z^{100}$ and $d(z) = \sum_{n=-\infty}^{\infty} z^n$. Then

$$c(z)\,d(z) = \sum_{n=-\infty}^{\infty} z^{n+21} - 5\sum_{n=-\infty}^{\infty} z^{n+100} = \sum_{n=-\infty}^{\infty} z^n - 5\sum_{n=-\infty}^{\infty} z^n = -4d(z)\ .$$

So far so good. Now try to compute the square $d(z)^2$. You get infinity. So the lesson is: you can't always multiply in $W[[z,z^{-1}]]$. We'll come back to this later.

But first, look again at that first product: $c(z)\,d(z) = -4d(z)$. One thing it tells us is that *we can't always divide* (certainly $c(z)$ and -4 are two very different power series!). But there's another lesson here: if you work out a few more multiplications of this kind, what you'll find is that $f(z)\,d(z) = f(1)\,d(z)$ for any f, at least for those f for which $f(1)$ exists (e.g. any $f \in W[z,z^{-1}]$). Thus $d(z)$ is what we would call the Dirac delta $\delta(z-1)$! (You can think of it as the Fourier expansion of the Dirac delta, followed by a change of variables). Unfortunately, the standard notation here is to write it without the '-1':

$$\delta(z) := \sum_{n=-\infty}^{\infty} z^n$$

and that is the notation we will also adopt. Similarly, $\delta(az)$ and $\delta'(z)$ etc (which are the formal series defined in the obvious way) act on $W[z,z^{-1}]$ in the way one would expect: $f(z)\,\delta(az) = f(\frac{1}{a})\,\delta(az)$ and $f(z)\,\delta'(z) = f'(1)\,\delta'(z)$. So of course it makes perfect sense that we couldn't work out $d(z)^2$: we were trying to square the Dirac delta, which we know is impossible!

A similar theory can be developed for several variables z_i, with identities such as $f(z_1,z_2)\,\delta(z_1/z_2) = f(z_2,z_2)\,\delta(z_1/z_2) = f(z_1,z_1)\,\delta(z_1/z_2)$.

But we must not get too overconfident:

Paradox 1. Consider the following product:

$$\delta(z) = \big[(\sum_{n=0}^{\infty} z^n)\,(1-z)\big]\,\delta(z) = (\sum_{n=0}^{\infty} z^n)\,\big[(1-z)\,\delta(z)\big] = (\sum_{n=0}^{\infty} z^n)\,\big[0\,\delta(z)\big] = 0\ .$$

When physicists are confronted with 'paradoxes' such as this, they tend to respond by keeping them in the back of their mind, by treading with care when they are involved in a calculation which reminds them of one of the paradoxes, and otherwise trusting their instincts. Mathematicians typically over-react: they kick themselves for getting overconfident and walking head-first into a 'paradox', and then they devise some rule which will absolutely guarantee that that paradox will always be safely avoided in the future. We will follow the mathematicians' approach, and in the next few paragraphs will describe their rule for avoiding Paradox 1: to forbid certain innocent-looking products.

Remember that we are actually interested in the vector space $W = \mathrm{End}(V)$. Suppose we have infinitely many matrices $w_i \in \mathrm{End}(V)$. We will call them *summable* if for every column vector $v \in V$, only finitely many products $w_i(v) \in V$ are different from 0. In other words, only finitely many of the matrices w_i have a nonzero first column, only finitely many have a nonzero second column, ...

We will certainly have a well-defined sum $\sum_i w_i(z)$ if for each fixed n, the set $\{w_i(n)\}$ (as i varies) of matrices is summable. All other sums are forbidden. We will certainly have a well-defined product[31] $\prod_{i=1}^m w_i(z)$ if for each n, the set $\{w_1(n_1)\,w_2(n_2)\,\cdots\,w_m(n_m)\}_{\sum n_i = n}$

---

[31] m here will be finite: we permit infinite sums but only finite products.

(vary the n_i subject to $\sum_i n_i = n$) is summable. All other products are forbidden. This is reasonable because the sum of those matrix products $w_1(n_1) \cdots w_m(n_m)$ will precisely equal the nth coefficient of the product $\prod_{i=1}^m w_i(z)$.

Note that there are certainly more general ways to have a well-defined product (or sum). For example, according to our rule, we cannot even add $\sum_n 2^{-n}$! This way has the advantage of not touching the more complicated realm of convergence issues. We are doing *algebra* here, not *analysis*. The way out of Paradox 1 is that $(\sum z^n)(1-z)$ doesn't equal 1 — rather, it's a forbidden product.

An interesting consequence of the fact that we are doing algebra instead of analysis is that the product $z^{\frac{1}{2}}\delta(z)$ here does not and cannot equal $1^{\frac{1}{2}}\delta(z) = \delta(z)$ — their formal power series are very different. In hindsight this 'failing' is understandable: algebraically, it seems artificial to prefer the positive root of 1 over the negative root.

Paradox 2. Expand $\frac{1}{1-z}$ in a formal power series in z to get $\sum_{n\geq 0} z^n$. Next, expand $\frac{1}{1-z} = \frac{-z^{-1}}{1-z^{-1}}$ in a formal power series in z^{-1} to get $-\sum_{n<0} z^n$. Subtract these; we presumably should get 0, but we actually get $\delta(z)$!

The analytic explanation is that the first expression converges only for $|z| < 1$, and the second for $|z| > 1$, so it would be naive to expect their difference to be 0. We see from this 'paradox' that *it really matters in which variable we expand rational functions.* For instance, at first glance the identity

$$z_0^{-1}\delta\left(\frac{z_1 - z_2}{z_0}\right) - z_0^{-1}\delta\left(\frac{z_2 - z_1}{-z_0}\right) = z_2^{-1}\delta\left(\frac{z_1 - z_0}{z_2}\right)$$

is nonsense; it only holds if you expand the terms in positive powers of z_2, z_1, and z_0 respectively. The procedure of expanding a function in positive and negative powers of a variable and then subtracting the results, yields what are called *expansions of zero*; it is possible to show that expansions of zero will always be linear combinations of Dirac deltas $\delta(az)$ and their various derivatives $\delta^{(k)}(az)$, as we saw in Paradox 2.

2.6. INGREDIENT #3: VERTEX OPERATOR ALGEBRAS

We are now prepared to introduce the important new structure called vertex operator algebras (VOAs). They are essentially the chiral algebras of RCFTs — see [26,27] for excellent motivation of the 7 axioms below. A more detailed treatment of the basic theory of VOAs is provided by e.g. [23,39,31]. Although VOAs are natural from the CFT perspective and appear to be an important and rapidly developing area in math, their definition is not easy: Borcherds is known to have said that you either know what they are, or you don't want to know.

A VOA is a (infinite-dimensional) graded vector space $V = \oplus_{n\in\mathbb{Z}} V_n$ with infinitely many bilinear products $u *_n v$ respecting the grading (in particular $V_k *_n V_\ell \subseteq V_{k+\ell-n-1}$), which obey infinitely many constraints. 'Bilinear' means that for any $a, a', b, b' \in \mathbb{C}$ and $u, u', v, v' \in V$, $(au+a'u') *_n (bv+b'v') = ab\, u *_n v + ab'\, u *_n v' + a'b\, u' *_n v + a'b'\, u' *_n v'$ — i.e. that the products are compatible with the vector space structure of V. The subspaces V_n

must all be finite-dimensional, and they must be trivial (i.e. $V_n = \{0\}$) for all sufficiently small n (i.e. for $n \approx -\infty$). Note that we can collect all these products into one generating function: a linear map $Y : V \to (\mathrm{End}V)[[z, z^{-1}]]$. That is, to each vector $u \in V$ we associate the formal power series (called a *vertex operator*) $Y(u, z) = \sum_{n \in \mathbb{Z}} u_n z^{-n-1}$. For each u, the coefficients u_n will be functions from V to V. The idea is that the product $u *_n v$ will now be written $u_n v := u_n(v)$. The bilinearity of $*_n$ translates into two things in this new language: that $Y(\star, z)$ is linear, and that each function u_n is itself linear (i.e. they are endomorphisms).

The constraints are:

VOA 1. (*regularity*) $u_n v = 0$ for all $n > N(u, v)$;

VOA 2. (*vacuum*) there is a vector $1 \in V$ such that $Y(1, z)$ is the identity (i.e. $1_n v = \delta_{n,-1} v$);

VOA 3. (*state-field correspondence*) $Y(u, 0)1 = u$;

VOA 4. (*conformal*) there is a vector $\omega \in V$, called the *conformal vector*, such that $L_n := \omega_{n+1}$ gives us a representation of the Virasoro algebra $\mathcal{V}$, with central term $C \mapsto cI$ for some $c \in \mathbb{C}$;

VOA 5. (*translation generator*) $Y(L_{-1}u, z) = \frac{d}{dz} Y(u, z)$;

VOA 6. (*conformal weight*) $L_0 u = nu$ whenever $u \in V_n$;

VOA 7. (*locality*) $(z - w)^M [Y(u, z), Y(v, w)] = 0$ for some integer $M = M(u, v)$.

We saw the Virasoro algebra in Part 1 (see (1.2.7)). The number c in **VOA 4** is called the *central charge*, and is an important invariant of V. The peculiar-looking **VOA 7** simply says that the commutator $[Y(u, z), Y(v, w)]$ of two vertex operators will be a finite linear combination of derivatives of various orders of the Dirac delta centred at $z - w$. A recommended exercise for the reader is to show that $M = 4$ works in **VOA 7** for $u = v = \omega$. Note that in a VOA, any $Y(u, z)v$ will be a finite sum — i.e. the series $Y(u, z)$ is summable (defined last section). It is a consequence of the axioms that $1 \in V_0$ and $\omega \in V_2$: for instance, **VOA 7** says all $u_n 1 = 0$ for any $n \geq 0$, so $L_0 1 = \omega_1 1 = 0$ and hence $1 \in V_0$.

In RCFT, V would be the 'Hilbert space of states' (more carefully, V will be a dense subspace of it), and $z = e^{t+ix}$ would be a local complex coordinate on a Riemann surface. L_0 generates time translations, and so its eigenvalues (the *conformal weights*) can be identified with energy. Physically, the requirement that $V_n \to 0$ for $n \to -\infty$ corresponds to the energy of the RCFT being bounded from below. Also, $z = 0$ in **VOA 3** corresponds to the time limit $t \to -\infty$. For each state u, the vertex operator $Y(u, z)$ is a holomorphic (chiral) quantum field. The vector 1 is the vacuum $|0\rangle$, and $Y(\omega, z)$ is the stress-energy tensor T. The most important axiom, **VOA 7**, says that vertex operators commute up to a possible pole at $z = w$, and so are local quantum fields. It is equivalent to the duality axiom of many treatments of CFT. In the physics literature, there is a minor notational difference: for $u \in V_k$, $Y(u, z) = \sum u_n z^{-n-1}$ is written $\sum u_{(n)} z^{-n-k}$. (Physicists prefer this because it cleans up some formulas a little; mathematicians abhor it because it artificially prefers the 'homogeneous' vectors $u \in V_k$.)

In Segal's language (see §1.1), $Y(u, z)$ appears quite naturally. Consider the physical event of two strings combining to form a third. To first order (i.e. the tree-level Feynman diagram), this would correspond in Segal's language to a 'pair-of-pants', or a sphere with three punctures, two of which are positively oriented (corresponding to the incoming strings) and the other being negatively oriented. We can think of the sphere as the Riemann sphere $\mathbb{C} \cup \{\infty\}$; put the punctures at ∞ (outgoing) and z and 0 (the incomings). Segal's functor $\mathcal{T}$ will associate to this a z-dependent homomorphism $\varphi_z : V \times V \to V$. We write $\varphi_z(u, v) \in V$ as $Y(u, z)v$. Incidentally, the symbol 'Y' was chosen because of this 'pair-of-pants' picture (time flows from the top of the 'Y' to the bottom), as was the name 'vertex operator'.

The original axioms by Borcherds were a little more complicated and general: he didn't require $\dim(V_n) < \infty$ nor the $V_n \to 0$ condition, and he only considered L_0 and L_{-1} rather than the full Virasoro algebra. The resulting generalisation is called a *vertex algebra.*

VOA 7 can be rewritten in the form (usually called the *Jacobi identity* for the VOA)

$$z_0^{-1}\delta(\frac{z_1 - z_2}{z_0})\, Y(u, z_1)\, Y(v, z_2) - z_0^{-1}\delta(\frac{z_2 - z_1}{-z_0})\, Y(v, z_2)\, Y(u, z_1) \qquad (2.6.1)$$

$$= z_2^{-1}\delta(\frac{z_1 - z_0}{z_2})\, Y(Y(u, z_0)v, z_2)\ ,$$

where the formal series are expanded in the appropriate way. This is the embodiment of commutativity and associativity in the VOA, as we will see. To bring it into a more useful form, hit it with $t \in V$ and expand out into $z_0^\ell z_1^m z_2^n$: we obtain

$$\sum_{i\geq 0}(-1)^i \binom{\ell}{i} \left(u_{\ell+m-i} \circ v_{n+i} - (-1)^\ell v_{\ell+n-i} \circ u_{m+i}\right) = \sum_{i \geq 0} \binom{m}{i} \left(u_{\ell+i}v\right)_{m+n-i}\ , \quad (2.6.2)$$

where for any $k \in \mathbb{Z}$, $j \in \mathbb{Z}_{\geq}$, $\binom{k}{j} := \frac{k\,(k-1)\cdots(k-j+1)}{j!}$. For instance, specialising (2.6.2) to $\ell = 0$ and $m = 0$, resp., gives us

$$[u_m, v_n] = \sum_{i\geq 0} \binom{m}{i} (u_i v)_{m+n-i} \qquad (2.6.3)$$

$$(u_\ell v)_n = \sum_{i\geq 0} (-1)^i \binom{\ell}{i} \left(u_{\ell-i} \circ v_{n+i} - (-1)^\ell v_{\ell+n-i} \circ u_i\right)\ . \qquad (2.6.4)$$

Why is (2.6.1) called the Jacobi identity? Put $\ell = m = n = 0$ in (2.6.2): we get $u_0(v_0t) - v_0(u_0t) = (u_0v)_0t$. If we now formally write $[xy] := x_0y$, then this becomes $[u[vt]] - [v[ut]] = [[uv]t]$, which is one of the forms of the Lie algebra Jacobi identity (1.2.1b). Even though $[xy] \neq -[yx]$ here, this formal little trick will turn out to be quite important next section.

The simplest examples of VOAs correspond to any even positive-definite lattice Λ; for their construction see e.g. [27,39]. Physically, they correspond to a bosonic string compactified on the torus $\mathbb{R}^n/\Lambda \cong S^1 \times \cdots \times S^1$ (where n is the dimension of Λ); the central charge $c = n$. Other important examples, first constructed by Frenkel-Zhu (again see e.g. [27,39]), correspond to affine Kac-Moody algebras $X_\ell^{(1)}$ at level $k \in \mathbb{Z}_>$, and physically to WZW theories on simply-connected compact group manifolds. (We discussed affine algebras in §1.4.) These have central charge $c = \frac{k\dim(X_\ell)}{k+h^\vee}$.

In 1984 Frenkel-Lepowsky-Meurman [23] constructed the *Moonshine module* $V^\natural$. It is a VOA with $c = 24$, with $V^\natural = V_0^\natural \oplus V_1^\natural \oplus V_2^\natural \oplus \cdots$, where $V_0^\natural = \mathbb{C}1$ is 1-dimensional, $V_1^\natural = \{0\}$ is trivial, and $V_2^\natural = (\mathbb{C}\omega) \oplus (\text{Griess algebra})$ is $(1 + 196883)$-dimensional. Its automorphism group (=symmetry group) is precisely the Monster $\mathbb{M}$. Each graded piece $V_n^\natural$ is a finite-dimensional representation of $\mathbb{M}$; Borcherds proved that in fact $V^\natural$ is the McKay-Thompson infinite-dimensional representation of $\mathbb{M}$. It can be regarded as the most natural representation of $\mathbb{M}$ — it is rather surprising that important aspects of a finite group need to be studied via an infinite-dimensional representation.

$V^\natural$ has an elegant physical interpretation. First construct the bosonic string on $\mathbb{R}^{24}/\Lambda_{24}$ (recall that Λ_{24} is the Leech lattice). The resulting $c = 24$ VOA has partition function (=graded dimension) $J(\tau) + 24$, but although its graded pieces (at least for $n > 0$) have the right dimensions, they don't carry a natural representation of $\mathbb{M}$ and so can't qualify for the McKay-Thompson representation. To get $V^\natural$, orbifold this Λ_{24} VOA by the order-2 automorphism of Λ_{24} sending $\vec{x} \mapsto -\vec{x}$. $V^\natural$ thus corresponds to a holomorphic $c = 24$ RCFT, and Moonshine is related to physics. Most of Moonshine can be interpreted physically, except perhaps the genus 0 property of the McKay-Thompson series T_g.

There is a formal parallel between e.g. lattices and VOAs. For example, the Leech lattice Λ_{24} and the Moonshine module $V^\natural$ play analogous roles: Λ_{24} is the unique even lattice which (i) is self-dual, (ii) contains no norm 2 vectors, and (iii) has dimension 24; $V^\natural$ is believed to be the unique VOA which (i) possesses only one irreducible representation (namely itself), (ii) contains no conformal weight 1 elements, and (iii) has central charge $c = 24$. Analogies of these kinds are always useful as they suggest new directions to explore, and the history of math blooms with them. The battlecry 'Why invent what can be profitably copied' is not only heard in Hollywood.

We will end this section on a more speculative note. Witten (1986) said that to understand string theory conceptually, we need a new analogue of Riemannian geometry. Huang (1997) has pushed this thought a little further, saying that there is a more classical 'particle-math' and a more modern 'string-math'. According to Huang we have the real numbers (particle physics) vrs the complex numbers (string theory); Lie algebras vrs VOAs; and the representation theory of Lie algebras vrs RCFT, etc. What are the stringy analogues of calculus, ordinary differential equations, Riemannian manifolds, the Atiyah-Singer Index theorem,...? At present these are all unknown. However, Huang suggests that just as we could imagine Moonshine as a mystery which is explained in some way by RCFT, perhaps the stringy version of calculus would similarly explain the mystery of 2-dimensional gravity, stringy ODEs would explain the mystery of infinite-dimensional integrable systems, stringy Riemannian manifolds would help explain the mystery of mirror symmetry, and the stringy index theorem would help explain the elliptic genus.

2.7. INGREDIENT #4: GENERALISED KAC-MOODY ALGEBRAS

In this section we investigate Lie algebras arising from VOAs. These Lie algebras are an interesting generalisation of Kac-Moody algebras. See e.g. [5,6,38 Chapter 11.13, 29].

Much of Lie theory (indeed much of algebra) is developed by analogy with simple properties of integers. In §2.2 I invited you to think of a finite group as a massive generalisation of the concept of whole number. Specifically, the number n can be identified with the cyclic group $\mathbb{Z}_n$ with n elements. A divisor d of n generalises to a normal subgroup of a group. A prime number then corresponds to a simple group. Multiplying numbers corresponds to taking the semidirect product of groups (more generally, taking extensions of groups). Then we find that every group has a unique set of simple building blocks (although unlike numbers, different groups can have the same list of building blocks).

For a finite-dimensional Lie algebra, a divisor is called an ideal; a prime is called simple; and multiplying corresponds to semidirect sum. Lie algebras behave simpler than groups but not as simple as numbers, and the analogy sketched above is a reasonably satisfactory one. In particular, simple Lie algebras are important for similar reasons that simple groups are, and as mentioned in §1.2 can also be classified (with *much* less effort). A good treatment of this important classification (over $\mathbb{C}$) is provided by [36]. The proof is now reaching the state of perfection of the formulation of classical mechanics. One unobvious discovery is that the best way to capture the structure of a simple Lie algebra is by an integer matrix, called the *Cartan matrix*, or equivalently but more effectively (since most entries in the Cartan matrix are 0's) by using a graph called the *(Coxeter-)Dynkin diagram*. For instance the Dynkin diagram for A_ℓ consists of ℓ nodes connected sequentially in a line. See Figure 6 in [59].

More precisely, define a *symmetrised Cartan matrix* to be a symmetric real matrix $A = (a_{ij})_{i,j\leq\ell}$ such that $a_{ij} \leq 0$ if $i \neq j$, $a_{ii} > 0$, each $2\frac{a_{ij}}{a_{ii}} \in \mathbb{Z}$, and A is positive-definite. Examples of 2×2 symmetrised Cartan matrices are[32]

$$\begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix}, \quad \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix}, \quad \begin{pmatrix} 1 & -1 \\ -1 & 2 \end{pmatrix}, \quad \begin{pmatrix} 2 & -3 \\ -3 & 6 \end{pmatrix}$$

The Dynkin diagram corresponding to A consists of ℓ nodes; the ith and jth nodes are connected with $4a_{ij}^2/a_{ii}a_{jj}$ lines, and if $a_{ii} \neq a_{jj}$, then we put an arrow over those lines pointing to i if $a_{ii} < a_{jj}$. The Dynkin diagrams corresponding to those four Cartan matrices are respectively

 ,  ,  , 
We may without loss of generality require A to be *indecomposable*, or equivalently that the Dynkin diagram be connected. Of the 4 given above, only the second is decomposable.

To any $\ell \times \ell$ symmetrisable Cartan matrix, we can construct the corresponding Lie algebra $\mathfrak{g}$ in the following way. For each i, create 3 generators e_i, f_i, h_i (so there are a total of 3ℓ generators). The relations these generators obey are given by the following brackets: $[e_i f_j] = \delta_{ij} h_i$, $[h_i e_j] = a_{ij} e_j$, $[h_i f_j] = -a_{ij} f_j$, and for $i \neq j$ $\mathrm{ad}(e_i)^n e_j = \mathrm{ad}(f_i)^n f_j = 0$ where $n = 1 - 2\frac{a_{ij}}{a_{ii}}$. By 'ad$(e)$' here I mean the function $\mathfrak{g} \to \mathfrak{g}$ defined by $\mathrm{ad}(e)f = [ef]$. So $\mathrm{ad}(e)^2 f = [e[ef]]$, $\mathrm{ad}(e)^3 f = [e[e[ef]]]$, etc.

---

[32] Note that our Cartan matrices differ from the usual definition, in which every diagonal entry equals 2.

To get a better feeling for these relations, consider a fixed i. The generators $e = \sqrt{\frac{2}{a_{ii}}}\, e_i, f = \sqrt{\frac{2}{a_{ii}}}\, f_i, h = \frac{2}{a_{ii}}\, h_i$ obey the relations (1.2.2b). In other words, every node in the Dynkin diagram corresponds to a copy of the A_1 Lie algebra. The lines connecting these nodes tells how these ℓ copies of A_1 intertwine.

For instance consider the first Cartan matrix given above. It corresponds to the Lie algebra A_2, or $\mathrm{sl}_3(\mathbb{C})$. The two A_1 subalgebras which generate it (corresponding to the 2 nodes of the Dynkin diagram) can be chosen to be the trace-zero matrices of the form

$$\begin{pmatrix} \star & \star & 0 \\ \star & \star & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad \begin{pmatrix} 0 & 0 & 0 \\ 0 & \star & \star \\ 0 & \star & \star \end{pmatrix}.$$

It can be shown that the Lie algebra corresponding to an indecomposable symmetrised Cartan matrix will be finite-dimensional and simple, and conversely that any finite-dimensional simple Lie algebra corresponds to an indecomposable symmetrisable Cartan matrix in this way.

A confusion sometimes arises between the terms 'generators' and 'basis'. Both generators and basis vectors build up the whole algebra; the difference lies in which operations you are permitted to use. For a basis, you are only allowed to use linear combinations (i.e. addition of vectors and multiplication by numbers), while for generators you are also permitted multiplication of vectors (or the bracket, in the Lie case). 'Dimension' refers to basis, while 'rank' usually refers in some way to generators. For instance the (commutative associative) algebra of polynomials in one variable x is infinite-dimensional — any basis needs infinitely many vectors. However, the single polynomial x is enough to generate it (so we could say that its rank is 1). Although those Lie algebras have 3ℓ generators, their dimensions in general will be greater.

From the point of view of generators and relations, the step from 'finite-dimensional simple' to 'symmetrisable Kac-Moody' is rather easy: the only difference is that we drop the 'positive-definite' condition (which was responsible for finite-dimensionality). Kac-Moody (KM) algebras are also generated by (finitely many) A_1 subalgebras, and their theory is quite parallel to that of the simple algebras. Compare Figures 6 and 9 in [59].

Now, it is easy to generalise something; the challenge is to generalise it in a rich and interesting direction. One natural and appealing strategy for generalisation was followed instinctively by a grad student named Robert Moody. Moody's original motivation for developing the theory of Kac-Moody algebras was the Weyl group. If there were Lie algebras for finite Coxeter groups, he asked, why not also for the Euclidean (=affine) ones? For another example of this style of generalisation, consider the question: What is the analogue of calculus (or manifolds) over weird fields — fields (like $\mathbb{Z}_p$) for which the usual limit definitions make no sense? This question leads to the riches of algebraic geometry. Nevertheless this generalisation strategy, even in the hands of a master, will not always be successful. For instance, consider all the trouble the following metaphor has caused: my watch has a maker, so so should the Universe.

Recently Borcherds produced a further generalisation of finite-dimensional simple Lie algebras, which is rather less obvious than that of Kac-Moody algebras. It is easy to associate a Lie algebra to a matrix A, but which class of matrices will yield a deep theory?

Borcherds found such a class by holding in his hand a single algebra (the fake Monster Lie algebra, see §2.9) which acted a lot like a KM algebra, even though it had 'imaginary simple roots'.

By a *generalised symmetrised Cartan matrix* $A = (a_{ij})$ we will mean a symmetric real matrix (possibly infinite), such that $a_{ij} \leq 0$ if $i \neq j$, and if $a_{ii} > 0$ then $2\frac{a_{ij}}{a_{ii}} \in \mathbb{Z}$ for all j. By a *universal generalised Kac-Moody algebra* (universal GKM) or *universal Borcherds-Kac-Moody algebra* $\mathfrak{g}$ we mean the algebra[33] with generators e_i, f_i, h_{ij}, and with relations: $[e_i f_j] = h_{ij}$; $[h_{ij} e_k] = \delta_{ij} a_{ik} e_k$; $[h_{ij} f_k] = -\delta_{ij} a_{ik} f_k$; if $a_{ii} > 0$ and $i \neq j$ then $\mathrm{ad}(e_i)^n e_j = \mathrm{ad}(f_i)^n f_j = 0$ for $n = 1 - 2\frac{a_{ij}}{a_{ii}}$; and if $a_{ij} = 0$ then $[e_i e_j] = [f_i f_j] = 0$.

For example the Heisenberg algebra (1.2.3) corresponds to the choice $A = (0)$, while any other 1×1 $A = (a)$ corresponds to A_1. A universal GKM algebra differs from a KM algebra in that it is built up from Heisenberg algebras as well as A_1, and these subalgebras intertwine in more complicated ways. Nevertheless *much of the theory for finite-dimensional simple Lie algebras continues to find an analogue in this much more general setting* (e.g. root-space decomposition, Weyl group, character formula,...). This unexpected fact is the point of GKM algebras.

To get a feel for these algebras, let us prove a few simple results concerning the h_{ij}. Note first that, using the above relations together with the Jacobi identity, we obtain $[h_{ij} h_{k\ell}] = \delta_{ij}(a_{jk} - a_{j\ell}) h_{k\ell}$. Comparing this with $[h_{k\ell} h_{ij}] = -[h_{ij} h_{k\ell}]$, we see that bracket must always equal 0. Hence all h's pairwise commute, and $h_{ij} = 0$ unless the ith and jth columns of A are identical. An easy exercise now is to show that when $i \neq j$, h_{ij} will lie in the centre of the algebra (i.e. h_{ij} will commute with all other generators).

Although the definition of universal GKM algebra is more natural, it turns out that an equivalent form can be more useful in practice. (It's simpler to describe over $\mathbb{R}$, so in most expositions the reals are used, but alas it's far too late for us to switch loyalties now.) By a *generalised Kac-Moody algebra* (or *Borcherds-Kac-Moody algebra*) $\mathfrak{g}$, we mean a (complex!) Lie algebra which is:

- $\mathbb{Z}$-graded, i.e. $\mathfrak{g} = \oplus_i \mathfrak{g}_i$, where $[\mathfrak{g}_i \mathfrak{g}_j] \subseteq \mathfrak{g}_{i+j}$;
- $\mathfrak{g}_i$ is finite-dimensional for $i \neq 0$;
- $\mathfrak{g}$ has an antilinear involution ω (i.e. $\omega(kx+y) = k^*\omega(x) + \omega(y)$, $[\omega(x)\omega(y)] = \omega([xy])$, and $\omega \circ \omega = id$.) which maps $\mathfrak{g}_i$ to $\mathfrak{g}_{-i}$ and acts as multiplication by -1 on some basis of $\mathfrak{g}_0$;
- $\mathfrak{g}$ has an invariant symmetric bilinear form $(\star, \star)$ (i.e. $([xy], z) = (x, [yz])$ and $(y, z) = (z, y) \in \mathbb{C}$), obeying $(\omega(x), \omega(y)) = (x, y)^*$, such that $(\mathfrak{g}_i, \mathfrak{g}_j) = 0$ if $i \neq -j$;
- the Hermitian form defined by $(x|y) := -(\omega(x), y)$ is positive-definite on $\mathfrak{g}_{i\neq 0}$.

Note that for some basis x_i of $\mathfrak{g}_0$, the third condition tells us $-[x_i x_j] = [(-x_i)(-x_j)] = [x_i x_j]$, i.e. $\mathfrak{g}_0$ has a trivial bracket. It plays the role of the Cartan subalgebra $\mathfrak{h}$ in the theory.

For example, let $\mathfrak{g} = \mathrm{sl}_2(\mathbb{C})$ and recall (1.2.5). Then $\mathfrak{g}_1 = \mathbb{C}e$, $\mathfrak{g}_0 = \mathbb{C}h$, $\mathfrak{g}_{-1} = \mathbb{C}f$ is the root-space decomposition. $\omega(x) = -x^\dagger$ is the Cartan involution. $(x, y) = \mathrm{tr}(xy)$ is the Killing form.

---

[33] As with KM algebras, usually we want to extend it by some derivations; enough derivations are added so that the simple roots are linearly independent.

It turns out [5] that any universal GKM algebra is a GKM algebra, and any GKM algebra can be constructed from a unique universal GKM algebra (by quotienting out part of the centre and adding derivations), so in that sense the two structures are equivalent. This theorem is important, because it tells us that *GKM algebras are the ultimate generalisation of simple Lie algebras,* in the sense that any further generalisation will lose some basic structural ingredient.

We know simple Lie algebras (and groups) arise in both classical and quantum physics, and the affine KM algebras are important in CFT, as we saw in Part 1. GKM algebras have recently appeared in the physics literature (see Harvey-Moore) in the context of BPS states in string theory.

How do GKM algebras arise in VOAs? If we define $[xy] := x_0 y$, then as mentioned in §2.6 we get from the VOA Jacobi identity the equation $[x[yz]] - [y[xz]] = [[xy]z]$. Thus our bracket will be anti-associative if it is anti-commutative. But is it anti-commutative? It can be shown

$$u_n v = \sum_{i=0}^{\infty} \frac{1}{i!}(-1)^{i+n+1}(L_{-1})^i (v_{n+i} u) \tag{2.7.1}$$

so $u_0 v \equiv -v_0 u$ if we look at things mod $L_{-1}V$.

Since our bracket is clearly bilinear, we thus get a Lie algebra structure on $V/L_{-1}V$. Similarly, we get a symmetric bilinear product on $V/L_{-1}V$, given by $\langle u, v\rangle := u_1 v$.

We would like $\langle \star, \star\rangle$ to respect the Lie algebra structure, i.e. be $[\star\star]$-invariant. We compute from (2.6.4)

$$\langle [uv], t\rangle = -[v\langle u, t\rangle] + \langle u, [vt]\rangle \ . \tag{2.7.2}$$

Since we would like to identify $\langle \star, \star\rangle$ with the bilinear form in the GKM algebra definition, we also would like it to be number-valued (i.e. have 1-dimensional range).

There is a simple way to satisfy both of these. First, restrict attention to V_1, i.e. the conformal weight 1 vectors: $V_1 \cap (V/L_{-1}V) = V_1/L_{-1}V_0$. Then $\langle u, v\rangle \in V_0$. Assume V_0 is 1-dimensional: i.e. $V_0 = \mathbb{C}1$. Then $\langle u, v\rangle$ will equal a number times 1, so call (u, v) that number. Also, $[\langle u, t\rangle v] = (u, t)1_0 v = 0$, so $\langle \star, \star\rangle$ and hence $(\star, \star)$, will be invariant. Of course, when $V_0 = \mathbb{C}1$, $L_{-1}V_0 = \{0\}$.

$V_1/L_{-1}V_0$ is generally too large in practice to be useful; a subalgebra can be defined as follows. Let P_n be the 'primary states with conformal weight n', i.e. the $u \in V_n$ killed by L_m for all $m > 0$. Then $\mathfrak{g}(V) := P_1/L_{-1}P_0$ will be a subalgebra of $V_1/L_{-1}V_0$. Through the assignment $u \mapsto u_0$, $\mathfrak{g}(V)$ acts on V and this action commutes with that of L_i. This association of a Lie algebra to a VOA is due to Borcherds (1986).

Similar arguments show that when V_0 is 1-dimensional and V_1 is 0-dimensional, then V_2 will necessarily be a commutative nonassociative algebra with product $u \times v := u_1 v \in V_2$ and identity element $\frac{1}{2}\omega$ (*proof*: $\omega \times u = L_0 u = 2u$). Now, those conditions on V_0, V_1 are satisfied by the Moonshine module $V^\natural$. We find that $V_2^\natural$ is none other than the Griess algebra extended by an identity element.

2.8. INGREDIENT #5: DENOMINATOR IDENTITIES

In §1.3, we discussed the representation theory of Lie algebras. An important invariant of a representation is its *character*. Simple Lie algebras possess a very useful formula for their characters, due to Weyl:

$$\mathrm{ch}_\lambda(z) := \sum_\mu \dim(L_\lambda(\mu))\, e^{\mu\cdot z} = e^{-\rho\cdot z}\,\frac{\sum_{w\in W} \pm e^{w(\lambda+\rho)\cdot z}}{\prod_{\alpha\in\Delta_+}(1-e^{-\alpha\cdot z})}\ , \tag{2.8.1}$$

where W is the Weyl group, Δ_+ the positive roots, and where $\oplus_\mu L_\lambda(\mu)$ is the weight-space decomposition of L_λ — i.e. the simultaneous eigenspaces of the h_i. Here z belongs to the Cartan subalgebra $\mathfrak{h}$; the character is complex-valued. Analogous statements hold for all GKM algebras.

It is rare indeed when a trivial special case of a theorem or formula produces something interesting. But that is what happens here. Consider the trivial representation: i.e. $x \mapsto 0$ for all $x \in X_\ell$. Then the character is identically 1, by definition: $ch_0 \equiv 1$. Thus the character formula tells us that a certain alternating sum over a Weyl group, equals a certain product over positive roots. These formulas, called *denominator formulas*, are nontrivial even in the finite-dimensional cases.

Consider for instance the smallest simple algebra, A_1. Here the identity indeed is too trivial: it reads $e^{z/2} - e^{-z/2} = e^{z/2}(1-e^{-z})$. For A_2 we get a sum of 6 terms equalling a product of 3 terms, and the complexity continues to rise from there.

Around 1970 Macdonald tried to generalise these finite denominator identities to infinite identities, corresponding to the extended Dynkin diagrams. These were later reinterpreted by Kac, Moody and others as denominator identities for affine nontwisted KM algebras. The simplest one was known classically as the Jacobi triple product identity:

$$\sum_{n=-\infty}^{\infty}(-1)^n x^{n^2} y^n = \prod_{m=1}^{\infty}(1-x^{2m})(1-x^{2m-1}y)(1-x^{2m-1}y^{-1})$$

We now know it to be the denominator identity for the simplest infinite-dimensional KM algebra, $A_1^{(1)}$.

Freeman Dyson is famous for his work in quantum field theory, but he started as an undergraduate in number theory and still enjoys it as a hobby. Dyson [20] found a curious formula for the Ramanujan τ-function, which can be defined by the generating function $\sum_{n=1}^{\infty}\tau(n)x^n = \eta^{24}(x) := x\prod_{m=1}^{\infty}(1-x^m)^{24}$. Dyson found the remarkable formula

$$\tau(n) = \sum \frac{(a-b)(a-c)(a-d)(a-e)(b-c)(b-d)(b-e)(c-d)(c-e)(d-e)}{1!\ 2!\ 3!\ 4!}$$

where the sum is over all 5-tuples $(a,b,c,d,e) \equiv (1,2,3,4,5) \pmod 5$ obeying $a+b+c+d+e=0$ and $a^2+b^2+c^2+d^2+e^2=10n$. Using this, an analogous formula can be found for η^{24}. Dyson knew that similar-looking formulas were also known for η^d for the values $d = 3, 8, 10, 14, 15, 21, 24, 26, 28, 35, 36, \ldots$.

What was ironic was that Dyson found that formula at the same time that Macdonald was finding the Macdonald identities. Both were at Princeton then, and would often chat a little when they bumped into each other after dropping off their daughters at school. But they never discussed work. Dyson didn't realise that his strange list of numbers has a simple interpretation: they are precisely the dimensions of the simple Lie algebras! $3 = \dim(\mathrm{A}_1)$, $8 = \dim(A_2)$, $10 = \dim(C_2)$, $14 = \dim(G_2)$, etc. In fact these formulas for η^d are none other than (specialisations of) the Macdonald identities. For example, Dyson's formula is the denominator formula for $A_4^{(1)}$ ($24 = \dim(A_4)$). If they had spoken, they would probably have anticipated the affine denominator identity interpretation.

One curiousity apparently still has no algebraic interpretation: No simple Lie algebra has dimension 26, so the formula for η^{26} can't correspond to any Macdonald identity.

Macdonald didn't close the book on denominator identities. More recently Kac and Wakimoto [40] have used denominator identities for Lie superalgebras to obtain nice formulas for various generator functions involving sums of squares, sums of triangular numbers (triangular numbers are numbers of the form $\frac{1}{2}k(k+1)$), etc. For instance, the number of ways n can be written as a sum of 16 triangular numbers is

$$\frac{1}{3 \cdot 4^3} \sum ab\,(a^2 - b^2)^2$$

where the sum is over all odd positive integers a, b, r, s obeying $ar + bs = 2n + 4$ and $a > b$.

Another example of denominator identities is Borcherds' use of them in proving the Moonshine conjectures. In particular this motivated his introduction of the GKM algebras. The denominator identities for other GKM algebras were used by Borcherds to obtain results on the moduli spaces of e.g. families of K3 surfaces. They are also often turned-around now and used for learning about the positive roots in a given GKM.

2.9. Proof of the Moonshine conjectures

The main Conway-Norton conjecture was proved almost immediately. Thompson showed that if $g \mapsto a_n(g)$ is a character for all $n \leq 1200$, then it will be for all n. He also showed that if certain congruence conditions hold for a certain number of $a_n(g)$ (all with $n \leq 100$), then all $g \mapsto a_n(g)$ will be *virtual* characters (i.e. a linear combination over $\mathbb{Z}$ of irreducible characters of $\mathbb{M}$; only if all coefficients are nonnegative will it be a true character). Atkin-Fong-Smith [54] used that to prove on a computer that indeed all were virtual characters. But their work didn't say anything about the underlying (possibly virtual) representation V. The real challenge was to construct (preferably in a natural manner) the representation which works. Frenkel-Lepowsky-Meurman [23] constructed a candidate for it (the Moonshine module $V^\natural$); it was Borcherds who finally proved $V^\natural$ obeyed the Conway-Norton conjecture. A good overview of Borcherds' work on Moonshine is provided in [32].

We want to show that the McKay-Thompson series $T_g(\tau) := q^{-1}\mathrm{tr}_{V^\natural}(gq^{L_0})$ of (2.1.4) equals the Hauptmodul $J_g(\tau)$ in (2.4.1) (the 'fudge factor' $q^{-1} = q^{-c/24}$ is familiar to e.g. KM algebras and CFT and was discussed at the end of §1.2). Borcherds' strategy was to bring in Lie theory and to use the corresponding denominator identity to provide useful combinatorial data. The first guess for this 'Monster Lie algebra' was the Kac-Moody algebra whose Dynkin diagram is essentially the Leech lattice (i.e. a node for each vector in Λ_{24}, and 2 nodes are connected by a number of edges depending on the value of a certain dot product). It was eventually discarded because some of the critical data (namely positive root multiplicities) needed in order to write down its denominator identity were too complicated. But looking at that failed attempt led Borcherds to a second candidate, now called the *fake Monster Lie algebra* $\mathfrak{g}'_{\mathbb{M}}$. In order to *construct* it, he developed the theory of VOAs; and in order to *understand* it, he developed the theory of GKM algebras. We will define it shortly. $\mathfrak{g}'_{\mathbb{M}}$ also turned out to be inadequate for proving the Moonshine conjectures; however it directly led him to the GKM algebra now called the true *Monster Lie algebra* $\mathfrak{g}_{\mathbb{M}}$. And that directly led to the proof of Moonshine.

Step 1: Construct $\mathfrak{g}_{\mathbb{M}}$ from $V^\natural = V_0^\natural \oplus V_1^\natural \oplus \cdots$. For later convenience, reparametrise these subspaces $V^i := V^\natural_{i+1}$. Recall the even indefinite lattice $II_{1,1}$ defined in (1.6.1). Of course the direct choice $\mathfrak{g}(V^\natural)$ is 0-dimensional because $V_1^\natural$ is trivial, so we must modify $V^\natural$ first.

The Monster Lie algebra is (essentially) defined to be the Lie algebra $\mathfrak{g}(V^\natural \otimes V_{II_{1,1}})$ associated to the vertex algebra $V^\natural \otimes V_{II_{1,1}}$ (strictly speaking, more of $\mathfrak{g}$ is quotiented away). By contrast, the fake Monster is the Lie algebra associated to the vertex algebra $V_{\Lambda_{24}} \otimes V_{II_{1,1}} \cong V_{II_{25,1}}$. Both of these are vertex algebras as opposed to VOAs, because of the presence of the indefinite lattices, but this isn't important here. $\mathfrak{g}_{\mathbb{M}}$ inherits a $II_{1,1}$-grading from $V_{II_{1,1}}$: the piece of grading (m,n) is isomorphic (as a vector space) to V^{mn}, if $(m,n) \neq (0,0)$; the (0,0) piece is isomorphic to $\mathbb{R}^2$. Borcherds uses the No-Ghost Theorem of string theory to show that the homogeneous pieces of $\mathfrak{g}_{\mathbb{M}}$ are those of $V^\natural$.

Both $\mathfrak{g}_{\mathbb{M}}$ and $\mathfrak{g}'_{\mathbb{M}}$ are GKM algebras; for instance the $\mathbb{Z}$-grading of $\mathfrak{g}_{\mathbb{M}}$ is given by $(\mathfrak{g}_{\mathbb{M}})_k = \oplus_{m+n=k} V^{mn}$ for $k \neq 0$, while the 0-part is $V^{-1} \oplus V^{-1}$. Although $\mathfrak{g}'_{\mathbb{M}}$ is not used in the proof of the Monstrous Moonshine conjectures, it is related to some kind of Moonshine for the finite simple group .1, which is 'half' of the automorphism group .0 of the Leech lattice Λ_{24}. $\mathfrak{g}_{\mathbb{M}}$ corresponds to the Cartan matrix

$$\begin{pmatrix} B_{-1,-1} & B_{-1,1} & B_{-1,2} & \cdots \\ B_{1,-1} & B_{1,1} & B_{1,2} & \cdots \\ B_{2,-1} & B_{2,1} & B_{2,2} & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{pmatrix} ,$$

where $B_{i,j}$ for $i,j \in \{-1,1,2,3,\ldots\}$ is the $a_i \times a_j$ block with fixed entry $-i-j$ (the a_i as usual are the coefficients $\sum_n a_n q^n$ of $j - 744$).

2nd step: Compute the denominator identity of $\mathfrak{g}_{\mathbb{M}}$: we get

$$p^{-1} \prod_{\substack{m>0 \\ n\in\mathbb{Z}}} (1-p^m q^n)^{a_{mn}} = j(z) - j(\tau) \tag{2.9.1}$$

where $p = e^{2\pi \mathrm{i} z}$. The result are various formulas involving the coefficients a_i, for instance $a_4 = a_3 + (a_1^2 - a_1)/2$. It turns out to be possible to 'twist' (2.9.1) by each $g \in \mathbb{M}$, obtaining

$$p^{-1} \exp[-\sum_{k>0} \sum_{\substack{m>0 \\ n\in\mathbb{Z}}} a_{mn}(g^k) \frac{p^{mk} q^{nk}}{k}] = T_g(z) - T_g(\tau) \ . \tag{2.9.2}$$

This looks a lot more complicated, but you can glimpse the Taylor expansion of $\ln(1-p^m q^n)$ there and in fact for $g = id$ (2.9.2) reduces to (2.9.1). This formula gives more generally identities like $a_4(g) = a_2(g) + (a_1(g)^2 - a_1(g^2))/2$, where $T_g(\tau) = \sum_i a_i(g)q^i$. These formulas involving the McKay-Thompson coefficients are equivalent to the replication formulae conjectured in §2.4.

3rd step: It was known earlier that all of the Hauptmoduls also obey those replication formula, and that anything obeying them will lie in a finite-dimensional manifold which we'll call R. In particular, if $B(q) = q^{-1} + \sum_{n>0} b_n q^n$ and $C(q) = q^{-1} + \sum_{n>0} c_n q^n$ both lie in R, and $b_n = c_n$ for $n \leq 23$, then $B(q) = C(q)$. In fact, it turns out that if we verify for each conjugacy class $[g]$ of $\mathbb{M}$ that the first, second, third, fourth and sixth coefficients of the McKay-Thompson series T_g and the corresponding Hauptmodul J_g agree, then $T_g = J_g$, and we are done.

That is precisely what Borcherds then did: he compared finitely many coefficients, and as they all equalled what they should, this concluded the proof of Monstrous Moonshine!

However there was a disappointing side to his proof. While no one disputed its *logical* validity, it did seem to possess a disappointing *conceptual gap*. In particular, the Moonshine conjectures were made in the hope that proving them would help explain what the Monster had to do with the j-function and the other Hauptmoduls. A good proof says much more than 'True' or 'False'. The case-by-case verification occurred at the critical point where the McKay-Thompson series were being compared directly to the Hauptmoduls. The proof showed that indeed the Moonshine module establishes some sort of relation between T_g and J_g (namely, they must lie in the same finite-dimensional space), but why couldn't it be just a happy meaningless accident that they be equal? Of course we believe it's more than merely an accident, so our proof should reflect this: we want a more conceptual explanation.

This conceptual gap has since been filled [17] — i.e. the case-by-case verification has been replaced with a general theorem. It turns out that something obeying the replicable formulas will also obey something called *modular equations*. A modular equation for a function f is a polynomial identity obeyed by $f(x)$ and $f(nx)$. The simplest examples come from the exponential and cosine functions: note that for any $n > 0$, $\exp(nx) = (\exp(x))^n$ and $\cos(nx) = T_n(\cos(x))$ where T_n is a Tchebychev polynomial. A more interesting example of a modular equation is obeyed by $J(\tau) = j(\tau) - 744$: put $X = J(\tau)$ and $Y = J(2\tau)$, then

$$\begin{aligned}(X^2 - Y)(Y^2 - X) = {} & 393768\,(X^2 + Y^2) + 42987520\,XY + 40491318744\,(X + Y) \\ & - 120981708338256\ .\end{aligned}$$

Finding modular equations (for various elliptic functions) was a passion of the great mathematician Ramanujan. His notebooks are filled with them. See e.g. [7] for an application of Ramanujan's modular equations to computing the first billion or so digits of π. Many modular equations are also studied in [10]. For more of their applications, see e.g. [16]. It can be shown that the only functions $f(\tau) = q^{-1} + a_1 q + \cdots$ which obey modular equations for all n, are $J(\tau)$ and the 'modular fictions' q^{-1} and $q^{-1} \pm q$ (which are essentially exp, cos, and sin).

It was proved in [17] that, roughly speaking, a function $B(\tau)=q^{-1}+\sum_{n>0}b_nq^n$ which obeys enough modular equations, will either be of the form $B(\tau)=q^{-1}+b_1q$, or will necessarily be a Hauptmodul for a modular group containing some $\Gamma_0(N)$. The converse is also true: for instance, a modular equation for the Hauptmodul J_{25} of $\Gamma_0(25)$ given in (2.3.5) is

$$(X^2-Y)(Y^2-X)=-2\,(X^2+Y^2)+4\,(X+Y)-4\ ,$$

where $X=J_{25}(\tau)$ and $Y=J_{25}(2\tau)$. To eliminate the conceptual gap, this result should then replace step 3. Steps 1 and 2 are still required, however.

This conceptual gap should not take away from what was a remarkable accomplishment by Borcherds: not only the proof of the Monstrous Moonshine conjectures, but also the definition of two new and important algebraic structures. I hope the preceding sections give the reader some indication of why Borcherds was awarded one of the 1998 Fields Medals.

Another approach to the Hauptmodul property is by Tuite [57], who related it to the (conjectured) uniqueness of $V^\natural$. Norton has suggested that the reason $\mathbb{M}$ is associated to *genus-zero* modular functions could be what he calls its '6-transposition' property [47].

So has Moonshine been explained? According to Conway, McKay, and many others, it hasn't. They consider VOAs in general, and $V^\natural$ in particular, to be too complicated to be God-given. The progress, though impressive, has broadened not lessened the fundamental mystery, they would argue.

For what it's worth, I don't completely agree. Explaining away a mystery is a little like grasping a bar of soap in a bathtub, or quenching a child's curiousity. Only extreme measures like pulling the plug, or enrollment in school, ever really work. True progress means displacing the mystery, usually from the particular to the general. Why is the sky blue? Because of how light scatters in gases. Why are Hauptmoduls attached to each $g\in\mathbb{M}$? Because of $V^\natural$. Mystery exists wherever we can ask 'why' — like beauty it's in the beholder's eye.

Moonshine is now 'leaving the nest'. We are entering a consolation phase, tidying up, generalising, simplifying, clarifying, working out more examples. Important and interesting discoveries will be made in the next few years, and yes there still is mystery, but no longer does a Moonshiner feel like an illicit distiller: Moonshine is now a day-job!

Acknowledgments. I warmly thank the Feza Gursey Institute in Istanbul, and in particular Teoman Turgut, for their invitation to the workshop and hospitality during my month-long stay. These notes are based on 16 lectures I gave there in Summer 1998. I've also benefitted from numerous conversations with Y. Billig, A. Coste, C. Cummins, M. Gaberdiel, J. McKay, M. Tuite, and M. Walton — Mark Walton in particular made a very careful reading of the manuscript (and hence must share partial blame for any errors still remaining). My appreciation as well goes to J.-B. Zuber and P. Ruelle for sharing with me their personal stories behind the discoveries of, respectively, A-D-E in $A_1^{(1)}$ and Fermat in $A_2^{(1)}$. The research was supported in part by NSERC.

Abstract

In these notes we give an introduction both to Monstrous Moonshine and to the classification of rational conformal field theories, using this as an excuse to explore several related structures and go on a little tour of modern math. We will discuss Lie algebras, modular functions, the finite simple group classification, vertex operator algebras, Fermat's Last Theorem, category theory, (generalised) Kac-Moody algebras, denominator identities, the A-D-E meta-pattern, representations of affine algebras, Galois theory, etc. This work is informal and pedagogical, and aimed mostly at grad students in math or math phys, but I hope that many interested nonexperts will find something of value here — like any good Walt Disney movie I try not to completely ignore the 'grown-ups'. My emphasis is on ideas and motivations, so these notes are intended to complement other papers and books where this material is presented with more technical detail. The level of difficulty varies significantly from topic to topic. The two parts — in fact any of the sections — can be read independently.

Table of Contents

Part 1. The classification of conformal field theories

1.1. Informal motivation 1
1.2. Lie algebras 4
1.3. Representations of finite-dimensional simple Lie algebras 10
1.4. Affine algebras and the Kac-Peterson matrices 13
1.5. The classification of physical invariants 17
1.6. The A-D-E meta-pattern 19
1.7. Simple-currents and charge-conjugation 24
1.8. Galois theory 28
1.9. The modern approach to classifying physical invariants 31

Part 2. Monstrous Moonshine

2.1. Introduction 35
2.2. Ingredient #1: Finite simple groups and the Monster 38
2.3. Ingredient #2: Modular functions and Hauptmoduls 40
2.4. The Monstrous Moonshine conjectures 46
2.5. Formal power series 48
2.6. Ingredient #3: Vertex operator algebras 51
2.7. Ingredient #4: Generalised Kac-Moody algebras 54
2.8. Ingredient #5: Denominator identities 59
2.9. Proof of the Moonshine conjectures 60

Part 1. The classification of conformal field theories

1.1. INFORMAL MOTIVATION

In this section we will sketch a very informal and 'hand-wavy' motivation to what we shall call the classification problem for rational conformal field theory (RCFT). Much of this material is more carefully treated in e.g. [18].

A CFT is a quantum field theory (QFT), usually with a two-dimensional space-time, whose symmetries include the conformal transformations. There are different approaches to CFT — for one of these see [26,27]. Another formulation which has been deeply influential is due to Graeme Segal [52]. It is motivated by string theory and is phrased in an important mathematical language called *category theory*.

A *category* consists of two types of things. One are called *objects*, and the other are called *arrows* (or *morphisms*). An arrow, written $f : A \rightarrow B$, has an initial and a final object (A and B respectively). Arrows f, g can be composed to yield a new arrow $f \circ g$, if the final object of g equals the initial object of f. Maps between categories are called *functors* if they take the objects (resp., arrows) of one to the objects (resp., arrows) of the other, and preserve composition.

The only difficulty people can have in understanding categories is in realising that there is no real content to them. It's just a language, highly abstract like the more familiar set theory, but in many contexts (a great example is the theory of knot invariants [58]) one which is both natural and suggestive. It tries to deflect some of our instinctive infatuation with objects (nouns), to the mathematically more fruitful one with structure-preserving maps between objects (verbs). A gentle introduction to the mathematics and philosophy of categories is [43]; we'll give a taste of this shortly.

The standard example of a category is called **Set**, where the 'objects' are sets, and the arrows from A to B are functions $A \rightarrow B$. A related example that Segal uses is **Vect**, where the objects are complex vector spaces and the arrows are linear maps. A rather trivial example of a functor $\mathcal{F} : \mathbf{Vect} \rightarrow \mathbf{Set}$ sends a vector space V to its underlying set, also called V — i.e. $\mathcal{F}$ simply 'forgets' the vector space structure on V and ignores the fact that the arrows f in **Vect** are linear. The other category Segal uses he calls **C**; its objects are disjoint unions of (parametrised) circles S^1, and the arrows are (conformal equivalence classes of) *cobordisms*, i.e. (Riemann) surfaces whose boundaries are those circles. Composition of arrows in **C** is accomplished by gluing the surfaces along the appropriate boundary circles.

Consider the usual definition of a one-to-one function: $f(x) = f(y)$ only when $x = y$. Category theory replaces this with the following. The arrow $f : A \rightarrow B$ is called 'monic' if for any arrow $g : C \rightarrow B$, there exists a unique arrow $h : C \rightarrow A$ such that $f \circ h = g$. So it's a sort of factorisation property. You can easily verify that in **Set** the notions of 'one-to-one' and 'monic' coincide. What does this redefinition gain us? It certainly doesn't seem any simpler. But it does change the focus from the *argument* of f, to the *global* functional behaviour of f, and a change of perspective can never be bad. And it allows us to transport the idea of one-to-one-ness to arbitrary categories. For instance, in the Riemann surface category **C**, the 'one-to-one functions' are the genus-0 cobordisms.

Or consider the notion of *product*. In category theory, we say that the triple (P, a, b) is a product of objects A, B if $a : P \to A$ and $b : P \to B$ are arrows, and if for any $f : C \to A$, $g : C \to B$, there is a unique arrow $h : C \to P$ such that $f = a \circ h$ and $g = b \circ h$. This notion unifies several constructions (each of which is the 'product' in an appropriately chosen category): Cartesian product of sets; intersection of sets; multiplication of numbers; the logical operator 'and'; direct product; infimum in a partially ordered set; etc. *Sum* can be defined similarly, unifying the constructions of disjoint union, 'or', addition, tensor product, direct sum, supremum, etc.

This generality of course comes with a price: it can wash away all of the endearing special features of a favourite theory or structure. There certainly are contexts where e.g. all human beings should be thought of as equal, but there are other contexts where the given human is none other than your mother and must be treated as such. It turns out that category theory provides a beautiful framework for understanding topological invariants such as the Jones-Reshetikhin-Turaev-Witten knot invariants (see e.g. [58]). And it seems to be a natural language for formulating CFT axiomatically, as we'll now see.

According to Segal, a CFT is a functor $\mathcal{T}$ from $\mathbf{C}$ to $\mathbf{Vect}$, which obeys various properties. The picture comes from string theory: the fundamental object is a 'vibrating' loop; a state is given by a collection of these loops; each classical Feynman path from the initial to the final states is a world-sheet, i.e. a surface Σ whose boundary is all the loops in the initial and final states. QFT assigns a complex number I (the action) to each of these world-sheets, and the quantum amplitude, written $\langle \text{final} | \text{initial} \rangle$, will then be the integral over all worldsheets of $e^{\mathrm{i}I/\hbar}$. (The quantum amplitude is how the theory makes contact with experiment, as it tells us the probability of the given process $|\text{initial}\rangle \mapsto |\text{final}\rangle$ happening.) This is what Segal is trying to capture formally. The vector spaces in $\mathbf{Vect}$ come in in order to handle uniformly and simultaneously the various 'vibrations' of the strings. In particular there is one basic vector space H (a Hilbert space of quantum states), and the functor will take n copies of S^1 to $H^n = H \otimes \cdots \otimes H$.

The simplest interesting example here is the 'tree-level creation of a string from the vacuum'. In this case the world-sheet looks like a bowl, i.e. *topologically* is a disk D (if we imagine the bowl to be made of rubber, we could grab its rim and stretch it down flat onto the table, so we say a bowl and a disk are topologically equivalent — see also §2.3). Segal's functor gives us a linear map $\mathcal{T}(D) : \mathbb{C} \to H$ (H^0 is just $\mathbb{C}$), which we can think of equivalently as the assignment of the vector $\mathcal{T}(D)(1)$ in H to D. In the case of the standard unit disk (i.e. where the parametrisation of the boundary S^1 is simply $\theta \mapsto e^{2\pi \mathrm{i}\theta}$), this vector is cal0led the *vacuum state* $\Omega = |0\rangle$.

For another example, consider the 'vacuum-to-vacuum expectation value'. The initial and final states (objects) here are both the empty set, so the world-sheets (arrows) are closed Riemann surfaces. As usual in QFT, we can organise these by how many internal 'loops' are involved (this number is called the *genus* of the surface): topologically, 0-loop (i.e. 'tree-level') world-sheets are spheres, 1-loop world-sheets are tori, etc. These closed Riemann surfaces are discussed in more detail in §2.3. The 0-loop contribution isn't very interesting (there is only one conformal equivalence class of spheres), so let us look at the 1-loop contribution. It will be of the form $\int \mathcal{Z}([\mathit{torus}])\, d[\mathit{torus}]$, where $\mathcal{Z}$ is a complex-valued function called the partition function, and $[\mathit{torus}]$ is a conformal equivalence class of tori. In the Segal formalism we recover this in the following way: the functor takes $[torus]$ to a linear function from $H^0 = \mathbb{C}$ to $H^0 = \mathbb{C}$. Any such linear function is simply a 1×1 matrix, i.e. a complex number, which we call $\mathcal{Z}([torus])$.

Now there is a nice parametrisation of conformal equivalence classes of tori, as we will see more explicitly in §2.3. Namely, a representative for each class can be chosen to be of the form $\mathbb{C}/(\mathbb{Z} + \mathbb{Z}\tau)$ where τ is in the upper half plane $\mathcal{H}$. Thus we can write $\mathcal{Z}$ as a function of a complex variable τ. However, different τ correspond to the same equivalence class of tori: the redundancy is exactly captured by the modular group $\mathrm{PSL}_2(\mathbb{Z})$. Namely, τ and $\frac{a\tau+b}{c\tau+d}$ are equivalent, whenever $a, b, c, d \in \mathbb{Z}$ and $ad - bc = 1$. Thus $\mathcal{Z}(\tau) = \mathcal{Z}(\frac{a\tau+b}{c\tau+d})$. In other words, the partition function is modular invariant![1]

There are two sectors in CFT, a holomorphic one and an antiholomorphic one, corresponding to the two directions ('left-' and 'right-moving') of motion on a string, or the two components of the group $\mathrm{Diff}(S^1)$ of diffeomorphisms of the circle. This means that many of the quantities (e.g. the partition function) factorise into parts depending holomorphically and anti-holomorphically on the modular parameters (e.g. τ in genus 1). In a *rational* CFT there are finitely many 'primary fields' $a \in \Phi$ — the precise meaning of this is not important here, but it says that the space of states for the theory decomposes into a finite sum[2] $H = \oplus_{a,b\in\Phi} M_{ab} H_a \otimes \overline{H}_b$, where M_{ab} are nonnegative integers which count the multiplicity of $H_a \otimes \overline{H}_b$ in H. The linear maps $\mathcal{T}(\Sigma) : H^m \to H^n$ in an RCFT will factorise similarly; this 'chiral factorisation' is captured by what Segal calls the 'modular functor' [52]. The partition function becomes

$$\mathcal{Z}(\tau) = \sum_{a,b\in\Phi} M_{ab}\, \chi_a(\tau)\, \chi_b(\tau)^* \tag{1.1.1}$$

for certain holomorphic functions χ_a. One of the primary fields (we'll denote it '0') corresponds to the vacuum Ω, and uniqueness of the vacuum means that $M_{00} = 1$.

H_0 is called a *chiral algebra*; in the language of §2.6, H_0 will be a vertex operator algebra (VOA). Φ parametrises the irreducible H_0-modules and the χ's are their characters; in an RCFT we require this number to be finite. For example, for the Moonshine VOA $V^\natural$ discussed in Part 2, Φ consists of only one element.

The higher-genus behaviour of an RCFT is determined from the lower-genus behaviour, by composition of 'arrows' (i.e. the gluing together of surfaces) in **C**. See Figure 3 of [30] to find how a genus-2 surface is built up from genus-0 ones. In fact, it's generally believed that an RCFT will be uniquely determined by: (i) the choice of chiral algebra; (ii) the partition function (which tells you the spectrum of the theory, i.e. how the two sectors link up); and (iii) the structure constants C_{ab}^c, which in the Segal formalism correspond to the surfaces called 'pairs-of-pants', equivalently disks with two interior disks removed. Our approach will be to start with a chiral algebra, and find all possible partition functions. We will thus ignore the important question of existence and uniqueness of the structure constants, though at least for our chiral algebras, it seems to be generally believed that the structure constants will be unique.

---

[1] In higher-dimensional string theories, a similar argument shows more generally that *automorphic forms* will appear naturally.

[2] It seems though that 'rational' logarithmic CFT is trying to teach us the lesson that this familiar requirement can and should be weakened. See Gaberdiel-Kausch (1999).

Perhaps all chiral algebras come from standard constructions (e.g. orbifolds and the Goddard-Kent-Olive (GKO) coset construction — see e.g. [18]) involving lattices and affine Kac-Moody algebras. For instance a $\mathbb{Z}_2$-orbifold of the VOA of the Leech lattice gives us the Moonshine module $V^\natural$, and the so-called minimal models come from GKO cosets involving $A_1^{(1)}$. This is in line with the spirit of Tannaka-Krein duality (and its generalisations by Deligne and Doplicher-Roberts), which roughly says that if a bunch of things *act like* they're the set of representations of a Lie group, then they *are* the set of representations of a Lie group.

In any case, one of the simplest, best understood, and important classes (called Wess-Zumino-Witten (WZW) models — see for instance [30,59] in this volume) of RCFTs correspond to affine Kac-Moody algebras at a positive integer level k. We will have much more to say later about these algebras, but for now let us remark that Φ here will be the (finite) set P_+^k of integrable level k highest weights λ. Their chiral algebras were constructed by Frenkel and Zhu. The following sections concern the attempt to classify the partition functions corresponding to Kac-Moody algebras — see especially §1.5. I will use this theme as an excuse to describe many other things, e.g. the A-D-E meta-pattern, Lie theory, Galois, fusion rings, ... I dedicate these notes to the profound friendship developing in recent years between mathematics and physics. As Victor Kac said in his 1996 Wigner medal acceptance speech, "Some of the best ideas come to my field from the physicists. And on top of this they award me a medal. One couldn't hope for a better deal."

1.2. LIE ALGEBRAS

Lie algebras (and their nonlinear partners *Lie groups*) appear in numerous places throughout math and mathematical physics. A nice introduction is [9]; Lie theory is presented with more of a physics flavour in [24], as well as [59].

An *algebra* is a vector space with a way to multiply vectors which is compatible with the vector space structure (i.e. the vector-valued product is *bilinear*: $(a\vec{u}+a'\vec{u}')\,(b\vec{v}+b'\vec{v}') = ab\,\vec{u}\vec{v} + ab'\,\vec{u}\vec{v}' + a'b\,\vec{u}'\vec{v} + a'b'\,\vec{u}'\vec{v}')$. For example, the complex numbers $\mathbb{C}$ can be thought of as a 2-dimensional algebra over $\mathbb{R}$ (a basis is 1 and $\mathrm{i} = \sqrt{-1}$; the *scalars* here are real numbers and the *vectors* are complex numbers). The quaternions are 4-dimensional over $\mathbb{R}$ and the octonions are 8-dimensional over $\mathbb{R}$. Incidentally, these are the only finite-dimensional algebras over $\mathbb{R}$ which obey the cancellation law: $\vec{u} \neq 0$ and $\vec{u}\vec{v} = 0$ implies $\vec{v} = 0$ (the reader should try to convince himself why the familiar vector product on $\mathbb{R}^3$ fails the cancellation law). This important little fact makes several unexpected appearances in math. For instance, it is trivially possible to 'comb the hair' on the circle S^1 without 'cheating' (i.e. needing a hair-part or exploiting a bald spot): just comb the hair clockwise for example. However it is not possible to comb the hair on the sphere S^2 (e.g. your own head) without cheating. The only other k-spheres S^k which can be combed (i.e. for which there exist k linearly independent continuous vector fields) are $k = 3$ and 7. This is intimately connected with the existence of $\mathbb{C}$, the quaternions, and octonions (namely,

S^1, S^3, S^7 can be thought of as the length 1 complex numbers, quaternions, and octonions, resp.).

In a *Lie* algebra $\mathfrak{g}$, the product is usually called a 'bracket' and is written $[xy]$. It is required to be 'anti-commutative' and 'anti-associative':

$$[xy] + [yx] = 0 \tag{1.2.1a}$$

$$[x[yz]] + [y[zx]] + [z[xy]] = 0 \tag{1.2.1b}$$

(like most other equalities in math, (1.2.1b) is usually called the *Jacobi identity*). Usually we will consider Lie algebras over $\mathbb{C}$, but sometimes over $\mathbb{R}$. Note that (1.2.1a) says $[xx] = 0$.

One important consequence of bilinearity is that it is enough to know the values of all the brackets $[x_i x_j]$ for $i < j$, for any basis $\{x_1, x_2, \ldots\}$ of $\mathfrak{g}$. (The reader should convince himself of this before proceeding.)

The simplest example of a Lie algebra is $\mathfrak{g} = \mathbb{C}$ (or $\mathfrak{g} = \mathbb{R}$), with the bracket $[xy]$ identically 0. In fact, this is the only 1-dimensional Lie algebra. It is a straightforward exercise for the reader to find all 2- and 3-dimensional Lie algebras (over $\mathbb{C}$) up to isomorphism (i.e. change of basis): there are precisely 2 and 6 of them, respectively (though one of the 6 depends on a complex parameter). Over $\mathbb{R}$, there are 2 and 9 (with 2 depending on real parameters). This exercise cannot be continued much further — e.g. not all 7-dimensional Lie algebras (over $\mathbb{C}$) are known. Nor is it obvious that this would be an interesting or valuable exercise. We should suspect that our definition of Lie algebra is probably a little too general for anything obeying it to be automatically an interesting structure. More often than not, a classification turns out to be a stale and useless list.

Two of the 3-dimensional Lie algebras are important in what follows. One of them is well-known to the reader: consider the vector-product (also called cross-product) in $\mathbb{C}^3$. Taking the standard basis $\{e_1, e_2, e_3\}$ of $\mathbb{C}^3$, the bracket can be defined by the relations

$$[e_1 e_2] = e_3 \ , \qquad [e_1 e_3] = -e_2 \ , \qquad [e_2 e_3] = e_1 \ . \tag{1.2.2a}$$

This Lie algebra, denoted A_1 or $\mathrm{sl}_2(\mathbb{C})$, can be called the 'mother of all (semi-simple) Lie algebras'. A more familiar realisation of A_1 uses a basis $\{e, f, h\}$ with relations

$$[ef] = h \ , \qquad [he] = 2e \ , \qquad [hf] = -2f \ . \tag{1.2.2b}$$

The reader can find the change-of-basis (valid over $\mathbb{C}$ but not $\mathbb{R}$) showing that (1.2.2) define isomorphic *complex* (but not *real*) Lie algebras.

Another important 3-dimensional Lie algebra is called the Heisenberg algebra[3] and is the algebra of the canonical commutation relations in quantum mechanics: choosing a basis x, p, h, it is defined by

$$[xp] = h \ , \qquad [xh] = [ph] = 0 \ . \tag{1.2.3}$$

---

[3] Actually, 'Heisenberg algebra' refers to a family of Lie algebras, with (1.2.3) being the one of lowest dimension.

From our definition, it is far from clear that Lie algebras, as a class, should be natural and worth studying. After all, there are infinitely many possible axiomatic systems: why should the one defining a Lie algebra be anything special *a priori*? Perhaps this could have been anticipated by the following line of reasoning.

Axiom. Groups are important and interesting.
Axiom. Manifolds are important and interesting.

Manifolds are structures where calculus is possible; locally, a manifold looks like a piece of $\mathbb{R}^n$ (or $\mathbb{C}^n$), but these pieces can be bent and stitched together to create more interesting shapes. For instance a circle is a 1-dimensional manifold, while Einstein claimed space-time is a curved 4-dimensional one.

Definition. A Lie group is a manifold with a compatible group structure.

This means that 'multiplication' and 'inverse' are differentiable maps. $\mathbb{R}$ is a Lie group, under addition: obviously, $\mu : \mathbb{R}^2 \to \mathbb{R}$ and $\iota : \mathbb{R} \to \mathbb{R}$ defined by $\mu(a,b) = a + b$ and $\iota(a) = -a$ are both differentiable. (Why isn't $\mathbb{R}$ a Lie group under multiplication?) A circle is also a Lie group: parametrise the points with the angle θ defined mod 2π (or mod 360 if you prefer); the 'product' of the point at angle θ_1 with the point at angle θ_2 will be the point at angle $\theta_1 + \theta_2$. Surprisingly, the only other k-sphere which is a Lie group is S^3 (the product can be defined using quaternions of unit length[4], or using the matrix group $\mathrm{SU}_2(\mathbb{C})$). Many but not all Lie groups can be expressed as matrix groups. Two other examples are GL_n (invertible $n \times n$ matrices) and SL_n (ones with determinant 1).

A consequence of the above axioms is then surely:

Corollary. Lie groups should be important and interesting.

Lie group structure theory can be thought of as a major generalisation of linear algebra. The basic constructions familiar to undergraduates have important analogues valid in many Lie groups. For instance, years ago we were taught to solve linear equations and invert matrices by using elementary row operations to reduce a matrix to row-echelon form. What this says is that any matrix $A \in \mathrm{GL}_n(\mathbb{C})$ can be factorised $A = BPN$, where N is uppertriangular with 1's on the diagonal, P is a permutation matrix, and B is an uppertriangular matrix. This is essentially what is called the Bruhat decomposition of the Lie group $\mathrm{GL}_n(\mathbb{C})$. More generally (where it applies to any 'reductive' Lie group G), P will be an element of the so-called 'Weyl group' of G (of which we'll have much more to say later), and B will be in a 'Borel subgroup'.

Lie groups appear throughout physics. E.g. the orthogonal group $\mathrm{SO}_3(\mathbb{R})$ is the configuration space of a rigid body centred at the origin, while $\mathrm{SU}_2(\mathbb{C})$ is the set of states of an electron at rest. The gauge group of the Standard Model of particle physics is $\mathrm{SU}_3(\mathbb{C}) \times \mathrm{SU}_2(\mathbb{C}) \times \mathrm{U}_1(\mathbb{C})$, while the Lorentz group of special relativity is $\mathrm{SO}_{3,1}(\mathbb{R})$.

There is an important relation between Lie groups and Lie algebras.

Fact. The tangent space of a Lie group is a Lie algebra. Any (finite-dimensional real or complex) Lie algebra is the tangent space to some Lie group.

---

[4] Similarly, the 7-sphere inherits from the octonions a *nonassociative* (hence nongroup) product, compatible with its manifold structure.

More precisely, the tangent space at 1 (i.e. the set of all infinitesimal generators of the Lie group) can be given a natural Lie algebra structure. A Lie algebra, being a linearised Lie group, is much simpler and easier to handle. The Lie algebra preserves the local properties of the Lie group, though it loses global topological properties (like boundedness). A Lie group has a single Lie algebra, but a Lie algebra can correspond to many different Lie groups. The Lie algebra corresponding to both $\mathbb{R}$ and S^1 is $\mathfrak{g} = \mathbb{R}$ with trivial bracket. The Lie algebra corresponding to both $S^3 = \mathrm{SU}_2(\mathbb{C})$ and $\mathrm{SO}_3(\mathbb{R})$ is the cross-product algebra on $\mathbb{R}^3$ (usually called $\mathrm{so}_3(\mathbb{R})$). Given the above fact, a safe guess would be:

Conjecture. Lie algebras are important and interesting.

From this line of reasoning, it should be expected that historically Lie groups arose first. Indeed that is the case: the Norwegian Sophus Lie introduced them in 1873 to try to develop a Galois theory for ordinary differential equations. As the reader may be aware, Galois theory is used for instance to show that not all 5th degree (or higher) polynomials can be explicitly 'solved' using radicals — we will meet Galois theory in §1.8. Lie wanted to study the explicit solvability (integrability) of differential equations, and this led him to develop what we now call Lie theory. The importance of Lie groups however have grown well beyond this initial motivation.

An important class of Lie algebras are the so-called finite-dimensional *simple* ones. Their definition and motivation will be studied in §2.7 below, but in a certain sense they serve as building blocks for all other finite-dimensional Lie algebras.

The classification of simple finite-dimensional Lie algebras over $\mathbb{C}$ is quite important and was accomplished at the turn of the century by Killing and Cartan. There are 4 infinite families A_ℓ ($\ell \geq 1$), B_ℓ ($\ell \geq 3$), C_ℓ ($\ell \geq 2$), and D_ℓ ($\ell \geq 4$), and 5 exceptionals E_6, E_7, E_8, F_4 and G_2. A_ℓ can be thought of[5] as $\mathrm{sl}_{\ell+1}(\mathbb{C})$, the $(\ell+1)\times(\ell+1)$ matrices with trace 0. The orthogonal algebras B_ℓ and D_ℓ can be identified with $\mathrm{so}_{2\ell+1}(\mathbb{C})$ and $\mathrm{so}_{2\ell}(\mathbb{C})$, resp., where $\mathrm{so}_n(\mathbb{C})$ is all $n \times n$ anti-symmetric matrices $A^t = -A$. The symplectic algebra C_ℓ is $\mathrm{sp}_{2\ell}(\mathbb{C})$, i.e. all $2\ell \times 2\ell$ matrices A obeying $A\Omega = -\Omega A^t$, where $\Omega = \begin{pmatrix} 0 & I_\ell \\ -I_\ell & 0 \end{pmatrix}$ and I_ℓ is the identity matrix. The exceptionals can be constructed e.g. using the octonions. In all these cases the bracket is given by the commutator

$$[AB] = [A, B] := AB - BA \tag{1.2.4}$$

(it is a good exercise for the reader to confirm that the commutator satisfies (1.2.1), and that e.g. $\mathrm{sl}_n(\mathbb{C})$ is indeed closed under it). To see that (1.2.2b) truly is $\mathrm{sl}_2(\mathbb{C})$, put

$$e = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad f = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}, \qquad h = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \tag{1.2.5}$$

Incidentally the names A, B, C, D have no significance: since the 4 series start at $\ell = 1, 2, 3, 4$, it seemed natural to call these A, B, C, D, resp. Unfortunately a bit of bad luck happened: B_2 and C_2 are isomorphic and so at random that algebra was placed in the orthogonal series; however affine Dynkin diagrams make it clear that it really is a symplectic algebra which accidentally looks orthogonal; hence in hindsight the names of the B- and C-series really should have been switched.

---

[5] Strictly speaking these are *representations* (see next section).

This classification changes if the *field* — the choice of scalars=numbers — is changed. By a field, we mean we can add, subtract, multiply and divide, such that all the usual properties like commutativity and distributivity are obeyed. Fields will make a few different appearances in these notes. $\mathbb{C}$, $\mathbb{R}$, and $\mathbb{Q}$ are fields, while $\mathbb{Z}$ is not (you can't always divide an integer by e.g. 3, and remain in $\mathbb{Z}$). The integers mod n, which we will write $\mathbb{Z}_n$, are a field iff n is prime (the reader can verify that in e.g. $\mathbb{Z}_4$, it is not possible to divide by the field element $[2] \in \mathbb{Z}_4$ even though $[2] \neq [0]$ there). $\mathbb{C}$ and $\mathbb{R}$ are examples of fields of characteristic 0 — this means that 0 is the only integer k with the property that $kx = 0$ for all x in the field. $\mathbb{Z}_p$ is the simplest example of a field with nonzero characteristic: in $\mathbb{Z}_p$, multiplying by the integer p has the same effect as multiplying by 0, and so we say $\mathbb{Z}_p$ has characteristic p. Strange fields have important applications in e.g. coding theory and, ironically, in number theory itself — see e.g. §1.8.

As always, $\mathbb{C}$ is better behaved than e.g. $\mathbb{R}$ because every polynomial can be factorised over $\mathbb{C}$ (we say $\mathbb{C}$ is *algebraically closed*) — this implies for example that every matrix has an eigenvector over $\mathbb{C}$ but not necessarily over $\mathbb{R}$. Over $\mathbb{R}$, the difference in the simple Lie algebra classification is that each symbol $X_\ell \in \{A_\ell, \ldots, G_2\}$ corresponds to a number of inequivalent algebras (over $\mathbb{C}$, each algebra has its own symbol). For example, 'A_1' corresponds to 3 different real simple Lie algebras, namely the matrix algebras $\mathrm{sl}_2(\mathbb{R})$, $\mathrm{sl}_2(\mathbb{C})$ (interpreted as a *real* vector space), and $\mathrm{so}_3(\mathbb{R})$. The simple Lie algebra classification has recently been done in any characteristic $p > 7$. It is surprising but very common that the smaller primes behave very poorly, and the classification for characteristic 2 is probably completely hopeless.

Associated with each simple algebra X_ℓ is a Weyl group, and a (Coxeter-)Dynkin diagram. The Weyl group is a finite reflection group, e.g. for A_ℓ it is the symmetric group $\mathfrak{S}_{\ell+1}$. See Figure 7 of [59] for the Weyl group of A_2. The Dynkin diagram of X_ℓ (see e.g. [24,36,38] or Figure 6 in [59]) is a graph with ℓ nodes, and with possibly some double and triple edges. It says how to construct X_ℓ abstractly using generators and relations — see §2.7. We will keep meeting both throughout these notes.

Another source of Lie algebras are the vector fields $\mathrm{Vect}(M)$ on a manifold M. A vector field v is a choice (in a smooth way) of a tangent vector $v(p) \in T_pM$ at each point of M. It can be thought of as a (1st order) differential operator, acting on functions $f : M \to \mathbb{R}$ (or $f : M \to \mathbb{C}$); at each point $p \in M$ take the directional derivative of f in the direction $v(p)$. For example the vector fields on the circle, $\mathrm{Vect}(S^1)$, can be thought of as anything of the form $g(\theta)\frac{d}{d\theta}$ where $g(\theta)$ can be any function with period 1. We can compose vector fields $u \circ v$, but this will result in a 2nd order differential operator: e.g.

$$(f(\theta)\frac{d}{d\theta}) \circ (g(\theta)\frac{d}{d\theta}) = f(\theta)\, g(\theta)\, \frac{d^2}{d\theta^2} + f(\theta)\, g'(\theta)\, \frac{d}{d\theta}\ .$$

Instead, the natural 'product' of vector fields is given by their commutator $[u, v] = u \circ v - v \circ u$, as it always results in a vector field: e.g.

$$[f(\theta)\frac{d}{d\theta}, g(\theta)\frac{d}{d\theta}] = (f(\theta)\, g'(\theta) - f'(\theta)\, g(\theta))\frac{d}{d\theta}$$

in $\mathrm{Vect}(S^1)$. $\mathrm{Vect}(M)$ with this bracket is an infinite-dimensional Lie algebra. In the case where M is a Lie group G, the Lie algebra of G can be interpreted as a certain finite-dimensional subalgebra of $\mathrm{Vect}(G)$ given by the 'left-invariant vector fields'.

Simple algebras need not be finite-dimensional. An example of an infinite-dimensional one is the *Witt algebra* $\mathcal{W}$, which can be defined (over $\mathbb{C}$) by the basis[6] L_n, $n \in \mathbb{Z}$, and the relations

$$[L_m L_n] = (m-n)L_{m+n} \ . \tag{1.2.6}$$

Using the realisation $L_n = -\mathrm{i}e^{-\mathrm{i}n\theta}\frac{d}{d\theta}$, the Witt algebra can also be interpreted as the polynomial subalgebra of the complexification $\mathbb{C} \otimes \mathrm{Vect}(S^1)$ — i.e. change the scalar field of $\mathrm{Vect}(S^1)$ from $\mathbb{R}$ to $\mathbb{C}$. Incidentally, infinite-dimensional Lie algebras need not have a corresponding Lie group: e.g. the real algebra $\mathrm{Vect}(S^1)$ is the Lie algebra of the Lie group $\mathrm{Diff}^+(S^1)$ of orientation-preserving diffeomorphisms $S^1 \to S^1$, but $\mathbb{C} \otimes \mathrm{Vect}(S^1)$ has no Lie group. $\mathrm{Diff}^+(S^1)$ plays a large role in CFT, by acting on the objects of Segal's category $\mathbf{C}$.

The Witt algebra appears naturally in CFT: e.g. using the realisation $L_n = -z^{n+1}\frac{d}{dz}$ it is the polynomial subalgebra of the Lie algebra $\mathrm{Vect}(\mathbb{C}/\{0\})$. Very carelessly, $\mathrm{Vect}(\mathbb{C}/\{0\})$ is often thought of as the infinitesimal conformal transformations on a suitable neighbourhood of 0 (yet clearly L_{-2}, L_{-3}, ... are singular at 0!). Indeed the CFT literature is very sloppy when discussing the conformal group in 2-dimensions. The unfortunate fact is that, contrary to claims, *there is no infinite-dimensional conformal group* for $\mathbb{C} \cong \mathbb{R}^2$. The best we can do is the 3-dimensional group $\mathrm{PSL}_2(\mathbb{C})$ of Möbius transformations $z \mapsto \frac{az+b}{cz+d}$, which are orientation-preserving conformal transformations for the Riemann sphere $\mathbb{C} \cup \{\infty\}$. There seem to be 2 ways out of this rather embarrassing predicament. One is to argue that we are really interested in 'infinitesimal conformal invariance' in some meromorphic sense, so the full Witt algebra can appear. The other way is to argue that it is the conformal group of 'Minkowski space' $\mathbb{R}^{1,1}$ (or better, its compactification $S^1 \times S^1$) rather than $\mathbb{R}^2 \cong \mathbb{C}$ (or its compactification S^2) which is relevant for CFT. That conformal group *is* infinite-dimensional; for $S^1 \times S^1$ it consists of 2 copies of $\mathrm{Diff}^+(S^1) \times \mathrm{Diff}^+(S^1)$. For a more careful treatment of this point, see [51].

For reasons we will discuss in §1.4, we are more interested in the *Virasoro algebra* $\mathcal{V}$ rather than the Witt algebra $\mathcal{W}$. This is a '1-dimensional central extension' of $\mathcal{W}$; as a vector space $\mathcal{V} = \mathcal{W} \oplus \mathbb{C}C$ with relations given by

$$[L_m L_n] = (m-n)L_{m+n} + \delta_{n,-m}\frac{m\,(m^2-1)}{12}\,C \tag{1.2.7a}$$

$$[L_m C] = 0 \ . \tag{1.2.7b}$$

'1-dimensional central extension' means $\mathcal{V}$ has one extra basis vector C, which lies in the *centre* of $\mathcal{V}$ (i.e. $[xC] = 0$ for all $x \in \mathcal{V}$), and sending $C \to 0$ recovers $\mathcal{W}$ (i.e. takes (1.2.7a) to (1.2.6)). A common mistake in the physics literature is to regard C as a number: it is in fact a vector, though in many (but not all) representations it is mapped to a scalar multiple of the identity.

---

[6] In infinite dimensions, to avoid convergence complications, only finite linear combinations of basis vectors are generally permitted. Infinite linear combinations would involve taking some 'completion'.

The reason for the strange-looking (1.2.7a) is that we have little choice: $\mathcal{V}$ is the unique nontrivial 1-dimensional central extension of $\mathcal{W}$. The factor $\frac{1}{12}$ there is conventional but standard, and has to do with 'zeta-function regularisation' in string theory — i.e. the divergent sum $\sum_{n=1}^{\infty} n$ is 'reinterpreted' as $\zeta(-1) = \frac{-1}{12}$, where $\zeta(s) = \sum_{n=1}^{\infty} n^{-s}$ is the Riemann zeta function. Incidentally $\zeta(s)$ can be written as the product $\prod_p (1-p^{-s})^{-1}$ over all primes $p = 2, 3, 5, \ldots$ (try to see why); hence $\zeta(s)$ has a lot to do with primes, in particular their distribution. In fact the most famous unsolved problem in math today is the Riemann conjecture, which says that $\zeta(s) \neq 0$ whenever $\mathrm{Re}(s) \neq \frac{1}{2}$. One researcher recently described this conjecture as saying that the primes have music in them.

In CFT, L_0 is the energy operator. For example the partition function is given by $\mathcal{Z}(\tau) = \mathrm{Tr}_H(q^{L_0-c/24} q^{*\bar{L}_0-c/24})$ and the (normalised) character χ_a equals $\mathrm{Tr}_{H_a}(q^{L_0-c/24})$ for $q = e^{2\pi \mathrm{i}\tau}$. cI is the scalar multiple of the identity to which C gets sent; it has a physical interpretation [18] involving Casimir (vacuum) energy, which depends on space-time topology, and the strange shift by $c/24$ is due to an implicit mapping from the cylinder to the plane.

1.3. REPRESENTATIONS OF FINITE-DIMENSIONAL SIMPLE LIE ALGEBRAS

The representation theory of the simple Lie algebras[7] can perhaps be regarded as an enormous generalisation of trigonometry. For instance the facts that $\frac{\sin(nx)}{\sin(x)}$ can be written as a polynomial in $\cos(x)$ for any $n \in \mathbb{Z}$, and that

$$\frac{\sin(mx)\,\sin(nx)}{\sin(x)} = \sin((m+n)x) + \sin((m+n-2)x) + \cdots + \sin((m-n)x)$$

for any $m, n \in \mathbb{Z}_>$, are both easy special cases of the theory.

The classic example of an algebraic structure are the numbers, and they prejudice us into thinking that commutativity and associativity are the ideal. We have learned over the past couple of centuries that commutativity can often be dropped without losing depth and usefulness, but most interesting structures seem to obey some form of associativity. Moreover, true associativity (as opposed to e.g. anti-associativity) really simplifies the arithmetic. Given the happy 'accident' that the commutator $[x, y] := xy - yx$ in any associative algebra obeys anti-associativity, it would seem to be both tempting and natural to study the ways (if any) in which associative algebras $\mathfrak{A}$ can 'model' or *represent* a given Lie algebra. Precisely, we are looking for a map $\rho : \mathfrak{g} \to \mathfrak{A}$ which preserves the linear structure (i.e. ρ is a linear function), and which sends the bracket $[xy]$ in $\mathfrak{g}$ to the commutator $[\rho(x), \rho(y)]$ in $\mathfrak{A}$.

In practice groups (resp., algebras) often appear as symmetries (resp., infinitesimal generators of symmetries). These symmetries often act linearly. In other words, in practise the preferred associative algebras will usually be matrix algebras, and this is the usual form for a representation and the only kind we will consider. The *dimension* of these representations is the size of the matrices.

---

[7] See e.g. [25] for more details. Historically, representations of Lie algebras were considered even before representations of finite groups.

Finding all possible representations, even for the simple Lie algebras, is probably hopeless. However, it is possible to find all *finite-dimensional* representations of the simple Lie algebras, and the answer is easy to describe. Given a simple Lie algebra X_ℓ, there is a representation L_λ for each ℓ-tuple $\lambda = (\lambda_1, \ldots, \lambda_\ell)$ of nonnegative integers. λ is called a *highest-weight*. Moreover, we can take direct sums $\oplus_i L_{\lambda^{(i)}}$ of finitely many of these representations. The matrices in such a direct sum will be in block form. It turns out that, up to change-of-basis, this exhausts all finite-dimensional representations of X_ℓ.

It is common to replace 'representation ρ of $\mathfrak{g}$' with the equivalent notion of '$\mathfrak{g}$-module M' — i.e. we think of the matrices $\rho(x)$ as linear maps $M \to M$. A $\mathfrak{g}$-*module* is a vector space on which $\mathfrak{g}$ acts (on the left). Instead of considering the matrix $\rho(x)$, we consider 'products' xv (think of this as the matrix $\rho(x)$ times the column vector v) for $v \in M$. This product must be bilinear, and must obey $[xy]v = x(yv) - y(xv)$.

To get an idea of what L_λ looks like, consider A_1. Recall its generators e, f, h and relations (1.2.2b). Choose any $\lambda \in \mathbb{C}$. Define $x_0 \neq 0$ to formally obey $hx_0 = \lambda x_0$ and $ex_0 = 0$. Define inductively $x_{i+1} := fx_i$ for $i = 0, 1, \ldots$. Define M_λ to be the span of all x_i — we will see shortly that they are linearly independent (so M_λ is infinite-dimensional). M_λ is a module of A_1: the calculations $hx_{i+1} = hfx_i = ([hf] + fh)x_i = (-2f + fh)x_i$ and $ex_{i+1} = efx_i = ([ef] + fe)x_i = (h + fe)x_i$ show inductively that $hx_m = (\lambda - 2m)x_m$ and $ex_m = (\lambda - m + 1)m\, x_{m-1}$. From these the reader can show that the x_i are linearly independent. M_λ is called a *Verma module*; λ is called its highest-weight, and x_0 is called a highest-weight vector.

Now specialise to $\lambda = n \in \mathbb{Z}_\geq := \{0, 1, 2, \ldots\}$. Note that $ex_{n+1} = 0$ and $hx_{n+1} = (-n-2)x_{n+1}$. This means that, for these n, M_n contains a *submodule* with highest-weight vector x_{n+1}, isomorphic to M_{-n-2}. x_{n+1} is called a *null vector*. In other words, we could set $x_{n+1} := 0$ and still have an A_1-module. We would then get a *finite-dimensional* module which we'll call $L_n := M_n/M_{-n-2}$ (not to be confused with the Virasoro generator in (1.2.7)). Its basis is $\{x_0, x_1, \ldots, x_n\}$ and so it has dimension $n + 1$.

For example, take $n = 1$. Note that what we get in terms of the basis $\{x_0, x_1\}$ is the familiar representation $\mathrm{sl}_2(\mathbb{C})$ given in (1.2.5).

The situation for the other simple Lie algebras X_ℓ is similar.

It turns out to be hard to compare representations: ρ and ρ' could be equivalent (i.e. differ merely by a change-of-basis) but look very different. Or if we are given a representation, we may want to decompose it into the direct sum of some $L_{\lambda^{(i)}}$. When working with representations, it is often very useful to avoid much of the extraneous basis-dependent detail present in the function ρ. Finite group theory suggests how to do this: we should use *characters*. The character of an A_1-module M is given by Weyl: write M as a direct sum of eigenspaces $M(m)$ of h; then define

$$\mathrm{ch}_M(z) := \sum_m \dim\, M(m)\; e^{mz}\ , \tag{1.3.1}$$

for any $z \in \mathbb{C}$. The m are called *weights* and the $M(m)$ *weight-spaces*. For example, for

L_n the weights are $m = n, n-2, \ldots, -n$, the weight-spaces $L_n(m)$ are $\mathbb{C}\, x_{(n-m)/2}$, and

$$\mathrm{ch}_n(z) = \sum_{i=0}^{n} e^{(n-2i)z} = \frac{\sin((n+1)\,z)}{\sin(z)}\ . \tag{1.3.2}$$

Analogous formulas apply to any algebra X_ℓ: the character will then be a function of an ℓ-dimensional subspace $\mathfrak{h}$ called the *Cartan subalgebra*, spanned by all the h_i (see §2.7), so can be thought of as a complex-valued function of ℓ complex variables. The weights m will lie in the dual space to $\mathfrak{h}$ — i.e. are linear maps $\mathfrak{h} \to \mathbb{C}$ — so will have ℓ components. See for instance Figure 8 in [59]. Incidentally, ℓ is called the *rank* of X_ℓ.

Weyl's definition works: two representations are equivalent iff their characters are identical, and $M = \oplus_i L_{\lambda^{(i)}}$ iff $\mathrm{ch}_M(z) = \sum_i \mathrm{ch}_{\lambda^{(i)}}(z)$. It also is enormously simpler: e.g. the smallest nontrivial representation of E_8 is a map from $\mathbb{C}^{248}$ to the space of 248×248 matrices, while its character is a function $\mathbb{C}^8 \to \mathbb{C}$. But why is Weyl's definition natural? How did he come up with it?

To answer that question, we must remind ourselves of the characters of finite groups[8]. A representation of a finite group G is a structure-preserving map ρ (i.e. a group homomorphism) from G to matrices. The group's product becomes matrix product. In these notes we will be exclusively interested in group representations over $\mathbb{C}$. Two representations ρ, ρ' are called *equivalent* if there exists a matrix (change-of-basis) U such that $\rho'(g) = U\rho(g)U^{-1}$ for all g. The character ch_ρ is the map $G \to \mathbb{C}$ given by the trace: $\mathrm{ch}_\rho(g) = \mathrm{tr}(\rho(g))$. We see that equivalent representations will have the same character, because of the fundamental identity $\mathrm{tr}(AB) = \mathrm{tr}(BA)$. This identity also tells us that the character is a 'class function', i.e. $\mathrm{ch}_\rho(hgh^{-1}) = \mathrm{tr}(\rho(h)\,\rho(g)\,\rho(h)^{-1}) = \mathrm{ch}_\rho(g)$ so ch_ρ is constant on each 'conjugacy class'. Group characters are also enormously simpler than representations: e.g. the smallest nontrivial representation of the Monster $\mathbb{M}$ (see Part 2) consists of almost 10^{54} matrices, each of size 196883×196883, while its character consists of 194 complex numbers. Incidentally, finite group representations behave analogously to the representations of X_ℓ: the role of the modules L_λ is played by the irreducible representations ρ_i, and any finite-dimensional representation of G can be decomposed uniquely into a direct sum of various ρ_i. The difference is that there are only finitely many ρ_i — their number equals the number of conjugacy classes of G.

We can use this group intuition here. In particular, given any Lie algebra X_ℓ and representation ρ, we can think of the map $e^x \mapsto e^{\rho(x)}$ as a representation of a Lie group $G(X_\ell)$ corresponding to X_ℓ (the exponential e^A of a matrix is defined by the usual power series; it will always converge). The trace of the matrix $e^{\rho(x)}$ will be the *group* character value at $e^x \in G(X_\ell)$, so we'll define it to be the *algebra* character value at $x \in X_\ell$. Again, it suffices to consider only representatives of each conjugacy class of $G(X_\ell)$, because the character will be a class function. Now, almost every matrix is diagonalisable (since almost any $n \times n$ matrix has n distinct eigenvalues), and so it would seem we aren't losing much by restricting $x \in X_\ell$ to *diagonalisable* matrices. Hence we may take our conjugacy class representatives to be *diagonal* matrices $x \in X_\ell$, i.e. (for $X_\ell = A_1$) to $x = zh$ for $z \in \mathbb{C}$ (h is diagonal in the x_i basis of L_λ). So the algebra character can be chosen to be a function of z. Finally, the trace of $e^{\rho(x)} = e^{z\rho(h)}$ will be given by (1.3.1). This completes the motivation for Weyl's character formula.

---

[8] Surprisingly, what we now call the characters of group representations were invented almost a decade before group representations were.

There is one other important observation we can make. Different diagonal matrices can belong to the same conjugacy class. For instance,

$$\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} a & 0 \\ 0 & b \end{pmatrix} \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}^{-1} = \begin{pmatrix} b & 0 \\ 0 & a \end{pmatrix} ,$$

so e^{zh} and e^{-zh} lie in the same $G(A_1) = \mathrm{SL}_2(\mathbb{C})$ conjugacy class. Hence $\mathrm{ch}_M(z) = \mathrm{ch}_M(-z)$. This symmetry $z \mapsto -z$ belongs to the *Weyl group* for A_1. Each X_ℓ has similar symmetries, and the Weyl group plays an important role in the whole theory, sort of analogous to the modular group for modular functions we'll discuss in §2.3.

Weyl found a generalisation of the right-side of (1.3.2), valid for all X_ℓ. The character of L_λ can be written as a fraction (2.8.1): the numerator will be a alternating sum over the Weyl group, and the denominator will be a product over 'positive roots'. This formula and its generalisations have profound consequences, as we'll see in §2.8.

Incidentally, the trigonometric identities given at the beginning of this section are the tensor product formula of representations (interpreted as the product and sum of characters), and the fact that an arbitrary character can be written as a polynomial in the fundamental characters, both specialised to A_1 (see (1.3.2) for the A_1 characters).

1.4. AFFINE ALGEBRAS AND THE KAC-PETERSON MATRICES

The theory of nontwisted affine Kac-Moody algebras (usually called *affine algebras* or *current algebras*) is extremely analogous to that of the finite-dimensional simple Lie algebras. Nothing infinite-dimensional tries harder to be finite-dimensional than affine algebras. Standard references for the following material are [38,41,24].

Let X_ℓ be any simple finite-dimensional Lie algebra. The affine algebra $X_\ell^{(1)}$ is essentially the *loop algebra* $\mathcal{L}(X_\ell)$, defined to be all possible 'Laurent polynomials' $\sum_{n\in\mathbb{Z}} a_n t^n$ where each $a_n \in X_\ell$ and all but finitely many $a_n = 0$. t here is an indeterminant. The bracket in $\mathcal{L}(X_\ell)$ is the obvious one: e.g. $[at^n, bt^m] = [ab]t^{n+m}$. Geometrically, $\mathcal{L}(X_\ell)$ is the Lie algebra of polynomial maps $S^1 \to X_\ell$ — hence the name (for that realisation, think of $t = e^{2\pi \mathrm{i}\theta}$). Hence there are many generalisations of the loop algebra (e.g. any manifold in place of S^1 will do), closely related ones called *toroidal algebras* being the Lie algebra of maps $S^1 \times \cdots \times S^1 \to X_\ell$. But the loop algebra is simplest and best understood, and the only one we'll consider. Note that $\mathcal{L}(X_\ell)$ is infinite-dimensional. Its Lie groups are the *loop groups*, consisting of all loops $S^1 \to G(X_\ell)$ in a Lie group for X_ℓ.

We saw S^1 before, in the discussion of the Witt algebra. Thus the Virasoro and affine algebras should be related. In fact, the Virasoro algebra acts on the affine algebras as 'derivations', and this connection plays an important technical role in the theory.

$X_\ell^{(1)}$ is in the same relation to the loop algebra, that the Virasoro $\mathcal{V}$ is to the Witt $\mathcal{W}$. Namely, it is its (unique nontrivial 1-dimensional) central extension — see e.g. (7.7.1) of [38] for the analogue of (1.2.7a) here. In addition, for more technical reasons, a further (noncentral) 1-dimensional extension is usually made: the derivation $t\frac{d}{dt}$ is included (see footnote 33). $X_\ell^{(1)}$ is the simplest of the infinite-dimensional Kac-Moody algebras. The superscript '(1)' denotes the fact that the loop algebra was twisted by an order-1 automorphism — i.e. that it is untwisted. It is called 'affine' because of its Weyl group, as we shall see.

Central extensions are a common theme in today's infinite-dimensional Lie theory[9]. Their *raison d'être* is always the same: a richer supply of representations. For example, $\mathcal{W}$ has several representations, but no nontrivial one is an 'irreducible unitary positive-energy representation' — the kind of greatest interest in math phys. On the other hand, its central extension $\mathcal{V}$ has a rich supply of those representations (e.g. there's one for each choice of $c > 1, h > 0$, namely the Verma module $V_{c,h}$ corresponding to $L_0 x_0 = hx_0, Cx_0 = cx_0$). At the level of groups, central extensions allow *projective* representations (i.e. representations up to a scalar factor) to become true representations. Projective representations (hence central extensions) appear naturally in QFT because a quantum state vector $|v\rangle$ is physically indistinguishable from any nonzero scalar multiple $\alpha|v\rangle$.

All of the quantities associated to X_ℓ have an analogue here: Dynkin diagram, Weyl group, weights,... For instance, the affine Dynkin diagram is obtained from the Dynkin diagram for X_ℓ by adding one node. See for example Figure 9 of [59]. The extra node is always labelled by a '0'. The Cartan subalgebra $\mathfrak{h}$ here will be $(\ell+2)$-dimensional. Many of these details will be discussed in more detail in §2.7 below.

The construction of $X_\ell^{(1)}$ is so trivial that it seems surprising anything interesting and new can happen here. But a certain 'miracle' happens...

No interesting representation of $X_\ell^{(1)}$ is finite-dimensional. The analogue for $X_\ell^{(1)}$ of the finite-dimensional representations of X_ℓ are called the *integrable highest-weight representations*, and will be denoted L_λ. The *highest-weight* λ here will be an $(\ell+1)$-tuple $(\lambda_0, \lambda_1, \ldots, \lambda_\ell)$, $\lambda_i \in \mathbb{Z}_\geq$ (strictly speaking, it will be an $(\ell+2)$-tuple, but the extra component is not important and is usually ignored). As for X_ℓ, the highest-weights can be thought of as the assignment of a nonnegative integer to each node of the Dynkin diagram. The construction of L_λ is as in the finite-dimensional case. They are called *integrable* because they are precisely those highest-weight representations which can be 'integrated' to a projective representation of the corresponding loop group, and hence a representation of a central extension of the loop group.

We define the character χ_λ as in (1.3.1), though now the weights m will be $(\ell+2)$-tuples, and there will be infinitely many of them. χ_λ will be a complex-valued function of $\ell+2$ complex variables $(\vec{z}, \tau, u)$ (see (1.4.1a) below). It can be written as an alternating sum over the Weyl group W, over a 'nice' denominator. The difference here is that W is now infinite.

Perhaps most of the interest in affine algebras can be traced to the 'miracle' that their Weyl groups are a semidirect product $Q^\vee \rtimes \overline{W}$ of translations in a lattice $\mathbb{Q}^\vee$ (the ℓ-dimensional 'co-root lattice' of X_ℓ — see §1.6) with the (finite) Weyl group $\overline{W}$ of X_ℓ.

---

[9] Incidentally the *finite-dimensional* simple Lie algebras do not have nontrivial central extensions.

See Figure 10 of [59] for the Weyl group of $A_2^{(1)}$. 'Semidirect product'[10] means that any element of W can be written uniquely as (t, w) for some translation t and some $w \in \overline{W}$, and $(t, w) \circ (t', w') = (\text{stuff}, w \circ w')$.

One thing this implies is that χ_λ will be of the form 'theta function'/denominator. Theta functions are classically-studied modular forms (we will discuss these terms in §2.3), and thus the modular group $\mathrm{SL}_2(\mathbb{Z})$ will make an appearance! To make this more precise, consider the highest-weight $\lambda = (\lambda_0, \lambda_1)$ of $A_1^{(1)}$, and write $k = \lambda_0 + \lambda_1$. Then

$$\chi_\lambda = \frac{\Theta_{\lambda_1+1}^{(k+2)} - \Theta_{-\lambda_1-1}^{(k+2)}}{\Theta_1^{(2)} - \Theta_{-1}^{(2)}} \tag{1.4.1a}$$

where these functions all depend on 3 complex variables z, τ, u, and

$$\Theta_m^{(n)}(z, \tau, u) := e^{-2\pi i n u} \sum_{\ell \in \mathbb{Z} + \frac{m}{2n}} \exp[\pi i n \tau \ell^2 - 2\sqrt{2}\pi i n \ell z] \ . \tag{1.4.1b}$$

In (1.4.1a) we can see the alternating sum over the Weyl group of A_1 in the numerator (and denominator, since we've used the $A_1^{(1)}$ denominator identity in writing (1.4.1a)). For general $X_\ell^{(1)}$, the denominator will always be independent of λ, and the theta function (1.4.1b) will become a multidimensional one involving a sum over $Q^\vee$ shifted by some weight and appropriately rescaled. The (co-)root lattice of A_1 is $\sqrt{2}\mathbb{Z}$. The key variable in (1.4.1a) is the modular one τ, which will lie in the upper half complex plane $\mathcal{H}$ (in order to have convergence). In the applications to CFT, the other variables are often set to 0.

The number k introduced in (1.4.1a) plays an important role in the general theory. In the representation L_λ, the central term C will get sent to some multiple of the identity — the multiplier is labelled k and is called the *level* of the representation. For any $X_\ell^{(1)}$ there is a simple formula expressing the level k in terms of the highest-weight λ; e.g. for $A_\ell^{(1)}$ and $C_\ell^{(1)}$ it is given by $k = \lambda_0 + \lambda_1 + \cdots + \lambda_\ell$. Write P_+^k for the (finite) set of level k highest-weights (so the size of P_+^k for $A_\ell^{(1)}$ is $\binom{k+\ell}{\ell}$). An important weight in P_+^k is $(k, 0, \ldots, 0)$. We will denote this '0'. In RCFT it corresponds to the vacuum.

The modular group $\mathrm{SL}_2(\mathbb{Z})$ acts on the Cartan subalgebra $\mathfrak{h}$ of $X_\ell^{(1)}$ in the following way:

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} (\vec{z}, \tau, u) = \left(\frac{\vec{z}}{c\tau + d}, \frac{a\tau + b}{c\tau + d}, u - \frac{c\,\vec{z} \cdot \vec{z}}{2(c\tau + d)}\right)$$

Under this action, the characters χ_λ also transform nicely: in particular we find for any level k weight λ

$$\chi_\lambda\left(\frac{\vec{z}}{\tau}, \frac{-1}{\tau}, u - \frac{\vec{z} \cdot \vec{z}}{2\tau}\right) = \sum_{\mu \in P_+^k} S_{\lambda\mu}\, \chi_\mu(\vec{z}, \tau, u) \tag{1.4.2a}$$

$$\chi_\lambda(\vec{z}, \tau + 1, u) = \sum_{\mu \in P_+^k} T_{\lambda\mu}\, \chi_\mu(\vec{z}, \tau, u) \tag{1.4.2b}$$

---

[10] This is also discussed briefly in section 2.2.

where S and T are complex matrices called the *Kac-Peterson matrices.* S will always be symmetric and unitary, and has many remarkable properties as we shall see. Its entries are related to Lie group characters at elements of finite order (see (1.4.5) below). T is diagonal and unitary; its entries are related to the eigenvalues of the quadratic Casimir.

For example, consider $A_1^{(1)}$ at level k. Then S and T will be $(k+1)\times(k+1)$ matrices given by

$$S_{\lambda\mu}=\sqrt{\frac{2}{k+2}}\,\sin(\pi\,\frac{(\lambda_1+1)(\mu_1+1)}{k+2})\ ,\qquad T_{\lambda\mu}=\exp[\pi\mathrm{i}\,\frac{(\lambda_1+1)^2}{2(k+2)}-\frac{\pi\mathrm{i}}{4}]\,\delta_{\lambda,\mu}\ . \tag{1.4.3}$$

One important place S appears is the famous *Verlinde formula*

$$N_{\lambda\mu}^{\nu}=\sum_{\kappa\in P_+^k}\frac{S_{\lambda\kappa}\,S_{\mu\kappa}\,S_{\nu\kappa}^*}{S_{0,\kappa}} \tag{1.4.4}$$

for the fusion coefficients $N_{\lambda\mu}^{\nu}$ of the corresponding RCFT. We will investigate some consequences of this formula in a later section. The fusion coefficients for the affine algebras are well-understood; see e.g. Section 4 of [59] for their interpretation (usually called the Kac-Walton formula) as 'folded tensor product coefficients'.

We will see in §1.7 that symmetries of the extended Dynkin diagram have consequences for S and T (simple-currents, charge-conjugation). There is a 'Galois action' on S which we will discuss in §1.8. There is a strange property of S and T called *rank-level duality* (see e.g. [45]): the matrices for $A_\ell^{(1)}$ at level k are closely related to those of $A_{k-1}^{(1)}$ at level $\ell+1$, and similar statements hold for $B_\ell^{(1)}$, $C_\ell^{(1)}$ and $D_\ell^{(1)}$. Another reason S is mathematically interesting is the formula

$$\frac{S_{\lambda\mu}}{S_{0\mu}}=\mathrm{ch}_{\bar{\lambda}}(-2\pi\mathrm{i}\,\frac{\overline{\mu+\rho}}{k+h^\vee})\ . \tag{1.4.5}$$

The right-side is a character of X_ℓ, and $\bar{\lambda}=(\lambda_1,\ldots,\lambda_\ell)$ means ignore the extended node. ρ is the 'Weyl vector' $(1,1,\ldots,1)$ and $h^\vee$ is called the *dual Coxeter number* and is the level of ρ. For $A_\ell^{(1)}$, $h^\vee=\ell+1$. Of course the right-side can also be regarded as a character for a Lie group associated to X_ℓ, in which case the argument would have to be exponentiated and would correspond to an element of finite order in the group. These numbers (1.4.5) have been studied by many people (most extensively by Pianzola) and have some nice properties. For instance Moody-Patera (1984) have argued that exploiting them leads to some quick algorithms for computing e.g. tensor product coefficients. Kac [37] found a curious application for them: a Lie theoretic proof of 'quadratic reciprocity'!

Quadratic reciprocity is one of the gems of classical number theory. It tells us that the equations

$$x^2\equiv a\ (\mathrm{mod}\ b)$$
$$y^2\equiv b\ (\mathrm{mod}\ a)$$

are related; more precisely, for fixed a and b (for simplicity take them to both be primes $\neq 2$) the questions of whether there is a solution x to the first equation and a solution y to the second, are related. They will both have the same yes or no answer, unless $a \equiv b \equiv 3 \pmod 4$, in which case they will have opposite answers. E.g. take $a = 23$ and $b = 3$, then we know the first equation does not have a solution (since $a \equiv 2 \pmod 3$ and $x^2 \equiv 2$ doesn't have a solution mod 3), and hence the second equation must have a solution (indeed, $y = 7$ works). There are now many proofs for quadratic reciprocity, and Kac used Lie characters at elements of finite order to find another one.

What is interesting here is that Kac's proof uses only certain special weights for A_ℓ. The natural question is: is it possible to find any generalisations of quadratic reciprocity using other weights and algebras? Many generalisations of quadratic reciprocity are known; will generalising Kac's argument recover them, or will they perhaps yield new reciprocity laws? It seems no one knows.

The relation (1.4.5) is important because it connects finite-dimensional Lie data with infinite-dimensional Lie data. The 'conceptual arrow' can be exploited both ways: in the generalisations of the arguments of §1.9 to other algebras, (1.4.5) allows us to use our extensive knowledge of finite-dimensional algebras to squeeze out some information in the affine setting; but also it is possible to use the richer symmetries of the affine data to see 'hidden' symmetries in finite-dimensional data. For example it can be used (Gannon-Walton 1995) to find a sort of Galois symmetry of dominant weight multiplicities in X_ℓ, which would be difficult or impossible to anticipate without (1.4.5).

1.5. The classification of physical invariants

We are interested in the following classification problem. Choose any affine algebra $X_\ell^{(1)}$ and level $k \in \mathbb{Z}_\geq$. Find all matrices $M = (M_{\lambda\mu})_{\lambda,\mu\in P_+^k}$ such that

(P1) $MS = SM$ and $MT = TM$, where S, T are the Kac-Peterson matrices (1.4.2);
(P2) each entry $M_{\lambda\mu} \in \mathbb{Z}_\geq$;
(P3) $M_{00} = 1$.

Any such M, or equivalently the corresponding partition function $\mathcal{Z} = \sum_{\lambda,\mu} M_{\lambda\mu}\chi_\lambda\chi_\mu^*$, is called a *physical invariant.*

The first and most important classification of physical invariants was the Cappelli-Itzykson-Zuber A-D-E classification for $A_1^{(1)}$ at all levels k [8]. We will give their result shortly. This implies for instance the minimal model RCFT classification, as well as the $N = 1$ super(symmetric)conformal minimal models. The other classifications of comparable magnitude are $A_2^{(1)}$ for all k; $A_\ell^{(1)}$, $B_\ell^{(1)}$ and $D_\ell^{(1)}$ for all $k \leq 3$; $(A_1 \oplus A_1)^{(1)}$ for all levels (k_1, k_2); and $(u(1) \oplus \cdots \oplus u(1))^{(1)}$ for all (matrix-valued) levels k. See e.g. [29] for references. The most difficult of these classifications is for $A_2^{(1)}$, done by Gannon (1994).

In other words, very little in this direction has been accomplished in the 15 or so years this problem has existed. But this is not really a good measure of progress. The effort instead has been directed primarily towards the full classification; most of these partial results are merely easy spin-offs from that more serious and ambitious assault.

The proof in [8] was very complicated and followed the following lines. First, an explicit basis was found for the vector space (called the 'commutant') of all matrices obeying (P1). Then (P2) and (P3) were imposed. Unfortunately their proof was long and formidable. Others tried to apply their approach to $A_2^{(1)}$, but without success. The eventual proof for $A_2^{(1)}$ was completely independent of the [8] argument, and exploited more of the structure implicit in the problem. As the $A_2^{(1)}$ argument became more refined, it became the model for the general assault. In §1.9 we sketch this new approach.

From this more general perspective, of these completed classifications only the level 2 $B_\ell^{(1)}$ and $D_\ell^{(1)}$ ones will have any lasting value (the orthogonal algebras at level 2 behave very peculiarly, possess large numbers of exceptional physical invariants, and must be treated separately). The others behave more generically and will fall out as special cases once the more general classifications are concluded. Other classifications which should be straightforward with our present understanding are $C_2^{(1)}$ at all k; $G_2^{(1)}$ at all k; and $B_\ell^{(1)}$ and $D_\ell^{(1)}$ at $k=4$. The $C_2^{(1)}$ should be easiest and would imply the $C_\ell^{(1)}$ level 2, as well as the $B_\ell^{(1)}$ and $D_\ell^{(1)}$ level 5, classifications. A very safe conjecture is that the only *exceptional* physical invariants (we define this term in §1.7) for $C_2^{(1)}$ occur at $k=3,7,8,12$ — this is known to be true for all $k \leq 500$. $G_2^{(1)}$ would be more difficult but also much more valuable; its only known exceptionals occur at $k=3,4$, and these are the only exceptionals for $k \leq 500$, and a very safe conjecture is that there are no other $G_2^{(1)}$ exceptionals. $B_\ell^{(1)}$ and $D_\ell^{(1)}$ at level 4 will also be more difficult, but also would be valuable; less is understood about its physical invariants and there is a good chance new exceptionals exist there.

The most surprising thing about the known physical invariant classifications is that there so few surprises: almost every physical invariant is 'generic'. We will see that the symmetries of the extended Dynkin diagram give rise to general families of physical invariants. We will call any physical invariants which do not arise in these generic ways (i.e. using what are called simple-currents or conjugations), *exceptional*. Many exceptionals have been found, and now we are almost at the point where we can safely conjecture the complete list of physical invariants for $X_\ell^{(1)}$ at any k, for X_ℓ a simple algebra.

Unfortunately the classification for semi-simple algebras $X_{\ell_1} \oplus \cdots \oplus X_{\ell_s}$ does not reduce to the one for simple ones. In fact, *any explicit classification of the physical invariants for $X^{(1)}$, for all semi-simple X, would easily be one of the greatest accomplishments in the history of math,* for it would include as a small part such monumental things as an explicit classification of all positive-definite integral lattices. Thus we unfortunately cannot expect an *explicit* classification for the *semi*-simple algebras.

To make this discussion more concrete and explicit, consider $A_1^{(1)}$. For convenience drop λ_0, so $P_+^k = \{0,1,\ldots,k\}$. Write J for the permutation (called a simple-current) $Ja := k-a$. Then the complete list of physical invariants for $A_1^{(1)}$ is

$$\mathcal{A}_{k+1} = \sum_{a=0}^{k} |\chi_a|^2 \;, \qquad\qquad \text{for all } k \geq 1$$

$$\mathcal{D}_{\frac{k}{2}+2} = \sum_{a=0}^{k} \chi_a \, \chi_{J^a a}^* \;, \qquad\qquad \text{whenever } \frac{k}{2} \text{ is odd}$$

$$\begin{aligned}
\mathcal{D}_{\frac{k}{2}+2} &= |\chi_0+\chi_{J0}|^2+|\chi_2+\chi_{J2}|^2+\cdots+2|\chi_{\frac{k}{2}}|^2\ , &&\text{whenever } \frac{k}{2} \text{ is even}\\
\mathcal{E}_6 &= |\chi_0+\chi_6|^2+|\chi_3+\chi_7|^2+|\chi_4+\chi_{10}|^2\ , &&\text{for } k=10\\
\mathcal{E}_7 &= |\chi_0+\chi_{16}|^2+|\chi_4+\chi_{12}|^2+|\chi_6+\chi_{10}|^2\\
&\quad +\chi_8\,(\chi_2+\chi_{14})^*+(\chi_2+\chi_{14})\,\chi_8^*+|\chi_8|^2\ , &&\text{for } k=16\\
\mathcal{E}_8 &= |\chi_0+\chi_{10}+\chi_{18}+\chi_{28}|^2+|\chi_6+\chi_{12}+\chi_{16}+\chi_{22}|^2\ , &&\text{for } k=28\ .
\end{aligned}$$

The physical invariants $\mathcal{A}_n$ and $\mathcal{D}_n$ are generic, corresponding respectively to the order 1 (i.e. identity) and order 2 (i.e. the simple-current J) Dynkin diagram symmetries, as we shall see in §1.7. Physically, they are the partition functions of WZW models on $\mathrm{SU}_2(\mathbb{C})$ and $\mathrm{SO}_3(\mathbb{R})$ group manifolds, resp. The exceptionals $\mathcal{E}_6$ and $\mathcal{E}_8$ are best interpreted as due to the $C_{2,1} \supset A_{1,10}$ and $G_{2,1} \supset A_{1,28}$ conformal embeddings (see §1.7; standard notation is to write '$X_{\ell,k}$' for '$X_\ell^{(1)}$ and level k'). The $\mathcal{E}_7$ exceptional is harder to interpret, but can be thought of as the first in an infinite series of exceptionals involving rank-level duality and D_4 triality.

Around Christmas 1985, Zuber wrote Kac about the $A_1^{(1)}$ physical invariant problem, and mentioned the physical invariants he and Itzykson knew at that point (what we now call $\mathcal{A}_\star$ and $\mathcal{D}_{even}$). A few weeks later, Kac wrote back saying he found one more invariant, and jokingly pointed out that it must be indeed quite exceptional as the exponents of E_6 appeared in it. "I must confess that I didn't pay much attention to that last remark (I hardly knew what Coxeter exponents were, at the time!)" [63]. By spring 1986, Cappelli arrived in Paris and got things moving again; together Cappelli-Itzykson-Zuber found $\mathcal{E}_7$, $\mathcal{D}_{odd}$, and then $\mathcal{E}_8$, and struggled to find more. "And it is only in August [1986], during a conversation with Pasquier, in which he was showing me his construction of lattice models based on Dynkin diagrams, that I suddenly remembered this cryptic but crucial! observation of Victor, rushed to the library to find a list of the exponents of the other algebras... and found with the delight that you can imagine that they were matching our list" [63]. Thus the A-D-E pattern to these physical invariants was discovered.

1.6. THE A-D-E META-PATTERN

Before we discuss *meta-patterns* in math, let's introduce the notion of *lattice*[11], a simple geometric structure we'll keep returning to in these notes. The standard reference for lattice theory is [13].

Consider the real vector space $\mathbb{R}^{m,n}$: its vectors look like $\vec{x} = (\vec{x}_+;\vec{x}_-)$ where $\vec{x}_+$ and $\vec{x}_-$ are m- and n-component vectors respectively, and dot products are given by $\vec{x}\cdot\vec{y} = \vec{x}_+\cdot\vec{y}_+ - \vec{x}_-\cdot\vec{y}_-$. The dot products $\vec{x}_\pm\cdot\vec{y}_\pm$ are given by the usual product and sum of components. For example, the familiar Euclidean (positive-definite) space is $\mathbb{R}^n = \mathbb{R}^{n,0}$, while Minkowski space is $\mathbb{R}^{3,1}$.

---

[11] There are many words in math which have several incompatible meanings. For example, there are *vector* fields and *number* fields, and modular *forms* and modular *representations*. 'Lattice' is another of these words. Aside from the geometric meaning we will use, it also refers to a 'partially ordered set'.

Now choose any basis $B = \{\vec{x}_1, \ldots, \vec{x}_{m+n}\}$ in $\mathbb{R}^{m,n}$. So $\mathbb{R}^{m,n} = \mathbb{R}\vec{x}_1 + \cdots + \mathbb{R}\vec{x}_{m+n}$. Define the set $\Lambda(B) := \mathbb{Z}\vec{x}_1 + \cdots + \mathbb{Z}\vec{x}_{m+n}$. This is a *lattice*, and all lattices can be formed in this way[12]. So a lattice is discrete and is closed under sums and integer multiples. For example, $\mathbb{Z}^{m,n}$ is a lattice (take the standard basis in $\mathbb{R}^{m,n}$). A more interesting lattice is the hexagonal lattice (also called A_2), given by the basis $B = \{(\frac{\sqrt{2}}{2}, \frac{\sqrt{6}}{2}), (\sqrt{2}, 0)\}$ of $\mathbb{R}^2$ — try to plot several points. If you wanted to slide a bunch of coins on a table together as tightly as possible, their centres would form this hexagonal lattice. Another important lattice is $II_{1,1} \subset \mathbb{R}^{1,1}$, given by $B = \{(\frac{1}{\sqrt{2}}; \frac{1}{\sqrt{2}}), (\frac{1}{\sqrt{2}}; \frac{-1}{\sqrt{2}})\}$; equivalently it can be thought of as the set of all pairs $(a, b) \in \mathbb{Z}^2$ with dot product

$$(a, b) \cdot (c, d) = ad + bc\ . \tag{1.6.1}$$

It is important to note that different choices of basis may or may not result in a different lattice. For a trivial example, consider $B = \{1\}$ and $B' = \{-1\}$ in $\mathbb{R} = \mathbb{R}^{1,0}$: they both give the lattice $\mathbb{Z} = \mathbb{Z}^{1,0}$. Two lattices are called *equivalent* if they only differ by a change-of-basis. E.g. $B = \{(\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}), (\frac{1}{\sqrt{2}}, \frac{-1}{\sqrt{2}})\}$ in $\mathbb{R}^2$ yields a lattice equivalent to $\mathbb{Z}^2$.

The *dimension* of the lattice is $m + n$. The lattice is called *positive-definite* if it lies in some $\mathbb{R}^m$ (i.e. $n = 0$). The lattice is called *integral* if all dot products $\vec{x} \cdot \vec{y}$ are integers, for $\vec{x}, \vec{y} \in \Lambda$. A lattice Λ is called *even* if it is integral and in addition all norms $\vec{x} \cdot \vec{x}$ are *even* integers. For example, $\mathbb{Z}^{m,n}$ is integral but not even, while A_2 and $II_{1,1}$ are even. The *dual* Λ^* of a lattice Λ consists of all vectors $\vec{x} \in \mathbb{R}^{m,n}$ such that $\vec{x} \cdot \Lambda \subset \mathbb{Z}$. So a lattice is integral iff $\Lambda \subseteq \Lambda^*$. A lattice is called *self-dual* if $\Lambda = \Lambda^*$. $\mathbb{Z}^{m,n}$ and $II_{1,1}$ are self-dual but A_2 is not.

There are lots of 'meta-patterns' in math, i.e. collections of seemingly different problems which have similar answers. Once one of these meta-patterns is identified it is always helpful to understand what is responsible for it. For example, while I was writing up my PhD thesis I noticed in several places the numbers 1, 2, 3, 4, and 6. For instance $\cos(2\pi r) \in \mathbb{Q}$ for $r \in \mathbb{Q}$ iff the denominator of r is 1, 2, 3, 4, or 6. This pattern was easy to explain: they are precisely those positive integers n with Euler totient $\phi(n) \leq 2$, i.e. there are at most 2 positive numbers less than n coprime[13] to n. The other incidences of these numbers can usually be reduced to this $\phi(n) \leq 2$ property (e.g. the dimension of the number field $\mathbb{Q}[\cos(2\pi\frac{a}{b})]$ (see §1.8) considered as a vector space over $\mathbb{Q}$ will be $\phi(b)/2$).

A more interesting meta-pattern involves the number 24 and its divisors. One sees 24 wherever modular forms naturally appear. For instance, we see it in the critical dimensions in string theory: $24 + 2$ and $8 + 2$. Another example: the dimensions of even self-dual positive-definite lattices must be a multiple of 8 (e.g. the E_8 root lattice defined shortly has dimension 8, while the Leech lattice discussed in §2.4 has dimension 24). The meta-pattern 24 is also understood: the fundamental problem for which it is the answer is the following one. Fix n, and consider the congruence $x^2 \equiv 1 \pmod{n}$. Certainly in order to have a chance of satisfying this, x and n must be coprime. The extreme situation is when *every* number x coprime to n satisfies this congruence:

---

[12] In most presentations a lattice is permitted to have smaller dimension than its ambient space, however that freedom gains no real generality.

[13] We say m,n are *coprime* if any prime p which divides m does not divide n, and vice versa.

$$\gcd(x,n) = 1 \qquad \Longleftrightarrow \qquad x^2 \equiv 1 \pmod{n} \ . \tag{1.6.2}$$

The reader can try to verify the following simple fact: n obeys this extreme situation (1.6.2) iff n divides 24.

What does this congruence property have to do with these other occurrences of 24? Let Λ be an even self-dual positive-definite lattice of dimension n. Then an elementary argument shows that there will exist an n-tuple $\vec{a} = (a_1, \ldots, a_n)$ of odd integers with the property that 8 must divide $\vec{a} \cdot \vec{a} = \sum_i a_i^2$. But $a_i^2 \equiv 1 \pmod 8$, and so we get $8|n$.

A much deeper and still not-completely-understood meta-pattern is called A-D-E (see [1] for a discussion and examples). The name comes from the so-called *simply-laced algebras*, i.e. the simple finite-dimensional Lie algebras whose Dynkin diagrams — see Figure 6 in [59] — contain only single edges (i.e. no arrows). These are the $A_\star$- and $D_\star$-series, along with the E_6, E_7 and E_8 exceptionals. The claim is that many other problems, which don't seem to have anything directly in common with simple Lie algebras, have a solution which falls into this A-D-E pattern (for an object to be meaningfully labelled X_ℓ, some of the data associated to the algebra X_ℓ should reappear in some form in that object). Let's look at some examples.

Consider even positive-definite lattices Λ. The smallest possible nonzero norm in Λ will be 2, and the vectors of norm 2 are special and are called *roots*. The reason they are special is that reflecting through them will always be an automorphism of Λ. That is, the reflection $\vec{u} \mapsto \vec{u} - 2\frac{\vec{u}\cdot\vec{\alpha}}{\vec{\alpha}\cdot\vec{\alpha}}\,\vec{\alpha}$ through $\vec{\alpha} \neq \vec{0}$ won't in general map Λ to itself, unless $\vec{\alpha}$ is a root of Λ. It is important in lattice theory to know the lattices which are spanned by their roots; it turns out these are precisely the orthogonal direct sums of lattices called A_n, D_n, and E_6, E_7 and E_8. They carry those names for a number of reasons. For example, the lattice called X_n will have a basis $\{\vec{\alpha}_1, \ldots, \vec{\alpha}_n\}$ with the property that the matrix $A_{ij} := \vec{\alpha}_i \cdot \vec{\alpha}_j$ is the Cartan matrix (see §2.7) for the Lie algebra X_n! Also, the reflection group generated by reflections in the roots of the lattice X_n will be isomorphic to the Weyl group of the Lie algebra X_n. Finally, to any simple Lie algebra there is canonically associated a lattice called the root lattice; for the simply-laced algebras, these will equal the corresponding lattice of the same name. Incidentally, the root lattices for the non-simply-laced simple algebras will (up to rescalings) be direct sums of the simply-laced root lattices.

We have already met the A_2 lattice: it is the densest packing of circles in the plane. It has long been believed that the obvious pyramidal way to pack oranges is also the densest possible way — the centres of the oranges form the A_3 root lattice. A controversial proof for this famous conjecture has been offered by W.-Y. Hsiang in 1991; in 1998 a new proof by Hale *et al* has been proposed. The densest known packings in dimensions 4,5,6,7,8 are D_4, D_5, E_6, E_7, E_8, resp. E_8 is the smallest even self-dual positive-definite lattice.

A famous A-D-E example is called the McKay[14] correspondence. Consider any finite subgroup G of the Lie group $\mathrm{SU}_2(\mathbb{C})$ (i.e. the 2×2 unitary matrices with determinant 1). For example, there is the cyclic group $\mathbb{Z}_n$ of n elements generated by the matrix

$$M_n = \begin{pmatrix} \exp[2\pi \mathrm{i}/n] & 0 \\ 0 & \exp[-2\pi \mathrm{i}/n] \end{pmatrix}$$

---

[14] He is the same John McKay we will celebrate in section 2.1.

Let R_i be the irreducible representations of G. For instance, for $\mathbb{Z}_n$, there are precisely n of these, all 1-dimensional, given by sending the generator M_n to $\exp[2k\pi\mathrm{i}/n]$ for each $k = 1, 2, \ldots, n$. Now consider the tensor product $G \otimes R_i$, where we interpret $G \subset \mathrm{SU}_2(\mathbb{C})$ here as a 2-dimensional representation. We can decompose that product into a direct sum $\oplus_j m_{ij} R_j$ of irreducibles (the m_{ij} here are multiplicities). Now create a graph with one node for each R_i, and with the ith and jth nodes ($i \neq j$) connected with precisely m_{ij} directed edges $i \to j$. If $m_{ij} = m_{ji}$, we agree to erase the double arrows from the m_{ij} edges. Then McKay observed that the graph of any G will be a distinct extended Dynkin diagram of A-D-E type! For instance, the cyclic group with n elements corresponds to the extended graph of A_{n-1}.

How was McKay led to his remarkable correspondence? He knew that the sum of the 'marks' $a_i = 1, 2, 3, 4, 5, 6, 4, 2, 3$ associated to each node of the extended E_8 Dynkin diagram equaled 30, the Coxeter number of E_8. So what did their *squares* add to? 120, which he recognised as the cardinality of one of the exceptional finite subgroups of $\mathrm{SU}_2(\mathbb{C})$, and that got him thinking...

Another famous example of A-D-E, due to Arnol'd, are the 'simple critical points' of smooth complex-valued functions f, on e.g. $\mathbb{C}^3$. For example, both $x^2 + y^2 + z^{n+1}$ and $x^2 + y^3 + z^5$ have singularities at $(0, 0, 0)$ (i.e. their first partial derivatives all vanish there), and they are assigned to A_n and E_8, respectively. The $\mathrm{SU}_2(\mathbb{C})$ subgroups can be related to singularities as follows. The group $\mathrm{SU}_2(\mathbb{C})$ acts on $\mathbb{C}^2$ in the obvious way (matrix multiplication). If G is a discrete subgroup, then consider the (ring of) polynomials in 2 variables w_1, w_2 invariant under G. It turns out it will have 3 generators $x(w_1, w_2)$, $y(w_1, w_2)$, $z(w_1, w_2)$, which are connected by 1 polynomial relation (syzygy). For instance, take G to be the cyclic group $\mathbb{Z}_n$, then we're interested in polynomials $p(w_1, w_2)$ invariant under $w_1 \mapsto \exp[2\pi\mathrm{i}/n] w_1$, $w_2 \mapsto \exp[-2\pi\mathrm{i}/n] w_2$. Any such invariant $p(w_1, w_2)$ is clearly generated by (i.e. can be written as a polynomial in) $w_1 w_2$, w_1^n and w_2^n. Choosing instead the generators $x = \frac{w_1^n - w_2^n}{2}$, $y = \mathrm{i}\,\frac{w_1^n + w_2^n}{2}$, $z = w_1 w_2$, we get the syzygy $z^n = -(x^2 + y^2)$. For any G, generators x, y, z can always be found so that the syzygy will be one of the polynomials associated to a simple singularity, and in fact will give the equation of the algebraic surface $\mathbb{C}^2/G$ as a 2-dimensional complex surface in $\mathbb{C}^3$ (e.g. the complex surfaces $\mathbb{C}^2/\mathbb{Z}_n$ and $\{(x, y, z) \in \mathbb{C}^3 \,|\, x^2 + y^2 + z^n = 0\}$ are equivalent).

Arguably the first A-D-E classification goes back to Theaetetus, around 400 B.C. He classified the regular solids. For instance the tetrahedron can be associated to E_6 while the cube is matched with E_7. This A-D-E is only partial, as there are no regular solids assigned to the A-series, and to get the D-series one must look at 'degenerate regular solids'.

The closest thing to an explanation of the A-D-E meta-pattern would seem to be the notion of 'additive assignments' on graphs (which is a picturesque way of describing the corresponding eigenvalue problem). Consider any graph $\mathcal{G}$ with undirected edges, and none of the edges run from a node to itself. We can also assume without loss of generality that $\mathcal{G}$ is connected. Assign a positive number a_i to each node. If this assignment has the property that for each i, $2a_i = \sum a_j$ where the sum is over all nodes j adjacent to i (counting multiplicities of edges), then we call it 'additive'. For instance, for the graph ○═○, the assignment $a_1 = 1 = a_2$ is additive, but the assignment $a_1 = 1, a_2 = 2$ is not. The question is, which graphs have an additive assignment? The answer is: precisely the extended Dynkin diagrams of A-D-E type! And their additive assignments are unique (up to constant proportionality) and are given by the *marks* a_i of the algebra (see e.g. the Table on p.54 of [38]). For example the extended A_n graph consists of $n+1$ nodes arranged in a circle, and its marks a_i all equal 1.

What do additive assignments have to do with the other A-D-E classifications? Consider a finite subgroup G of $\mathrm{SU}_2(\mathbb{C})$. Take the dimension of the equation $G \otimes R_i = \oplus_j m_{ij} R_j$: we get $2d_i = \sum_j m_{ij} d_j$ where $d_j = \dim(R_j)$. Hence the dimensions of the irreducible representations define an additive assignment for each of McKay's graphs, and hence those graphs must be of A-D-E type (provided we know $m_{ij} = m_{ji}$).

As Cappelli-Itzykson-Zuber observed, the physical invariants for $A_1^{(1)}$ also realise the A-D-E pattern, in the following sense. The *Coxeter number* h of the name $\mathcal{X}_\ell$ (i.e. the sum $\sum_i a_i$ of the marks) equals $k+2$, and the *exponents* m_i of X_ℓ equal those $a \in P_+^k$ for which $M_{aa} \neq 0$ (for the simply-laced algebras, the m_i are defined by writing the eigenvalues of the corresponding Cartan matrix (see §2.7) as $4\sin^2(\frac{\pi m_i}{2h})$ — the m_i are integers and the smallest is always 1). Probably what first led Kac to his observation about the E_6 exponents was that $k+2$ (this is how k enters most formulas) for his exceptional equalled the Coxeter number 12 for E_6. More recently, the operator algebraists Ocneanu [48] and independently Böckenhauer-Evans [4] found an A-D-E interpretation for the off-diagonal entries M_{ab} of the $A_1^{(1)}$ physical invariants, using subfactor theory.

We are not claiming that this $A_1^{(1)}$ classification is 'equivalent' to any other A-D-E one — that would miss the point of meta-patterns. What we really want to do is to identify some critical combinatorial part of an $A_1^{(1)}$ proof with critical parts in other A-D-E classifications — this is what we did with the other meta-patterns. A considerably simplified proof of the $A_1^{(1)}$ classification is now available [29], so hopefully this task will now be easier.

There has been some progress at understanding this $A_1^{(1)}$ A-D-E. Nahm [46] constructed the invariant $\mathcal{X}_\ell$ in terms of the compact simply-connected Lie group of type X_ℓ, and in this way could interpret the $k+2=h$ and $M_{m_i m_i} \neq 0$ coincidences. A very general explanation for A-D-E has been suggested by Ocneanu [48] using his theory of path algebras on graphs; although his work has never been published, others are now rediscovering (and publishing!) similar work (see e.g. [4]). Nevertheless, the A-D-E in CFT remains almost as mysterious now as it did a dozen years ago — for example it still isn't clear how it directly relates to additive assignments.

There are 4 other claims for A-D-E classifications of families of RCFT physical invariants, and all of them inherit their (approximate) A-D-E pattern from the more fundamental $A_1^{(1)}$ one. One is the $c<1$ minimal models, also proven in [8], and another is the $N=1$ superconformal minimal models, proved by Cappelli (1987). In both cases the physical invariants are parametrised by pairs of A-D-E diagrams. The list of known $c=1$ RCFTs also looks like A-D-E (two series parametrised by $\mathbb{Q}_+$, and three exceptionals), but the completeness of that list has never been rigourously established.

The fourth classification often quoted as A-D-E, is the $N=2$ superconformal minimal models. Their classification was done by Gannon (1997). The connection here with A-D-E turns out to be rather weak: e.g. 20, 30, and 24 distinct invariants would have an equal right to be called $\mathcal{E}_6$, $\mathcal{E}_7$, and $\mathcal{E}_8$ respectively. It would appear that the frequent claims that the $N=2$ minimal models fall into an A-D-E pattern are rather dubious.

Hanany-He [35] suggest that the $A_1^{(1)}$ A-D-E pattern can be related to subgroups $G \subset \mathrm{SU}_2(\mathbb{C})$ by orbifolding 4-dimensional $N=4$ supersymmetric gauge theory by G, resulting in an $N=2$ superCFT whose 'matter matrix' can be read off from the Dynkin diagram corresponding to G. The same game can be played with finite subgroups of $\mathrm{SU}_3(\mathbb{C})$, resulting in $N=1$ superCFTs whose matter matrices correspond to graphs very reminiscent of the 'fusion graphs' of Di Francesco-Petkova-Zuber (see e.g. [62]) corresponding to $A_2^{(1)}$ physical invariants. [35] use this to conjecture a McKay-type correspondence between singularities of type $\mathbb{C}^n/G$, for $G \subset \mathrm{SU}_n(\mathbb{C})$, and the physical invariants of $A_{n-1}^{(1)}$. This in their view would be the form A-D-E takes for higher rank physical invariants. Their actual conjecture though is still somewhat too vague.

For a final example of meta-pattern, consider 'modular function' (see §2.3). After all, they appear in a surprising variety of places and disguises. Maybe we shouldn't regard their ubiquity as fortuitous, instead perhaps there's a deeper common 'situation' which is the source for that ubiquity. Just as 'symmetry' yields 'group', or 'rain-followed-by-heat' breeds mosquitos. Math is not above metaphysics; like any area it grows by asking questions, and changing your perspective — even to a metaphysical one — should suggest new questions.

1.7. SIMPLE-CURRENTS AND CHARGE-CONJUGATION

The key properties[15] of the matrix S are that it's unitary and symmetric (so M in §1.5 equals SMS^*),

$$S_{0\mu} > 0 \text{ for all } \mu \in P_+^k \ , \tag{1.7.1}$$

and that the numbers $N_{\lambda\mu}^{\nu}$ defined by Verlinde's formula (1.4.4) are nonnegative integers. These are obeyed by the matrix S in any (unitary) RCFT. From these basic properties, we will obtain here some elementary consequences which have important applications.

But first, let's make an observation which isn't difficult to prove, but doesn't appear to be generally known.

Verlinde's formula looks strange, but it is quite generic,

and we can see it throughout math and mathematical physics. Consider the following.

Let $\mathfrak{A}$ be a commutative associative algebra, over $\mathbb{R}$ say. Suppose $\mathfrak{A}$ has a finite basis Φ (over $\mathbb{R}$) containing the unit 1. Define the 'structure constants' $N_{ab}^c \in \mathbb{R}$, for $a,b,c \in \Phi$, by $ab = \sum_{c\in\Phi} N_{ab}^c c$. Suppose there is an algebra homomorphism $*$ (so $*$ is linear, and $(xy)^* = x^* y^*$) which permutes the basis vectors (so $\Phi^* = \Phi$), and we have the relation $N_{ab}^1 = \delta_{b,a^*}$. We call any such algebra $\mathfrak{A}$ a *fusion algebra.* Then any fusion algebra will necessarily have a unitary matrix S with $S_{1a} > 0$ and with the structure constants given by Verlinde's formula. Algebraically, the relation $S = S^t$ holds if $\mathfrak{A}$ is 'self-dual' in a certain natural sense.

---

[15] A good exercise for the reader is to prove that if S is unitary and symmetric, and obeys (1.7.1), then there will be at most finitely many physical invariants M for that S,T.

Define the 'fusion matrices' N_λ by $(N_\lambda)_{\mu\nu} = N_{\lambda\mu}^\nu$. Then Verlinde's formula says that the μth column $S_{\uparrow\mu}$ of S is an eigenvector of each fusion matrix N_λ, with eigenvalue $\frac{S_{\lambda\mu}}{S_{0\mu}}$.

Useful Fact. If v is a simultaneous eigenvector of each fusion matrix N_λ, then there exists a constant $c \in \mathbb{C}$ and a $\lambda \in P_+^k$ such that $v = c\,S_{\uparrow\lambda}$.

For one consequence, take the complex conjugate of the eigenvector equation $N_\lambda\, S_{\uparrow\mu} = \frac{S_{\lambda\mu}}{S_{0\mu}}\, S_{\uparrow\mu}$: we get that the vector $S_{\uparrow\mu}^*$ is a simultaneous eigenvector of all N_λ, and hence must equal $c\,S_{\uparrow\gamma}$ for some number c and weight $\gamma \in P_+^k$, both depending on μ. Write $\gamma = C\mu$; then C defines a permutation of P_+^k. The reader can verify that unitarity of S forces $|c| = 1$, while (1.7.1) forces $c > 0$. Thus $c = 1$ and we obtain the formula

$$S_{\lambda\mu}^* = S_{\lambda,C\mu} = S_{C\lambda,\mu}\ . \tag{1.7.2}$$

Also, unitarity and symmetry of S forces $C = S^2$, while conjugating twice shows $C^2 = id.$ C is an important matrix in RCFT, and is called *charge-conjugation*. When $C = id.$, then the matrix S is real.

Note that (1.7.1) now implies $C0 = 0$. Also $CT = TC$. Hence $M = C$ will always define a physical invariant, and if M is any other physical invariant, the matrix product $MC = CM$ will define another physical invariant. Also, $N_{C\lambda,C\mu}^{C\nu} = N_{\lambda\mu}^\nu$ and $(N_\lambda)^t = CN_\lambda = N_\lambda C = N_{C\lambda}$.

For the WZW (=affine) case, C has a special meaning: $C\lambda$ is the highest-weight 'contragredient' to λ. C corresponds to an order 2 (or 1) symmetry of the (unextended) Dynkin diagram. For example, for $A_\ell^{(1)}$, we have $C(\lambda_0, \lambda_1, \ldots, \lambda_{\ell-1}, \lambda_\ell) = (\lambda_0, \lambda_\ell, \lambda_{\ell-1}, \ldots, \lambda_1)$. For $A_1^{(1)}$ then, $C = id.$, which can also be read off from (1.4.3).

The algebras $D_{even}^{(1)}$ all have at least one nontrivial symmetry of the (unextended) Dynkin diagram which isn't the charge-conjugation. The most interesting example is $D_4^{(1)}$, which has 5 of these. By a *conjugation*, we will mean any symmetry of the unextended Dynkin diagram.

To go much further, we need a fascinating tool called *Perron-Frobenius theory* — a collection of results concerning the eigenvalues and eigenvectors of nonnegative matrices (i.e. matrices in which every entry is a nonnegative real number). Whenever you have such matrices in your problem, and it is natural to multiply them, then there is a good chance Perron-Frobenius theory will tell you something interesting. The basic result here is that if A is a nonnegative matrix, then there will be a nonnegative eigenvector $x \geq 0$ with eigenvalue $\rho \geq 0$, such that if λ is any other eigenvalue of A, then $|\lambda| \leq \rho$. There are lots of other results (see e.g. [44]), e.g. ρ must be at least as large as any diagonal entry of A, and there must be a row-sum of A no bigger than ρ, and another row-sum no smaller than ρ.

For instance, consider

$$A = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}\ , \qquad B = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}\ .$$

Perron-Frobenius eigenvectors for A and B are $\begin{pmatrix}1\\1\\1\end{pmatrix}$ and $\begin{pmatrix}2\\1\\1\end{pmatrix}$, with eigenvalues 3 and 2 resp. The other eigenvalue of A is 0 (multiplicity 2), while those of B are 0 and -1.

Fusion matrices N_λ are nonnegative, and it is indeed natural to multiply them:

$$N_\lambda N_\mu = \sum_{\nu\in P_+^k} N_{\lambda\mu}^\nu N_\nu \ .$$

So we can expect Perron-Frobenius to tell us something interesting. This is the case, and we obtain the curious-looking inequalities

$$S_{\lambda 0}\, S_{0\mu} \geq |S_{\lambda\mu}|\, S_{00} \ . \tag{1.7.3}$$

Squaring both sides, summing over μ and using unitarity, we get that $S_{\lambda 0} \geq S_{00}$. In other words, the ratio $\frac{S_{\lambda 0}}{S_{00}}$, called the *quantum-dimension* of λ, will necessarily be ≥ 1.

The term 'quantum-dimension' comes from quantum groups, where $\frac{S_{\lambda 0}}{S_{00}}$ is the quantum-dimension of the module labelled by λ of the quantum group $U_q(X_\ell)$.

The borderline case then [16] is when a quantum-dimension *equals* 1. Any such weight is called a *simple-current*. The theory of simple-currents was developed most extensively by Schellekens and collaborators (see e.g. [50]). The simple-currents for the affine algebras were classified by J. Fuchs (1991), and the result is that (with one unimportant exception: $E_8^{(1)}$ at level 2) they all correspond to symmetries of the extended Dynkin diagrams. In particular, applying any such symmetry to the vacuum $0 = (k, 0, \ldots, 0)$ gives the list of simple-currents. For instance, the $\ell + 1$ weights of the form $(0, \ldots, k, \ldots, 0)$ (k in the ith spot) are the simple-currents for $A_\ell^{(1)}$. There are 2 simple-currents for $B_\ell^{(1)}$, $C_\ell^{(1)}$ and $E_7^{(1)}$, 3 for $E_6^{(1)}$, and 4 for $D_\ell^{(1)}$. Simple-currents play a large role in RCFT, as we shall see.

Let j be any simple-current. Then (1.7.3) becomes $S_{0\mu} \geq |S_{j\mu}|$ for all μ, so unitarity forces $S_{0\mu} = |S_{j\mu}|$, that is

$$S_{j\mu} = \exp[2\pi \mathrm{i}\, Q_j(\mu)]\, S_{0\mu} \qquad \forall \mu \in P_+^k \tag{1.7.4}$$

for some rational numbers $0 \leq Q_j(\mu) < 1$. Hence by diagonalising, we get $N_j N_{Cj} = I$. But the inverse of a nonnegative matrix A is itself nonnegative, only if A is a 'generalised permutation matrix', i.e. a permutation matrix except the 1's can be replaced by any positive numbers. But N_j and N_{Cj} are also integral, and so they must in fact be permutation matrices. Write $(N_j)_{\lambda\mu} = \delta_{\mu, J\lambda}$ for some permutation J of P_+^k. So $j = J0$. Then

$$\delta_{\lambda,\mu} = N_{j,\lambda}^{J\mu} = \sum_\nu \exp[2\pi \mathrm{i}\, Q_j(\nu)]\, S_{\lambda\nu}\, S_{J\mu,\nu}^* \ ,$$

---

[16] This seems to be a standard trick in math: when some sort of bound is established, look at the extremal cases which realise that bound. If your bound is a good one, it should be possible to say something about those extremal cases, and having something to say is always of paramount importance. This trick is used for instance in the definition of 24 last section, and the definition of normal subgroup in section 2.2.

so taking absolute values and using the triangle inequality and unitarity of S, we find that (1.7.4) generalises:

$$S_{J\lambda,\mu} = \exp[2\pi \mathrm{i}\, Q_j(\mu)]\, S_{\lambda\mu} \ . \tag{1.7.5}$$

The simple-currents form a finite abelian group, corresponding to the composition of the permutations J. For any simple-currents J, J', we get the symmetry $N_{J\lambda,J'\mu}^{\nu} = N_{\lambda\mu}^{JJ'\nu}$. The $\mathbb{Q}/\mathbb{Z}$-valued functions Q_j define gradings on the fusion rings, and conversely any grading corresponds to a simple-current in this way.

For example, the simple-current $j = (0, k)$ of $A_1^{(1)}$ at level k corresponds to $Q_j(\lambda) = \lambda_1/2$ and the permutation $J\lambda = (\lambda_1, \lambda_0)$. We can see this directly from (1.4.3). For $A_2^{(1)}$ level k, there are 2 nontrivial simple-currents, $(0, k, 0)$ and $(0, 0, k)$. The first of these corresponds to triality $Q(\lambda) = (\lambda_1 + 2\lambda_2)/3$ and $\lambda \mapsto (\lambda_2, \lambda_0, \lambda_1)$, while the second to $(2\lambda_1 + \lambda_2)/3$ and $\lambda \mapsto (\lambda_1, \lambda_2, \lambda_0)$. Similar statements hold for all affine algebras: e.g. for $B_\ell^{(1)}$ level k, the nontrivial simple-current has $Q_j(\lambda) = \lambda_\ell/2$ and $J\lambda = (\lambda_1, \lambda_0, \lambda_2, \ldots, \lambda_\ell)$.

One of the applications of simple-currents is that physical invariants can be built from them in generic ways. These physical invariants all obey the selection rule

$$M_{\lambda\mu} \neq 0 \quad \Longrightarrow \quad \mu = J\lambda \quad \text{for some simple}-\text{current } J = J(\lambda, \mu) \ . \tag{1.7.6}$$

We will call any such physical invariant M a *simple-current invariant.* A special case is the $\mathcal{D}_{\frac{k}{2}+2}$ physical invariant for $A_1^{(1)}$ at even level k. Up to a fairly mild assumption, all simple-current invariants have been classified for any RCFT by Schellekens and collaborators; given that assumption, they can all be constructed by generic methods. The basic construction is due to Bernard [3], though it has been generalised by others. In the WZW case, all simple-current invariants (except some for $D_\ell^{(1)}$) correspond to strings on nonsimply-connected Lie groups.

By a *generic physical invariant* of $X_\ell^{(1)}$ we mean one of the form $M = C'M'C''$ where C', C'' are (charge-)conjugations, and M' is a simple-current invariant. In other words, M is constructed in generic ways from symmetries of the extended Dynkin diagram of X_ℓ. Any other M are called *exceptional.*

All known results point to the validity of the following guess:

Conjecture. Choose a simple algebra X_ℓ. Then for all sufficiently large k, all physical invariants of $X_\ell^{(1)}$ at level k will be generic.

In other words, any given $X_\ell^{(1)}$ will have only finitely many exceptionals. For instance, for $A_1^{(1)}$ and $A_2^{(1)}$ at any $k > 28$ and $k > 21$ resp., all physical invariants are generic. For $C_2^{(1)}$ and $G_2^{(1)}$, $k > 12$ and $k > 4$ resp. should work.

The richest source of exceptionals are *conformal embeddings.* In some cases the affine representations L_λ for some algebra $X_\ell^{(1)}$ (necessarily at level 1) can be decomposed into *finite* direct sums of representations of some affine subalgebra $Y_m^{(1)}$ (at some level k). In this case, a physical invariant for $X_\ell^{(1)}$ level 1 will yield a physical invariant for $Y_m^{(1)}$ level k, obtained by replacing every $X_\ell^{(1)}$ level 1 character χ_λ by the appropriate finite sum of

$Y_m^{(1)}$ level k characters. An example will demonstrate this simple idea: $A_1^{(1)}$ level 28 is a conformal subalgebra of $G_2^{(1)}$ level 1, and we have the character decompositions

$$\begin{aligned}\chi_{(1,0,0)} &= \chi'_{(28,0)} + \chi'_{(18,10)} + \chi'_{(10,18)} + \chi'_{(0,28)} \\ \chi_{(0,0,1)} &= \chi'_{(22,6)} + \chi'_{(16,12)} + \chi'_{(12,16)} + \chi'_{(6,22)} \ .\end{aligned}$$

Thus the unique level 1 $G_2^{(1)}$ physical invariant $|\chi_0|^2 + |\chi_{(0,0,1)}|^2$ yields what we call the $\mathcal{E}_8$ physical invariant of $A_1^{(1)}$. All level 1 physical invariants are known, as are all conformal embeddings and the corresponding character decompositions (branching rules).

1.8. Galois Theory

Evariste Galois was a brilliantly original French mathematician. Born shortly before Napoleon's ill-fated invasion of Russia, he died shortly before the ill-fated 1832 uprising in Paris. His last words: "Don't cry, I need all my courage to die at 20".

Galois grew up in a time and place confused and excited by revolution. He was known to say "if I were only sure that a body would be enough to incite the people to revolt, I would offer mine". On May 2 1832, after frustration over failure in love and failure to convince the Paris math establishment of the depth of his ideas, he made his decision. A duel was arranged with a friend, but only his friend's gun would be loaded. Galois died the day after a bullet perforated his intestine. At his funeral it was discovered that a famous general had also just died, and the revolutionaries decided to use the general's death rather than Galois' as a pretext for an armed uprising. A few days later the streets of Paris were blocked by barricades, but not because of Galois' sacrifice: his death had been pointless [56].

Galois theory in its most general form is the study of relations between objects defined implicitly by some conditions. For example, the objects could be the solutions to a given differential equation. In the incarnation of Galois we are interested in here, the objects are numbers, namely the zeros of certain polynomials. We will sketch this theory below, but see e.g. the article by Stark in [60] for more details.

Gauss seems to have been the first to show that 'weird' (complex) numbers could tell us about the integers. For instance, suppose we are interested in the equation $n = a^2 + b^2$. Consider $5 = 2^2 + 1^2$. We can write this as $5 = (2 + \mathrm{i})(2 - \mathrm{i})$, so we are led to consider complex numbers of the form $a + b\mathrm{i}$, for $a, b \in \mathbb{Z}$. These are now called 'Gaussian integers'. Suppose we know the following theorem:

Fact. Let $p \in \mathbb{Z}$ be any prime number. Then p factorises over the Gaussian integers iff $p = 2$ or $p \equiv 1 \pmod 4$.

By 'factorise' there, we mean $p = zw$ where neither z nor w is a 'unit': ± 1, $\pm\mathrm{i}$.

Now suppose p is a prime, $= 2$ or $\equiv 1 \pmod 4$, and we write $p = (a + b\mathrm{i})(c + d\mathrm{i})$. Then $p^2 = (a^2 + b^2)(c^2 + d^2)$, so $a^2 + b^2 = c^2 + d^2 = p$. Conversely, suppose $p = a^2 + b^2$, then $p = (a + b\mathrm{i})(a - b\mathrm{i})$. Thus:

Consequence. [17] Let $p \in \mathbb{Z}$ be any prime number. Then $p = a^2 + b^2$ for $a, b \in \mathbb{Z}$ iff $p = 2$ or $p \equiv 1 \pmod 4$.

Now we can answer the question: can a given n be written as a sum of 2 squares $n = a^2 + b^2$? Write out the prime decomposition $n = \prod p^{a_p}$. Then $n = a^2 + b^2$ has a solution iff a_p is *even* for every $p \equiv 3 \pmod 4$. For instance $60 = 2^2 \cdot 3^1 \cdot 5^1$ cannot be written as the sum of 2 squares, but $90 = 2^1 \cdot 3^2 \cdot 5^1$ can. We can also find (and count) all solutions: e.g. $90 = 2 \cdot 3^2 \cdot 5 = \{(1+\mathrm{i})3(1+2\mathrm{i})\}\{(1-\mathrm{i})3(1-2\mathrm{i})\}$, giving $90 = (-3)^2 + 9^2$.

This problem should give the reader a small appreciation for the power of using nonintegers to study integers. Nonintegers often lurk in the shadows, secretly watching their more arrogant brethren the integers strut. One of the consequences of their presence can be the existence of certain 'Galois' symmetries. Such happens in RCFT, as we will show below.

Look at complex conjugation: $(wz)^* = w^* z^*$ and $(w+z)^* = w^* + z^*$. Also, $r^* = r$ for any $r \in \mathbb{R}$. So we can say that $*$ is a structure-preserving map $\mathbb{C} \to \mathbb{C}$ (called an *automorphism* of $\mathbb{C}$) fixing the reals. We will write this $* \in \mathrm{Gal}(\mathbb{C}/\mathbb{R})$. '$\mathrm{Gal}(\mathbb{C}/\mathbb{R})$' is the Galois group of $\mathbb{C}$ over $\mathbb{R}$; it turns out to contain only $*$ and the identity.

A way of thinking about the automorphism $*$ is that it says that, as far as the real numbers are concerned, i and $-$i are identical twins.

Let $\mathbb{F}$ be any *field* containing $\mathbb{Q}$ (we defined 'field' in §1.2). The *Galois group* $\mathrm{Gal}(\mathbb{F}/\mathbb{Q})$ then will be the set of all automorphisms=symmetries of $\mathbb{F}$ which fix all rationals.

For example, take $\mathbb{F}$ to be the set of all numbers of the form $a + b\sqrt{5}$, where $a, b \in \mathbb{Q}$. Then $\mathbb{F}$ will be a field, which is commonly denoted $\mathbb{Q}[\sqrt{5}]$ because it is generated by $\mathbb{Q}$ and $\sqrt{5}$. Let's try to find its Galois group. Let $\sigma \in \mathrm{Gal}(\mathbb{F}/\mathbb{Q})$. Then $\sigma(a + b\sqrt{5}) = \sigma(a) + \sigma(b)\sigma(\sqrt{5}) = a + b\sigma(\sqrt{5})$, so once we know what σ does to $\sqrt{5}$, we know everything about σ. But $5 = \sigma(5) = \sigma(\sqrt{5}^2) = (\sigma(\sqrt{5}))^2$, so $\sigma(\sqrt{5}) = \pm\sqrt{5}$ and there are precisely 2 possible Galois automorphisms here (one is the identity). As far as $\mathbb{Q}$ is concerned, $\pm\sqrt{5}$ are interchangeable: it cannot see the difference.

For a more important example, consider the *cyclotomic field* $\mathbb{F} = \mathbb{Q}[\xi_n]$, where $\xi_n := \exp[2\pi\mathrm{i}/n]$ is an nth root of 1. So $\mathbb{Q}[\xi_n]$ consists of all complex numbers which can be expressed as polynomials $a_m\xi_n^m + a_{m-1}\xi_n^{m-1} + \cdots + a_0$ in ξ_n with rational coefficients a_i. Once again, to find the Galois group $\mathrm{Gal}(\mathbb{Q}[\xi_n]/\mathbb{Q})$, it is enough to see what an automorphism σ does to the generator ξ_n. Since $\xi_n^n = 1$, we see that it must send it to another nth root of 1, ξ_n^ℓ say; in fact it is easy to see that $\sigma(\xi_n)$ must be another 'primitive' nth root of 1, i.e. ℓ must be coprime to n. So $\mathrm{Gal}(\mathbb{Q}[\xi_n]/\mathbb{Q})$ will be isomorphic to the multiplicative group $\mathbb{Z}_n^\times$ of numbers between 1 and n coprime to n. The rationals can't see any difference between the primitive nth roots of 1 — for instance $\mathbb{Q}$ can't tell that $\xi_n^{\pm 1}$ are 'closer to 1' than the other primitive roots. So any $\sigma \in \mathrm{Gal}(\mathbb{Q}[\xi_n]/\mathbb{Q})$ will correspond to some $\ell \in \mathbb{Z}_n^\times$, and to see what σ does to some $z \in \mathbb{Q}[\xi_n]$ what we do is write z as a polynomial in ξ_n and then replace each occurrence of ξ_n with ξ_n^ℓ. For example,

$$\sigma\big(\cos(2\pi a/n)\big) = \sigma\left(\frac{\xi_n^a + \xi_n^{-a}}{2}\right) = \frac{\xi_n^{a\ell} + \xi_n^{-a\ell}}{2} = \cos(2\pi a\ell/n) \ .$$

---

[17] This result was first stated by Fermat in one of his infamous margin notes (another is discussed in Section 2.3), and was finally proved a century later by Euler. A remarkable 1-line proof was found by Zagier [61].

So to summarise, Galois automorphisms are a massive generalisation of the idea of complex conjugation. If in your problem complex conjugation seems interesting, then there is a good chance more general Galois automorphisms will play an interesting role. This is what happens in RCFT, as we now show.

Fact. [14] Suppose S is unitary and symmetric and each $S_{0a} > 0$.

(a) If in addition the numbers N_{ab}^c given by Verlinde's formula (1.4.4) are rational, then the entries S_{ab} of S must lie in a cyclotomic field.

(b) The numbers N_{ab}^c will be rational iff for any $\sigma \in \mathrm{Gal}(\mathbb{Q}[S]/\mathbb{Q})$, there is a permutation $a \mapsto a^\sigma$, and a choice of signs $\epsilon_\sigma(a) \in \{\pm 1\}$, such that

$$\sigma(S_{ab}) = \epsilon_\sigma(a)\, S_{a^\sigma,b} = \epsilon_\sigma(b)\, S_{a,b^\sigma} \ . \tag{1.8.1}$$

'$\mathbb{Q}[S]$' in part (b) denotes the field generated by $\mathbb{Q}$ and all matrix entries S_{ab}. The argument follows the one given for the charge-conjugation C at the beginning of the last section. The kinds of complex numbers which lie in cyclotomic fields are $\sin(\pi r)$, $\cos(\pi r)$, $\sqrt{r}$ and $r\mathrm{i}$ for any $r \in \mathbb{Q}$. Almost all complex numbers fail to lie in any cyclotomic field: e.g. generic cube roots, 4th roots, ..., of rationals, as well as transcendental numbers like e, π and e^π.

Of course the affine algebras satisfy the conditions of the Fact, as does more generally the modular matrix S for any unitary RCFT, and so these will possess the Galois action. For the affine algebras this action has a geometric interpretation in terms of multiplying weights by an integer ℓ and applying Weyl group elements — see [14] for a description.

This Fact is useful in both directions: as a way of testing whether a conjectured matrix S has a chance of producing the integral fusions we want it to yield; and more importantly as a source of a symmetry of the RCFT which generalises charge-conjugation. Any statement about charge-conjugation seems to have an analogue for any of these Galois symmetries, although it is usually more complicated.

As an example, consider $A_1^{(1)}$: (1.4.3) shows explicitly that $S_{\lambda\mu}$ lies in the cyclotomic field $\mathbb{Q}[\xi_{4(k+2)}]$. Write $\{x\}$ for the number congruent to x mod $2(k+2)$ satisfying $0 \le \{x\} < 2(k+2)$. Choose any Galois automorphism σ, and let $\ell \in \mathbb{Z}_{4(k+2)}^\times$ be the corresponding integer. Then if $\{\ell(a+1)\} < k+2$, we will have $a^\sigma = \{\ell(a+1)\} - 1$, while if $\{\ell(a+1)\} > k+2$, we'll have $a^\sigma = 2(k+2) - \{\ell(a+1)\} - 1$. The sign $\epsilon_\sigma(a)$ will depend on a contribution from $\sqrt{\frac{2}{k+2}}$ (which for most purposes can be ignored), as well as the sign $+1$ or -1, resp., depending on whether or not $\{\ell(a+1)\} < k+2$.

Consider specifically $k = 10$, and the Galois automorphism σ_5 corresponding to $\ell = 5$. Then the permutation is $0 \leftrightarrow (6,4)$, $(9,1) \leftrightarrow (1,9)$, $(8,2) \leftrightarrow (2,8)$, $(4,6) \leftrightarrow (0,10)$, while $(7,3)$ and (5,5) are fixed.

This Galois symmetry has been used to find certain exceptional physical invariants, but its greatest use so far is as a powerful selection rule we will describe next section.

In this final section we include some of the basic tools belonging to the 'modern' classifications of physical invariants, and we give a flavour of their proofs. We will state them for the $A_1^{(1)}$ level k problem given above, but everything generalises without effort. See [29] and references therein for more details. Recall the matrices S, T in (1.4.3).

First note that commutation of M with T implies the selection rule

$$M_{\lambda\mu} \neq 0 \quad \Longrightarrow \quad (\lambda_1+1)^2 \equiv (\mu_1+1)^2 \pmod{4(k+2)} \ . \tag{1.9.1}$$

It is much harder to squeeze information out of the commutation with S, but the resulting information turns out surprisingly to be much more useful. In fact, commutation with S is almost incompatible with the constraint $M_{\lambda\mu} \in \mathbb{Z}_{\geq}$.

Note that the vacuum $0 \in P_+^k$ is both physically and mathematically special; our strategy will be to find all possible 0th rows and columns of M, and then for each of these possibilities to find the remaining entries of M.

The easiest result follows by evaluating $MS = SM$ at $(0, \lambda)$ for any $\lambda \in P_+^k$:

$$\sum_{\mu \in P_+^k} M_{0\mu}\, S_{\mu\lambda} \geq 0 \ , \tag{1.9.2}$$

with equality iff the λth column of M is identically 0. (1.9.2) has two uses: it severely constrains the values of $M_{0\mu}$ (similarly $M_{\mu 0}$), and it says precisely which columns (and rows) are nonzero.

Next, let's apply the triangle inequality to sums involving (1.7.5). Choose any $i, j \in \{0,1\}$. Then

$$M_{J^i 0, J^j 0} = \sum_{\lambda,\mu} (-1)^{\lambda_1 i}\, S_{0\lambda}\, M_{\lambda\mu}\, (-1)^{\mu_1 j}\, S_{0\mu} \ .$$

Taking absolute values, we obtain

$$M_{J^i 0, J^j 0} \leq \sum_{\lambda,\mu} S_{0\lambda}\, M_{\lambda\mu}\, S_{0\mu} = M_{00} = 1 \ .$$

Thus $M_{J^i 0, J^j 0}$ can equal only 0 or 1. If it equals 1, then we obtain the selection rule:

$$\lambda_1 i \equiv \mu_1 j \pmod 2 \text{ whenever } M_{\lambda\mu} \neq 0 \ ;$$

this implies the symmetry $M_{J^i\lambda, J^j\mu} = M_{\lambda\mu}$ for all $\lambda, \mu \in P_+^k$. We can see both of these in the list of physical invariants for $A_1^{(1)}$ level k. This explains a lot of the properties of those invariants. For instance, try to use this selection rule to explain why no χ_{odd} appears in the exceptional called $\mathcal{E}_8$.

Our M is nonnegative, and although multiplying M's may not give us back a physical invariant, it will give us a matrix commuting with S and T. In other words, the commutant is much more than merely a vector space, it is in fact an algebra. Thus we should expect Perron-Frobenius to tell us something here. A first application is the following.

Suppose $M_{\lambda 0}=\delta_{\lambda,0}$ — i.e. the 0th column of M is all zeros except for $M_{00}=1$. Then Perron-Frobenius implies (with a little work) that M will be a permutation matrix — i.e. there is some permutation π of P_+^k such that $M_{\lambda\mu}=\delta_{\mu,\pi\lambda}$, and $S_{\pi\lambda,\pi\mu}=S_{\lambda\mu}$. This nice fact applies directly to the $\mathcal{A}_\star$ and $\mathcal{D}_{odd}$ physical invariants of $A_1^{(1)}$.

This is proved by studying the powers $(M^t\,M)^L$ as L goes to infinity: its diagonal entries will grow exponentially with L, unless there is at most one nonzero entry on each row of M, and that entry equals 1.

More careful reasoning along those lines tells us about the other generic situation here. Namely, suppose $M_{\lambda 0}\neq 0$ only for $\lambda=0$ and $\lambda=J0$, and similarly for $M_{0\lambda}$ — i.e. the 0th row and column of M are all zeros except for $M_{J^i0,J^j0}=1$. Then the λth row (or column) of M will be identically 0 iff λ_1 is odd. Moreover, let λ,μ be any non-fixed-points of J, and suppose $M_{\lambda\mu}\neq 0$. Then

$$M_{\lambda\nu}=\begin{cases}1 & \text{if } \nu=\mu \text{ or } \nu=J\mu\\ 0 & \text{otherwise}\end{cases}$$

with a similar formula for $M_{\nu\mu}$. This applies to the $\mathcal{D}_{even}$ and $\mathcal{E}_7$ invariants of $A_1^{(1)}$.

Our final ingredient is the Galois symmetry (1.8.1) obeyed by S. Choose any Galois automorphism σ. It will correspond to some integer ℓ coprime to $2(k+2)$. From (1.8.1) and $M=SMS^*$ we get, for all λ,μ, the important relation

$$M_{\lambda\mu}=\epsilon_\sigma(\lambda)\,\epsilon_\sigma(\mu)\,M_{\lambda^\sigma,\mu^\sigma}\ . \tag{1.9.3}$$

From (1.9.3) and the positivity of M, we obtain the powerful *Galois selection rule*

$$M_{\lambda\mu}\neq 0 \quad\Longrightarrow\quad \epsilon_\sigma(\lambda)=\epsilon_\sigma(\mu)\ . \tag{1.9.4}$$

Next let us quickly sketch how these tools are used to obtain the $A_1^{(1)}$ classification. For details the reader should consult [29].

The first step will be to find all possible values of λ such that $M_{0\lambda}\neq 0$ or $M_{\lambda 0}\neq 0$. These λ are severely constrained. We know two generic possibilities: $\lambda_1=0$ (good for all k), and $\lambda=J0$ (good when $\frac{k}{2}$ is even). We now ask the question, what other possibilities for λ are there? Our goal is to prove (1.9.7). Assume $\lambda\neq 0,J0$, and write $a=\lambda_1+1$ and $n=k+2$.

There are only two constraints on λ which we will need. One is (1.9.1):

$$(a-1)\,(a+1)\equiv 0 \ (\mathrm{mod}\ 4n)\ . \tag{1.9.5}$$

More useful is the Galois selection rule (1.9.4), which we can write as $\sin(\pi\ell\frac{a}{n})\sin(\pi\ell\frac{1}{n})>0$, for all those ℓ. But a product of sines can be rewritten as a difference of cosines, so

$$\cos(\pi\,\ell\,\frac{a-1}{n})>\cos(\pi\,\ell\,\frac{a+1}{n})\ . \tag{1.9.6}$$

(1.9.6) is strong and easy to solve; the reader should try to find her own argument.

What we get is that, provided $n \neq 12, 30$, M obeys the strong condition

$$M_{\lambda 0} \neq 0 \text{ or } M_{0\lambda} \neq 0 \qquad \Longrightarrow \qquad \lambda \in \{0, J0\}\ . \tag{1.9.7}$$

Consider first **case 1**: $M_{\lambda 0} = \delta_{\lambda,0}$. From above, we know $M_{\lambda\mu} = \delta_{\mu,\pi\lambda}$ for some permutation π of P_+^k obeying $S_{\lambda\mu} = S_{\pi\lambda,\pi\mu}$. We know $\pi 0 = 0$; put $\mu := \pi(k-1,1)$. Then $\sin(\pi\frac{2}{n}) = \sin(\pi\frac{\mu_1+1}{n})$, and so we get either $\mu = (k-1,1)$ or $\mu = J(k-1,1)$. By T-invariance (1.9.1), the second possibility can only occur if $4 \equiv (n-2)^2 \pmod{4n}$, i.e. 4 divides n. But for those n, $\mathcal{D}_{\frac{n}{2}+1}$ is also a permutation matrix, so replacing M if necessary with the matrix product $M\,\mathcal{D}_{\frac{n}{2}+1}$, we can always require $\mu = (k-1,1)$, i.e. π also fixes $(k-1,1)$. It is now easy to show π must fix any λ, i.e. that M is the identity matrix $\mathcal{A}_{n-1}$.

The other possibility, **case 2**, is that both $M_{0,J0} \neq 0$ and $M_{J0,0} \neq 0$. (1.9.1) says $1 \equiv (n-1)^2 \pmod{4n}$, i.e. $\frac{n}{2}$ is odd. The argument here is similar to that of **case 1**, but with $(k-2,2)$ playing the role of $(k-1,1)$. We can show that $M_{(k-2,2),(k-2,2)} \neq 0$, except possibly for $k = 16$, where we find the exceptional $\mathcal{E}_7$. Otherwise we get $M = \mathcal{D}_{\frac{n}{2}+1}$.

For more general $X_\ell^{(1)}$ level k, the approach is

(i) to look at all the constraints on the $\lambda \in P_+^k$ for which $M_{0\lambda} \neq 0$ or $M_{\lambda 0} \neq 0$. Most important here are $TM = MT$ (which will always be some sort of norm selection rule) and the Galois selection rule (1.9.4). Generically, what we will find is that such a λ must equal $J0$ for some simple-current J, as in (1.9.7) for $A_1^{(1)}$.

(ii) Solve this generic case (in the $A_1^{(1)}$ classification, these were the physical invariants $\mathcal{A}_\star$, $\mathcal{D}_\star$ and $\mathcal{E}_7$).

(iii) Solve the nongeneric case. The worst of these are the orthogonal algebras at $k = 2$, as well as the places where conformal embeddings (see §1.7) occur.

(ii) has recently been completed for all simple X_ℓ, as has the $k = 2$ part of (iii). (i) is the main remaining task in the physical invariant classification for simple X_ℓ.

A natural question to ask is whether A-D-E has been observed in e.g. the $A_2^{(1)}$ classification. The answer is no, although the fusion graph theory of Di Francesco-Petkova-Zuber [62] is an attempt to assign to these physical invariants graphs reminiscent of the A-D-E Dynkin diagrams. Also, there is related work trying to understand the $A_2^{(1)}$ classification in terms of subgroups of $\mathrm{SU}_3(\mathbb{C})$ (as opposed to $\mathrm{SU}_2(\mathbb{C})$ for $A_1^{(1)}$) — see e.g. [35]. Finding the $A_3^{(1)}$, $A_4^{(1)}$,... classifications would permit the clarification and testing of this vaguely conjectured relation between the $A_n^{(1)}$ physical invariants, and singularities $\mathbb{C}^{n+1}/G$ for G a finite subgroup of $\mathrm{SU}_{n+1}(\mathbb{C})$.

However, a few years ago Philippe Ruelle was walking in a library in Dublin. He spotted a yellow book in the math section, called *Complex Multiplication* by Lang. A strange title for a book by Lang! After all, there can't be all that much even Lang could really say about complex multiplication! Ruelle flipped it to a random page, which turned out to be p.26. On there he found what we would call the Galois selection rule for $A_2^{(1)}$, analysed and solved for the cases where $k+3$ is coprime to 6. Lang however didn't know about physical invariants; he was reporting on work by Koblitz and Rohrlich on decomposing the Jacobians of the Fermat curve $x^n + y^n = z^n$ into their prime pieces, called 'simple factors' in algebraic geometry. n here corresponds to $k + 3$. Similarly, Itzykson discovered traces of the $A_2^{(1)}$ exceptionals — these occur when $k + 3 = 8, 12, 24$ — in the Jacobian of $x^{24} + y^{24} = z^{24}$. See [2] for further observations along these lines. These 'coincidences' are still far from understood. Nor is it known if, more generally, the $A_\ell^{(1)}$ level k classification will somehow be related to the hypersurface $x_1^n + \cdots + x_\ell^n = z^n$, for $n = k + \ell + 1$.

The $(u(1) \oplus \cdots \oplus u(1))^{(1)}$ classification has connections to rational points on Grassmannians. The Grassmannian is (essentially) the moduli space for the Narain compactifications of the (classical) lattice string. It would be very interesting to interpret other large families of physical invariants as special points on other moduli spaces.

These new connections relating various physical invariant classifications to other areas of math seem to indicate that although the physical invariant classifications are difficult, they could be well worth the effort and be of interest outside RCFT. Once the physical invariant lists are obtained, we will still have the fascinating task of explaining and developing all these mysterious connections. These thoughts keep me going!

Another motivation for completing these lists comes from their relation to subfactor theory in von Neumann algebras[18]. These algebras (see e.g. [22]) can be thought of as symmetries of a (generally infinite) group. Their building blocks are called *factors.* Jones initiated the combinatorial study of *subfactors* N of M (i.e. inclusions $N \subseteq M$ where M, N are factors), relating it to e.g. knots, and for this won a Fields medal in 1990. Jones assigned to each subfactor $N \subseteq M$ a numerical invariant called an 'index', a sort of (generally irrational) ratio of dimensions. Graphs (called principal and dual principal) are also associated to subfactors. A much more refined subfactor invariant, called a 'paragroup', has been introduced by Ocneanu. It is essentially equivalent to a (2+1)-dimensional topological field theory. Moreover, any RCFT can be assigned a paragroup, and any paragroup (via a process called asymptotic inclusion which is akin to Drinfeld's quantum doubling of Hopf algebras) yields an RCFT. See [22] for details.

Böckenhauer-Evans [4] have recently developed this much further, and have clarified the fusion graph ↔ physical invariant relation. The fusion graphs will correspond to subfactor principal graphs. In the work of Di Francesco-Petkova-Zuber, that relation seems to be only empirical (i.e. nonconceptual).

Subfactor theory together with singularity theory is our best hope at present for understanding and generalising the A-D-E meta-pattern.

---

[18] For reasons of necessity, in the following discussion I'll take more liberties than usual in the presentation.

Part 2. Monstrous Moonshine

2.1. INTRODUCTION

In 1978, John McKay made a very curious observation. One of the well-known[19] functions of classical number theory is the j-function[20], given by

$$j(\tau) := \frac{(1+240\sum_{n=1}^{\infty}\sigma_3(n)\,q^n)^3}{q\prod_{n=1}^{\infty}(1-q^n)^{24}} = \frac{\Theta_{E_8}(\tau)^3}{\eta(\tau)^{24}}$$
$$= q^{-1} + 744 + 196\,884\,q + 21\,493\,760\,q^2 + 864\,299\,970\,q^3 + \cdots \tag{2.1.1}$$

Here as elsewhere in this paper, $q = \exp[2\pi\mathrm{i}\,\tau]$. Also, $\sigma_3(n) = \sum_{d|n} d^3$, Θ_{E_8} is the theta function of the E_8 root lattice, and η is the Dedekind eta. What is important here are the values of the first few coefficients. What McKay noticed was that $196\,884 \approx 196\,883$. Closer inspection shows $21\,493\,760 \approx 21\,296\,876$, and $864\,299\,970 \approx 842\,609\,326$. In fact,

$$196\,884 = 196\,883 + 1 \tag{2.1.2a}$$
$$21\,493\,760 = 21\,296\,876 + 196\,883 + 1 \tag{2.1.2b}$$
$$864\,299\,970 = 842\,609\,326 + 21\,296\,876 + 2\cdot 196\,883 + 2\cdot 1 \tag{2.1.2c}$$

The numbers on the right-side are the dimensions of the smallest irreducible representations of the Monster finite simple group $\mathbb{M}$ (in 1978 it still wasn't certain that $\mathbb{M}$ even existed so back then these numbers were merely conjectural). The same game could be played with other coefficients of the j-function. With numbers so large, it seemed to him doubtful that this numerology was merely a coincidence. On the other hand, it was hard to imagine any deep conceptual connection between the Monster and the j-function: they seem completely unrelated.

In November 1978 he mailed the 'McKay equation' (2.1.2a) to John Thompson. At first Thompson dismissed this as nonsense, but after checking the next few coefficients he became convinced. He then added a vital piece to the puzzle. It should be well-known that when one sees a nonnegative integer, it often helps to try to interpret it as the dimension of some vector space. Essentially, that is what McKay was proposing here. (2.1.2) are really hinting that there is a 'graded' representation V of $\mathbb{M}$:

$$V = V_{-1} \oplus V_1 \oplus V_2 \oplus V_3 \oplus \cdots$$

where $V_{-1} = \rho_0$, $V_1 = \rho_1 \oplus \rho_0$, $V_2 = \rho_2 \oplus \rho_1 \oplus \rho_0$, $V_3 = \rho_3 \oplus \rho_2 \oplus \rho_1 \oplus \rho_1 \oplus \rho_0 \oplus \rho_0$, etc, where ρ_i are the irreducible representations of $\mathbb{M}$ (ordered by dimension), and that

$$j(\tau) - 744 = \dim_q(V) := \dim(V_{-1})\,q^{-1} + \sum_{i=1}^{\infty}\dim(V_i)\,q^i\ , \tag{2.1.3}$$

---

[19] 'Well-known' is math euphemism for 'a basic result of which until recently we were utterly ignorant.' As Conway later said, "the j-function was 'well-known' to other people, but not 'well-known' to me."

[20] This and other technical terms used in this introduction will be carefully explained in the following subsections. This section is merely offered as a quick overview.

the graded dimension of V.

Thompson suggested that we twist $\dim_q(V)$, i.e. that more generally we consider the series (now called the *McKay-Thompson series*)

$$T_g(\tau) := \mathrm{ch}_{V,q}(g) = \mathrm{ch}_{V_{-1}}(g)\, q^{-1} + \sum_{i=1}^{\infty} \mathrm{ch}_{V_i}(g)\, q^i \ , \tag{2.1.4}$$

for each element $g \in \mathbb{M}$. The point is that, for any group representation ρ, the character value $\mathrm{ch}_\rho(id.)$ equals the dimension of ρ, and so $T_{id.}(\tau) = j(\tau) - 744$ and we recover (2.1.2) as special cases. But there are many other possible choices of $g \in \mathbb{M}$. Thompson couldn't guess what these functions T_g would be, but he suggested that they too might be interesting. This is a nice thought: when we see a positive integer, we should try to interpret it as a dimension of a vector space; if there is a symmetry present, then it may act on the vector space — i.e. our vector space may carry a representation of that symmetry group — in which case we can apply the Thompson trick and see what if any significance the other character values have in our context.

Conway and Norton [12] did precisely what Thompson asked. Conway called it "one of the most exciting moments in my life" [11] when he opened Jacobi's foundational (but 150 year old!) book on elliptic and modular functions and found that the first few terms of the McKay-Thompson series agreed perfectly with the first few terms of certain special functions, namely the Hauptmoduls of various genus 0 modular groups. Monstrous Moonshine was officially born.

The word 'moonshine' here is English slang for 'unsubstantial or unreal'. It was chosen by Conway to convey as well the feeling that things here are dimly lit, and that Conway-Norton were 'distilling information illegally' from the Monster character table.

In fact the first incarnation of Moonshine goes back to Andrew Ogg in 1975. He was in France describing his result that the primes p for which the group $\Gamma_0(p)+$ has genus 0, are $\{2, 3, 5, 11, 13, 17, 19, 23, 29, 31, 41, 47, 59, 71\}$. $\Gamma_0(p)+$ is the group generated by $\begin{pmatrix} 0 & 1 \\ -p & 0 \end{pmatrix}$ and $\Gamma_0(p)$, and is the normaliser of $\Gamma_0(p)$ in $\mathrm{SL}_2(\mathbb{R})$ (this sentence will make a little more sense after §2.3, but it isn't important here to understand it). He also attended a lecture by Jacques Tits, who was describing a newly conjectured simple group. When Tits wrote down the prime decomposition of the order of that group (see (2.2.1) below), Ogg noticed its prime factors precisely equalled his list of primes. Presumably as a joke, he offered a bottle of Jack Daniels' whisky to the first person to explain the coincidence.

The next step was accomplished by Griess in 1980, with the construction of the Monster[21] $\mathbb{M}$, and with it the proof that the conjectured character table for $\mathbb{M}$ was correct. Griess did this by explicitly constructing the 196883-dimensional representation ρ_1; it turns out to have a (commutative nonassociative) algebra structure, now called the *Griess algebra*. Though this paper was clearly important, the construction was artificial and 100 pages long: since the Monster is presumably a natural mathematical object (see §2.2), an elegant construction for it should exist. This was ultimately accomplished in the mid 1980s with the construction by Frenkel-Lepowsky-Meurman [23] of the Moonshine module

---

[21] Griess also came up with the symbol for the Monster; Conway came up with the name.

$V^\natural$ and its interpretation by Borcherds as a *vertex operator algebra*. The Griess algebra appears naturally in $V^\natural$, as we shall see. $V^\natural$ does indeed seem to be a 'natural' mathematical structure, and $\mathbb{M}$ is its automorphism group: in fact $V^\natural$ is the graded representation V of $\mathbb{M}$ conjectured by McKay and Thompson.

Connections with physics (CFT) go back to Dixon-Ginsparg-Harvey [19] in 1988, in a paper titled "Beauty and the beast: Superconformal symmetry in a Monster module". The Moonshine module $V^\natural$ can be interpreted as the string theory for a $\mathbb{Z}_2$-orbifold of free bosons compactified on the torus $\mathbb{R}^{24}/\Lambda_{24}$ (Λ_{24} is the Leech lattice). Many aspects of Moonshine make complete sense within CFT, but some (e.g. the genus zero property) remain more obscure. (Though in 1987 Moore speculated that the 0-genus of $\Gamma_0(a)+$ could be related to the vanishing of the cosmological constant in certain string theories related to $\mathbb{M}$, and Tuite [57] related genus-zero with the conjectured uniqueness of $V^\natural$.) Nevertheless this helps make the words of Dyson ring prophetic: "I have a sneaking hope, a hope unsupported by any facts or any evidence, that sometime in the twenty-first century physicists will stumble upon the Monster group, built in some unsuspected way into the structure of the universe" [21].

Finally, in 1992 Borcherds [5] completed the proof of the Conway-Norton conjectures by showing $V^\natural$ is the desired representation V. The full conceptual relationship between the Monster and the Hauptmoduls (like j) seems to remain 'dimly lit', although much progress has been realised. This is a subject where it is much easier to conjecture than to prove, and we are still awash in unresolved conjectures.

McKay also noticed in 1978 that similar coincidences hold if $\mathbb{M}$ and $j(\tau)$ are replaced with the Lie group $E_8(\mathbb{C})$ and $(qj(q))^{\frac{1}{3}} = 1 + 248q + \cdots$. This turns out to be much easier to explain, and in 1980 both Kac and Lepowsky remarked that the unique level 1 highest-weight representation of the affine algebra $E_8^{(1)}$ has graded dimension $(qj(q))^{\frac{1}{3}}$.

Moonshiners have a little chip on their shoulders. Modern math, they say, tends to be a little too infatuated with the pursuit of generalisations for generalisations' sake. Surely a noble goal for math is to find interesting and fundamentally new theorems. It can be argued that both history and common-sense suggest that to this end it is most profitable to look simultaneously at both exceptional structures and generic structures, to understand the special features of the former in the context of the latter, and to be led in this way to a new generation of exceptional and generic structures. Moonshiners would sympathise with those biologists who study the duck-billed platypus and lungfish rather than hide them in the closet as monsters: BECAUSE they appear to be unique, those animals presumably have much to teach us about our general understanding of evolution, etc.

It often seems to people that Moonshine can't be very deep: the Conway-Norton conjectures seem to be so finite[22] and specialised. There only are 171 distinct McKay-Thompson series T_g in Monstrous Moonshine, after all. The whole point though is to try to understand *why* the Monster and the Hauptmoduls are so related, and then to try to extend and apply this understanding to other contexts. Moonshine is still young, and our understanding remains incomplete. But already math has benefitted: e.g. we now have a natural definition of $\mathbb{M}$ (as the automorphism group of $V^\natural$), and Moonshine helped lead us to the rich structures of generalised Kac-Moody algebras and vertex operator algebras.

---

[22] Indeed the Moonshine conjectures *are* finite (it is enough to check the first 1200 coefficients), and a slightly weaker form was quickly proved on a computer by Atkin, Fong and Smith [54]. However this sort of argument adds no light to Moonshine, and tells us nothing of V except that it exists.

We will see that Moonshine involves the interplay between *exceptional structures* such as the number 24, the Leech lattice Λ_{24}, the Monster group $\mathbb{M}$, and the Moonshine module $V^\natural$, and *generic structures* such as modular functions, vertex operator algebras, generalised Kac-Moody algebras, and conformal field theories. The following sections will introduce the reader to many of these structures, as we use Moonshine as another happy excuse to take a second little tour through modern mathematics.

2.2. INGREDIENT #1: FINITE SIMPLE GROUPS AND THE MONSTER

A readable introduction to the basics of finite group representation theory is [25]. The finite simple groups are described in [33]; see also [11]. Group representations were introduced in §1.3.

A *normal* subgroup H of a group is one obeying $gHg^{-1} = H$ for all $g \in G$. These are important because the set G/H of 'cosets' gH has a natural group structure precisely when H is normal. Every group has two trivial normal subgroups: itself and $\{1\}$. If these are the only normal subgroups, the group is called *simple*. It is conventional to regard the trivial group $\{1\}$ as not simple (just as 1 is conventionally regarded as not prime). An alternate definition of a (finite) simple group G is that if $\varphi : G \to H$ is any group homomorphism (i.e. structure-preserving map: $\varphi(gg') = \varphi(g)\varphi(g')$), then φ is either constant (i.e. $\varphi(G) = \{1\}$), or φ is one-to-one.

The importance of simple groups is provided by the *Jordan-Hölder Theorem*. By a 'composition series' for a group G, we mean a nested sequence

$$G = H_0 \supset H_1 \supset H_2 \supset \cdots \supset H_k \supset H_{k+1} = \{1\}$$

of groups such that H_i is normal in H_{i-1}, and H_{i-1}/H_i (called a 'composition factor') is simple. Any finite group G has at least one composition series. If $H'_0 \supset \cdots \supset H'_{\ell+1} = \{1\}$ is a second composition series for G, then Jordan-Hölder says that $k = \ell$ and, up to a reordering π, the simple groups H_{i-1}/H_i and $H'_{\pi j-1}/H'_{\pi j}$ are isomorphic.

For example, the cyclic group $\mathbb{Z}_n$ of order(=size) n — you can think of it as the integers modulo n under addition — is simple iff n is prime. Consider the group $\mathbb{Z}_{12} = \langle 1 \rangle$. Two composition series are

$$\mathbb{Z}_{12} \supset \langle 2 \rangle \supset \langle 4 \rangle \supset \langle 0 \rangle$$
$$\mathbb{Z}_{12} \supset \langle 3 \rangle \supset \langle 6 \rangle \supset \langle 0 \rangle$$

corresponding to composition factors $\mathbb{Z}_2$, $\mathbb{Z}_2$, $\mathbb{Z}_3$, and $\mathbb{Z}_3$, $\mathbb{Z}_2$, $\mathbb{Z}_2$. Of course this is consistent with Jordan-Hölder. This is reminiscent of the fact that $2 \cdot 2 \cdot 3 = 3 \cdot 2 \cdot 2$ are both prime factorisations of 12.

There is some value to regarding finite groups as a massive generalisation of the notion of number. The number n can be identified with the cyclic group $\mathbb{Z}_n$. The divisor of a number corresponds to a normal subgroup, so a prime number corresponds to a simple group. The Jordan-Hölder Theorem generalises the uniqueness of prime factorisations. That you can build up any number by multiplying primes, is generalised to building up a group by semi-direct products (more generally, by group extensions): if H is a normal subgroup of G, then G will be an extension of H by the quotient group G/H.

Note however that $\mathbb{Z}_6 \times \mathbb{Z}_2$ and $\mathfrak{S}_3 \times \mathbb{Z}_2$ — both different from $\mathbb{Z}_{12}$ — will also have $\mathbb{Z}_2, \mathbb{Z}_2, \mathbb{Z}_3$ as composition factors: unlike for numbers, 'multiplication' here does not give a unique answer. The semidirect product $\mathbb{Z}_2 \rtimes \mathbb{Z}_2$ can equal either $\mathbb{Z}_4$ or $\mathbb{Z}_2 \times \mathbb{Z}_2$, depending on how the product is taken. More precisely, the notation $G \rtimes G'$ means a group where every element can be written uniquely as a pair (g, g'), for $g \in G$ and $g' \in G'$, and where the group operation is $(g, g')(h, h') = (\text{stuff}, gh)$.

Thus simple groups have an importance for group theory approximating what primes have for number theory. One of the greatest accomplishments of twentieth century math is surely the classification of the finite simple groups. (On the other hand, group extensions turn out to be technically quite difficult and leads one into group cohomology.) This work, completed in the early 1980s (although gaps are continually being discovered and filled in the arguments), runs to approximately 15 000 journal pages, spread over 500 individual papers, and is the work of a whole generation of group theorists. A modern revision is currently underway (see e.g. [34]) to simplify the proof and find and fill all gaps, but the final proof is still expected to be around 4000 pages long. The resulting list is:

- the cyclic groups $\mathbb{Z}_p$ (p a prime);
- the alternating groups $\mathfrak{A}_n$ for $n \geq 5$;
- 16 families of Lie type;
- 26 sporadics.

We've already met the cyclic groups. The alternating group $\mathfrak{A}_n$ consists of the even permutations in the symmetric group $\mathfrak{S}_n$, and so has order(=size) $\frac{1}{2}\,n!$. The groups of Lie type are essentially Lie groups defined over finite fields[23] $\mathbb{F}_q$ (such as $\mathbb{Z}_p$), sometimes 'twisted' in certain senses. The simplest example is $\mathrm{PSL}_n(\mathbb{F}_q)$, which consists of the $n \times n$ matrices with entries in $\mathbb{F}_q$, with determinant 1, quotiented out by the centre of $\mathrm{SL}_n(\mathbb{F}_q)$ (namely the scalar matrices $\mathrm{diag}(a, a, \ldots, a)$ for $a^n = 1$) (except for $\mathrm{PSL}_2(\mathbb{Z}_2)$ and $\mathrm{PSL}_2(\mathbb{Z}_3)$, which aren't simple).

Note that the determinant $|\rho(g)|$ for any representation ρ of any (noncyclic) simple group must be 1, otherwise we would violate the homomorphism definition of simple group (try to see why). Also, the centre of any (noncyclic) simple group must be trivial (why?). The smallest noncyclic simple group is $\mathfrak{A}_5$, with order 60.[24] It is the same as (isomorphic to) $\mathrm{PSL}_2(\mathbb{Z}_5)$ and $\mathrm{PSL}_2(\mathbb{F}_4)$, and can also be expressed as the group of all rotations (reflections have determinant -1 and so cannot belong to any simple group) of $\mathbb{R}^3$ that bring a regular icosahedron back to itself.

---

[23] There is a finite field with q elements, iff q is a power of a prime. For each such q, there is only 1 field of that size. The field with prime p elements is the integers taken mod p.

[24] This implies, incidentally, that if G and H are any two groups with the same order below 60, then they will have the same composition factors.

The smallest sporadic group is the Mathieu group M_{11}, order 7920, discovered in 1861[25]. The largest is the Monster $\mathbb{M}$, conjectured by Fischer and Griess in 1973 and finally proved to exist by Griess in 1980. Its order is[26]

$$\|\mathbb{M}\| = 2^{46} \cdot 3^{20} \cdot 5^9 \cdot 7^6 \cdot 11^2 \cdot 13^3 \cdot 17 \cdot 19 \cdot 23 \cdot 29 \cdot 31 \cdot 41 \cdot 47 \cdot 59 \cdot 71 \approx 8 \times 10^{53} \ . \quad (2.2.1)$$

20 of the 26 sporadics are involved in (i.e. are quotients of subgroups of) the Monster. Some relations among $\mathbb{M}$, the Leech lattice Λ_{24} and the largest Mathieu group M_{24} are given in Chapters 10 and 29 of [13].

Moonshine hints at a tantalising connection between the classification of finite simple groups, and the classification of RCFTs discussed in Part 1. Speculates [23] (page xli): "One can certainly hope for a uniform description of the finite simple groups as automorphism groups of certain vertex operator algebras — or conformal quantum field theories. If such a quantum field theory could somehow be attached a priori to a finite simple group, the classification of such theories, a problem of great current interest among string theorists, might some day be part of a new approach to the classification of the finite simple groups. On the other hand, can the known classification of the finite simple groups help in the classification of conformal field theories?"

2.3. INGREDIENT #2: MODULAR FUNCTIONS AND HAUPTMODULS

A readable introduction to some of the topics discussed in this section is [16,42,60].

We know from complex analysis that the group $\mathrm{SL}_2(\mathbb{R})$ of 2×2 matrices with real entries and determinant 1, acts on the upper-half plane $\mathcal{H} = \{\tau \in \mathbb{C} \,|\, \mathrm{Im}(\tau) > 0\}$ by fractional linear (or *Möbius*) transformations:

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} \cdot \tau := \frac{a\tau + b}{c\tau + d} \ . \qquad (2.3.1)$$

For example the matrix $S := \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ corresponds to the function $\tau \mapsto -1/\tau$, while the matrix $T := \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ corresponds to the translation $\tau \mapsto \tau + 1$. Since $\pm \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ correspond to the same Möbius transformation, strictly speaking our group here is $\mathrm{PSL}_2(\mathbb{R}) = \mathrm{SL}_2(\mathbb{R})/\{\pm I\}$.

The only reason this action (2.3.1) of the 2×2 matrices on complex numbers (or more precisely the Riemann sphere $\mathbb{C} \cup \{\infty\}$) might not look strange to us, is because familiarity breeds numbness. What we really have is a natural action of $n \times n$ matrices on $\mathbb{C}^n$, and this induces their action on $\mathbb{C}^{n-1}$ (together with a codimension-2 set of 'points at infinity') by interpreting $\mathbb{C}^n$ as projective coordinates for $\mathbb{C}^{n-1}$. Specialising to $n = 2$ gives us (2.3.1). In projective geometry, 'parallel lines' intersect at ∞. Projective coordinates allow one to treat 'finite' and 'infinite' points on an equal footing.

---

[25] Although his arguments apparently weren't very convincing. In fact some people, including the Jordan of Jordan-Hölder fame, argued in later papers that the largest of Mathieu's sporadic groups couldn't exist.

[26] The inquisitive reader, hungry for more 'coincidences', may have noticed that 196883 and 21296876 — see (2.1.2) — exactly divide the order of the Monster. Indeed this will hold for any finite group: the dimensions of the irreducible representations of a finite group will always divide its order.

Consider $\Gamma := \mathrm{SL}_2(\mathbb{Z})$, the subgroup of $\mathrm{SL}_2(\mathbb{R})$ consisting of the matrices with integer entries. It can be shown that it is generated by S and T (in other words, every matrix $\alpha \in \Gamma$ can be expressed as a monomial in S and T). For reasons that will be clear shortly, consider the extended upper-half plane $\overline{\mathcal{H}} := \mathcal{H} \cup \{\mathrm{i}\infty\} \cup \mathbb{Q}$ — the extra points $\{\mathrm{i}\infty\} \cup \mathbb{Q}$ are called *cusps*. Γ acts on $\overline{\mathcal{H}}$ (e.g. S interchanges 0 and $\mathrm{i}\infty$). By a *modular function* for Γ, we mean a meromorphic function $f : \overline{\mathcal{H}} \to \mathbb{C}$, symmetric with respect to Γ: i.e. $f(\alpha(\tau)) = f(\tau)$ for all $\alpha \in \Gamma$. Note that we require f to be meromorphic at the cusps (e.g. polynomials are meromorphic at $\mathrm{i}\infty$, but e^z is not).

It is not obvious why modular functions should be interesting, but in fact they are one of the most fundamental notions in modern number theory (see the last paragraph of §1.6). For example, consider the question of writing numbers as sums of squares. We can write $5 = 1^2 + (-2)^2 = (-1)^2 + 1^2 + 0^2 + 1^2 + (-1)^2$, to give a couple of trivial examples. Let $N_n(k)$ be the number of ways we can write the integer n as a sum of k squares, counting order and signs. For example $N_5(1) = 0$ (since 5 is not a perfect square), $N_5(2) = 8$ (since $5 = (\pm 1)^2 + (\pm 2)^2 = (\pm 2)^2 + (\pm 1)^2$), $N_5(3) = 24$, etc. Their generating functions are:[27]

$$\sum_{n=0}^{\infty} N_n(k)\, q^n = (\theta_3(q))^k \ ,$$

where

$$\theta_3(q) = 1 + 2q + 2q^4 + \cdots = \sum_{n \in \mathbb{Z}} q^{n^2}$$

is called a *theta function*. It turns out that θ_3 transforms nicely with respect to Γ, once we make the change-of-variables $q = \exp[\pi \mathrm{i} \tau]$. This takes work to show. For example, θ_3 is clearly invariant under the action of $\begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}$, and a little work (from e.g. Poisson summation) shows that $\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ takes $\theta_3(\tau)$ to $\sqrt{\frac{\tau}{\mathrm{i}}}\,\theta_3(\tau)$. θ_3 is not precisely a modular function (it is a 'modular form of weight $\frac{1}{2}$' for $\Gamma_0(4)$), but this simple example illustrates the point that Γ (and related groups) appear throughout number theory. More on this shortly.

That important change-of-variables $q = \exp[\pi \mathrm{i} \tau]$ was introduced by Jacobi early last century, in his analysis of 'elliptic integrals'. The theory is beautiful and poorly remembered today, which is very disappointing considering how much of modern math was touched by it. I strongly recommend the book [10], written over a century ago; the style and motivation of math in our century is different from that in Jacobi's, and we've lost a little in motivation what we've gained in power. I'll briefly sketch Jacobi's theory.

---

[27] A fundamental principle in math is: whenever you have a subscript with an infinite range, make a power series (called a *generating function*) out of it.

Just as we could develop a theory of 'circular functions' (i.e. sine etc.) starting from the integral $s(a) = \int_0^a \frac{dx}{\sqrt{1-x^2}}$, so can we develop a theory of 'elliptic functions' starting from the 'elliptic integral' $F(k,a) = \int_0^a \frac{dx}{\sqrt{(1-x^2)(1-k^2x^2)}}$. Inverting $s(a)$ gives a function both more useful and with nicer properties than $s(a)$: we call it $\sin(u)$. Similarly, for any k the elliptic function $\mathrm{sn}(k,u)$ is defined by $u = F(k, \mathrm{sn}(k,u))$. Just as we can define a numerical constant π by $\sin(\frac{1}{2}\pi) = 1$ (i.e. $\frac{1}{2}\pi = \int_0^1 \frac{dx}{\sqrt{1-x^2}}$), we get a function $K(k) = \int_0^1 \frac{dx}{\sqrt{(1-x^2)(1-k^2x^2)}}$. Just as $\sin(u)$ has period $4(\frac{1}{2}\pi)$, so has sn u-period $4K(k)$. sn also turns out to have u-period $4\mathrm{i}\,K(k')$ where $k' = \sqrt{1-k^2}$ — today we take this as the starting point and define an elliptic function to be doubly periodic (see [42] or Cohen in [60]).

The theta functions aren't elliptic functions, but they are closely related, and e.g. sn can be written as a quotient of them. In Jacobi's language, we have

$$\theta_3\left(\frac{\mathrm{i}\,K(k')}{K(k)}\right) = \sqrt{\frac{2K(k)}{\pi}}\ .$$

The 'modular transformation' $\tau \mapsto \frac{-1}{\tau}$ corresponds to interchanging the 'modulus' k with the 'complementary modulus' k', and thus is completely natural in Jacobi's theory. The important formula $\theta_3(\frac{-1}{\tau}) = \sqrt{\frac{\tau}{\mathrm{i}}}\,\theta_3(\tau)$ is trivial here.

A certain interpretation of modular functions also indicates their usefulness, and played an important role in Part 1. A *torus* is something that looks like the surface of a bagel, at least as far as its topology is concerned. For example, the Cartesian product $S^1 \times S^1$ of circles is a torus (think of one circle being the contact-circle of the bagel with the table on which it rests, then from each point on that horizontal circle imagine placing a vertical circle perpendicular to it, like a rib; together all these ribs fill out the bagel's surface). A more sophisticated example of a torus is an elliptic curve (a complex curve of the form $y^2 = ax^3 + bx^2 + cx + d$ and a special point on it playing the role of 0). A final example is the quotient $\mathbb{C}/\Lambda$ of the complex plane $\mathbb{C}$ with a 2-dimensional lattice Λ (we saw lattices in §1.6; Λ here will be a discrete doubly-periodic set of points in $\mathbb{C}$, containing 0). It turns out that certain equivalence classes of tori (e.g. with respect to conformal or complex-analytic equivalence) always contain a representative torus of the form $\mathbb{C}/\Lambda$, where Λ consists of all points $\mathbb{Z} + \mathbb{Z}\,\tau$, for some $\tau \in \mathcal{H}$. (Incidentally, the cusps correspond to degenerate tori.) In other words, these equivalence classes are parametrized by complex numbers τ in $\mathcal{H}$. So if we have a complex-valued function F on the set of all tori, which is e.g. conformally invariant (an example is the genus-one partition function $\mathcal{Z}$ in conformal field theories — see §1.1), then we can consider F as a well-defined function $F : \mathcal{H} \to \mathbb{C}$. However, it turns out that different points τ in $\mathcal{H}$ correspond to the same equivalence class of tori: e.g. the lattice for τ is the same as that for $\tau + 1$, and these are a rescaling of that for $-1/\tau$. Thus $F(\tau) = F(\tau + 1) = F(-1/\tau)$, because $\tau, \tau + 1, -1/\tau$ all represent equivalent tori. Since $\tau \mapsto \tau + 1$ and $\tau \mapsto -1/\tau$ generate $\mathrm{PSL}_2(\mathbb{Z})$, what in fact we find is that F has Γ as its group of symmetries. One often says that Γ is the 'modular group of the torus', and that the orbit space $\Gamma\backslash\mathcal{H}$ is the 'moduli space' of (conformal equivalence classes of) tori. $\mathcal{H}$ is called its 'Teichmüller space' or 'universal cover'. This is exactly analogous to $S^1 = \mathbb{R}/\mathbb{Z}$: $\mathbb{R}$ is its universal cover and $\mathbb{Z}$ is its 'modular group' (or 'mapping class group'). Another example: the Teichmüller space for (conformal equivalence classes of) 'pair-of-pants', or equivalently a disc minus two open interior disks, is $\mathbb{R}^3$ (an ordered triple), while its modular group is the symmetric group $\mathfrak{S}_3$ and its moduli space consists of unordered triples. Incidentally, we write $\Gamma\backslash\mathcal{H}$ instead of $\mathcal{H}/\Gamma$ because the group Γ acts on $\mathcal{H}$ 'on the left'. A good introduction to the geometry here is [55].

In any case, a surprising number of innocent-looking questions in number theory can be dragged (usually with effort) into the richly developed realm of elliptic curves and modular functions, and it is there they are often solved. For instance, we all know the ancient Greeks were interested in Pythagorean triples: find all integer solutions a, b, c to $a^2 + b^2 = c^2$, i.e. find all integer (or if you prefer, rational) right-angle triangles. They solved this by elementary means: choose any integers (or rationals) x, y and put $u = \frac{x^2-y^2}{x^2+y^2}$, $v = \frac{2xy}{x^2+y^2}$; then $u^2 + v^2 = 1$ and (multiplying by the denominator) this gives all Pythagorean triples.

There are two ways of extending this problem. One is to ask which $n \in \mathbb{Z}$ can arise as areas of these rational right-angle triangles. It turns out $n = 5$ is the smallest one: $a = \frac{3}{2}$, $b = \frac{20}{3}$, $c = \frac{41}{6}$ works ($5 = \frac{1}{2}(\frac{3}{2})(\frac{20}{3})$ and $(\frac{3}{2})^2 + (\frac{20}{3})^2 = (\frac{41}{6})^2$). This is a hard problem — just try to show $n = 1$ cannot work. $n = 157$ turns out to work: the simplest triangle has a and b as quotients of integers of size around 10^{25}, and c as the quotient of integers around 10^{47}. Although this problem was studied by the ancient Greeks and also by the Arabs in the 10th century, it was finally cracked in the 1980s. It was solved by first translating it into the question of whether the elliptic curve $y^2 = x^3 - n^2x$ has infinitely-many rational points, and then applying all the rich 20th century machinery to answering that question.

The other continuation of the Pythagorean triples question is more famous: find all integer solutions to $a^n + b^n = c^n$ (or equivalently all rational solutions to $a^n + b^n = 1$). 350 years ago Fermat wrote in the margin of the book he was reading (the book was describing the Greek solution to Pythagorean triples) that he had found a "truly marvelous" proof that for $n > 2$ there are no nontrivial solutions, but that the margin was too narrow to contain it. This result came to be known as 'Fermat's Last Theorem'[28] and despite considerable effort no one has succeeded in rediscovering his proof. Most people today believe that Fermat soon realised his 'proof' wasn't valid, otherwise he would have alluded to it in later letters. In any case, a very long and complicated proof was finally achieved in the 1990s: the 'Taniyama conjecture' says that a certain function associated to any elliptic curve over $\mathbb{Q}$ will be modular; if $a^n + b^n = c^n$ for some $n > 2$, then the elliptic curve $y^2 = x^3 + (a^n - b^n)x^2 - a^nb^n$ will violate the Taniyama conjecture; finally Wiles proved the Taniyama conjecture is true.

To most mathematicians, the 'area-n problem' and 'Fermat's Last Theorem' are interesting only because they can be related to elliptic curves and modular forms — it's easy to ask hard questions in math, but most questions tend to be stale. Number theory is infatuated with modular stuff because (in increasing order of significance) (a) it's exceedingly rich, with lots of connections to other areas of math and math phys; (b) it's a battleground on which many innocent-looking but hard-to-crack problems can be slain; and (c) last generation's number theorists also worked on modular stuff.

---

[28] It was called his 'Last Theorem' because it was the last of his 48 margin notes to be proved by other mathematicians — another one is discussed in Section 1.8. The story of Fermat's Last Theorem is a fascinating one, but alas this footnote is too small to do it credit. See for instance the excellent book [53].

In any case, modular functions turn out to be important for math (and mathematical physics) even though they may at first glance look artificial. Poincaré explained how to study them. He said to look at the orbits of $\overline{\mathcal{H}}$ with respect to Γ. For example, one orbit, hence one point in $\Gamma\backslash\overline{\mathcal{H}}$, contains all cusps. We write this as $\Gamma\backslash\overline{\mathcal{H}}$, and give it the natural topological structure (i.e. 2 points $[\tau],[\tau'] \in \Gamma\backslash\overline{\mathcal{H}}$ are considered 'close' if the 2 sets $\Gamma\tau, \Gamma\tau'$ nearly overlap). Note first that by applying T repeatedly, every point in $\mathcal{H}$ corresponds to a point in the vertical strip $-\frac{1}{2} \leq \mathrm{Re}(\tau) \leq \frac{1}{2}$ — in fact to a unique point in that strip, if we avoid the two edges. S is an inversion through the unit circle, so it permits us to restrict to those points in the vertical strip which are distance at least 1 from the origin. The resulting region R is called a fundamental region for Γ. Apart from the boundary of R, every Γ-orbit will intersect R in one and only one point.

What should we do about the boundary? Well, the edge $\mathrm{Re}(\tau) = -\frac{1}{2}$ gets mapped by T to the edge $\mathrm{Re}(\tau) = \frac{1}{2}$, so we should identify (=glue together) these. The result is a cylinder running off to infinity, with a strange lip at the bottom. S tells us how we should close that lip: identify $\mathrm{i}e^{\mathrm{i}\theta}$ and $\mathrm{i}e^{-\mathrm{i}\theta}$. This seals the bottom of the cylinder, so we get an infinitely tall cup with a strangely puckered base. In fact the top of this cup is also capped off, by the cusp $\mathrm{i}\infty$. So what we have (topologically speaking) is a *sphere*. It does not look like a smooth sphere, but in fact it inherits the smoothness of $\mathcal{H}$.

Incidentally, topological manifolds of dimension ≤ 3 always have a unique compatible smooth structure. 'Topological structure' means you can speak of continuity or closeness, 'smooth structure' means you can also do calculus. On the other hand, $\mathbb{R}^4$ has infinitely many smooth structures compatible with its topological structure; mysteriously, all other Euclidean spaces $\mathbb{R}^n$ have a unique smooth structure! Thus both mathematics and physics single out 4-space. Coincidence???

So anyways, what this construction of $\Gamma\backslash\overline{\mathcal{H}}$ means is that a modular function can be reinterpreted as a meromorphic complex-valued function on this sphere. This is very useful, because our undergraduate complex variables class taught us all about meromorphic complex-valued functions f on the Riemann sphere $\mathbb{C} \cup \infty$. There are many meromorphic functions on $\mathbb{C}$, but to also be meromorphic at ∞ forces f to be *rational*, i.e. $f(w) = \frac{\text{some polynomial } P(w)}{\text{some polynomial } Q(w)}$, where w is the complex parameter on the Riemann sphere. So our modular function $f(\tau)$ will simply be some rational function P/Q evaluated at the change-of-variables function $w = c(\tau)$ which maps us from our sphere $\Gamma\backslash\overline{\mathcal{H}}$ to the Riemann sphere. There are many different choices for this function $c(\tau)$, but the standard one is $c(\tau) = j(\tau)$, the j-function of (2.1.1)[29]. Thus, any modular function can be written as a rational function $f(\tau) = P(j(\tau))/Q(j(\tau))$ in the j-function. Conversely, any such function will be modular.

This is analogous to saying that any function $g(x)$ periodic under $x \mapsto x+1$ can be thought of as a function on the unit circle $S^1 \subset \mathbb{C}$ evaluated at the change-of-variables function $x \mapsto e^{2\pi \mathrm{i}x}$, and hence has a Fourier expansion $\sum_n g_n \exp[2\pi \mathrm{i}nx]$.

---

[29] Historically, j was the standard choice, but in Moonshine the preferred choice would be the function $J = j - 744$ with zero constant term.

We can generalise this argument. Consider a subgroup G of $\mathrm{SL}_2(\mathbb{R})$ which is both not too big, and not too small. 'Not too big' means it should be *discrete*, i.e. the matrices in G can only get so close to the identity matrix $\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$. To make sure G is 'not too small', it is enough to require that G contains some subgroup of the form

$$\Gamma_0(N) := \{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}_2(\mathbb{Z}) \,|\, c \equiv 0 \pmod{N} \} \ , \tag{2.3.2a}$$

i.e. G must contain all matrices in Γ whose bottom-left entry is a multiple of N. So G must contain T, for example. We will also be interested only in those G which obey

$$\begin{pmatrix} 1 & t \\ 0 & 1 \end{pmatrix} \in G \ \Rightarrow \ t \in \mathbb{Z} \tag{2.3.2b}$$

i.e. the only translations in G are by integers. We will call a function $f : \overline{\mathcal{H}} \to \mathbb{C}$ a *modular function for* G if it is meromorphic (including at the cusps $\mathbb{Q} \cup \{\mathrm{i}\infty\}$), and if also f is symmetric with respect to G: $f \circ \alpha = f$ for all $\alpha \in G$. This implies we will be able to expand f as a Laurent series in q. We analyse this as before: look at the orbit space $\Sigma = G \backslash \overline{\mathcal{H}}$; because G is not too big, Σ will be a (Riemann) surface; because G is not too small, Σ will be compact.

The compact Riemann surfaces have been classified (up to homeomorphism — i.e. considering only topology as relevant), and are characterised by a number called the *genus*. Genus 0 is a sphere, genus 1 is a torus, genus 2 is like two tori resting side-by-side, etc. For example, the surface of a wine glass, or a fork, is topologically a sphere, while a coffee cup and a key will (usually) be tori. Eye glasses with the lenses popped out is a 2-torus, while a ladder with n rungs on it has genus $n-1$.

We will call G 'genus g' if its surface Σ has genus g. For example, $G = \Gamma_0(2)$ and $G = \Gamma_0(25)$ are both genus 0, while $\Gamma_0(50)$ is genus 2 and $\Gamma_0(24)$ is genus 3. Once again, we are interested here in the genus 0 case. As before, this means that there is a change-of-variables function we'll denote J_G which has the property that it's a modular function for G, and all other modular functions for G can be written as a rational function in it. Because of (2.3.2), we can choose J_G to look like

$$J_G(\tau) = q^{-1} + a_1(G)\, q + a_2(G)\, q^2 + \cdots$$

So J_G plays exactly the same role for G that $J := j - 744$ plays for Γ. J_G is called the Hauptmodul for G. (Incidentally for genus > 0, two generators, not one, are needed.)

For example, $\Gamma_0(2)$, $\Gamma_0(13)$ and $\Gamma_0(25)$ are all genus 0, with Hauptmoduls

$$J_2(\tau) = q^{-1} + 276\, q - 2048\, q^2 + 11202\, q^3 - 49152\, q^4 + 184024\, q^5 + \cdots \tag{2.3.3}$$

$$J_{13}(\tau) = q^{-1} - q + 2\, q^2 + q^3 + 2\, q^4 - 2\, q^5 - 2\, q^7 - 2\, q^8 + q^9 + \cdots \tag{2.3.4}$$

$$J_{25}(\tau) = q^{-1} - q + q^4 + q^6 - q^{11} - q^{14} + q^{21} + \cdots \tag{2.3.5}$$

The smaller the modular group, the smaller the coefficients of the Hauptmodul. In this sense, the j-function is optimally bad among the Hauptmoduls: e.g. for it $a_{23} \approx 10^{25}$.

An obvious question is, how many genus 0 groups (equivalently, how many Hauptmoduls) are there? It turns out that $\Gamma_0(p)$ is genus 0, for a prime p, iff $p-1$ divides 24. Thompson in 1980 proved that for any g, there are only finitely many genus g groups obeying our two conditions (2.3.2). In particular this means there are only finitely many Hauptmoduls. Over 600 Hauptmoduls with integer coefficients $a_i(G)$ are presently known.

2.4. The Monstrous Moonshine Conjectures

We are now ready to make precise the main conjecture of Conway and Norton [12]. (We should emphasise though that there have been several other conjectures, some of which turned out to be partially wrong.)

They conjectured that for each element g of the Monster $\mathbb{M}$, there is a Hauptmodul

$$J_g(\tau) = q^{-1} + \sum_{n=1}^{\infty} a_n(g)\, q^n \tag{2.4.1}$$

for a genus 0 group G_g such that each coefficient $a_n(g)$ is an integer, and for each n the map $g \mapsto a_n(g)$ is a character of $\mathbb{M}$. They also conjectured that G_g contains $\Gamma_0(N)$ as a normal subgroup, for some N depending on the order of g.

Another way of saying this is that there exists an infinite-dimensional graded representation $V = V_{-1} \oplus \bigoplus_{n=1}^{\infty} V_n$ of $\mathbb{M}$ such that the McKay-Thompson series $T_g(\tau)$ in (2.1.4) is a Hauptmodul.

There are around 8×10^{53} elements to the Monster, so naively we may expect around 8×10^{53} different Hauptmoduls $J_g = T_g$. However the character of a representation evaluated at g and at hgh^{-1} will always be the same, so $J_g = J_{hgh^{-1}}$. Hence the relevant quantity is the number of conjugacy classes, which for $\mathbb{M}$ is only 194. Moreover, a character evaluated at g^{-1} will always be the complex conjugate of its value at g, but here all character values $\chi_{V_n}(g)$ are integers (according to the conjecture). Thus $J_g = J_{g^{-1}}$. The total number of distinct Hauptmoduls J_g arising in Monstrous Moonshine turns out to be only 171.

For example, if we choose g to be the identity, we recover $T_{id.} = J$. It turns out that there are precisely 2 different conjugacy classes of order 2 elements, one of them giving the Hauptmodul J_2 in (2.3.3). Similarly for 13, but J_{25} doesn't correspond to any conjugacy class of $\mathbb{M}$.

Moonshine provides an explanation for a forgotten mystery of classical mathematics: why are the coefficients of the j-function *positive* integers? On the other hand, that they are *integers* has long been important to number theory (complex multiplication, class field theory — see e.g. [16]).

There are lots of other less important conjectures. One which played a role in ultimately proving the main conjecture involves the *replication formulae.* Conway-Norton want to think of the Hauptmoduls J_g as being intimately connected with $\mathbb{M}$; if so, then the group structure of $\mathbb{M}$ should somehow directly relate different J_g. In particular, consider the power map $g \mapsto g^p$. Now, it was well-known that $j(\tau)$ has the property that $j(p\tau) + j(\frac{\tau}{p}) + j(\frac{\tau+1}{p}) + \cdots + j(\frac{\tau+p-1}{p})$ equals a polynomial in j, for any prime p (*sketch* *of proof:* it's a modular function for Γ, and hence equals a rational function of j; since its only poles will be at the cusps, the denominator polynomial must be trivial). Hence the same will hold for J. Explicitly we get

$$J(2\tau) + J(\frac{\tau}{2}) + J(\frac{\tau+1}{2}) = J^2(\tau) - 2a_1 \tag{2.4.2a}$$

$$J(3\tau) + J(\frac{\tau}{3}) + J(\frac{\tau+1}{3}) + J(\frac{\tau+2}{3}) = J^3(\tau) - 3a_1 J(\tau) - 3a_2 \tag{2.4.2b}$$

where $J(\tau) = \sum_k a_k q^k$. Slightly more complicated formulas hold in fact for any composite n. Conway and Norton conjectured that these formulas have an analogue for the Moonshine functions J_g in (2.4.1). In particular, (2.4.2) become for any $g \in \mathbb{M}$

$$J_{g^2}(2\tau) + J_g(\frac{\tau}{2}) + J_g(\frac{\tau+1}{2}) = J_g^2(\tau) - 2a_1(g) \tag{2.4.3a}$$

$$J_{g^3}(3\tau) + J_g(\frac{\tau}{3}) + J_g(\frac{\tau+1}{3}) + J_g(\frac{\tau+2}{3}) = J_g^3(\tau) - 3a_1(g)\, J_g(\tau) - 3a_2(g). \tag{2.4.3b}$$

These are examples of the replication formulae.

'Replication' concerns the power map $g \mapsto g^n$ in $\mathbb{M}$. Can Moonshine see more of the group structure of $\mathbb{M}$? A step in this direction was made by Norton [47], who associated a Hauptmodul to commuting elements g, h in $\mathbb{M}$. Physically [19], this corresponds to orbifold traces, i.e. the $V^\natural$ RCFT with boundary conditions twisted by g and h in the 'time' and 'space' directions. Still, we would like to see more of $\mathbb{M}$ in Moonshine.

An important part of the Monstrous Moonshine conjectures came a few years after [12]. Frenkel-Lepowsky-Meurman [23] constructed a graded infinite-dimensional representation $V^\natural$ of $\mathbb{M}$ and conjectured (correctly) that it is the representation in (2.1.4). $V^\natural$ has a very rich algebraic structure, which will be discussed in §2.6.

A major claim of [23] was that $V^\natural$ is a 'natural' structure (hence their notation). To see what they mean by that, it's best to view another simpler example of a natural construction: that of the *Leech lattice* Λ_{24}. Recall the discussion of (root) lattices in §1.6.

Λ_{24} is one of the most interesting lattices, and is related to Moonshine. It can be defined using 'laminated lattices'. Start with the 0-dimensional lattice $\Lambda_0 = \{0\}$, which consists of just a single point. Use it to construct a 1-dimensional lattice, with minimal (nonzero) norm 4, built out of infinitely many copies of Λ_0 laid side by side. The result of course is simply the even integers $2\mathbb{Z}$, which we will call here Λ_1. Now construct a 2-dimensional lattice, of minimum norm 4, built out of infinitely many copies of Λ_1 laid next to each other. There are lots of ways to do this, but choose the densest lattice possible. The result is unique: it is the hexagonal lattice A_2 scaled by a factor of $\sqrt{2}$: call it Λ_2. Continue in this way: Λ_3, Λ_4, Λ_5, Λ_6, Λ_7, and Λ_8 will be the root lattices A_3, D_4, D_5, E_6, E_7 and E_8, respectively, all scaled by $\sqrt{2}$. See [13] chapter 6 for a more complete treatment of laminated lattices.

The 24th repetition of this construction yields the Leech lattice. It is the unique 24-dimensional self-dual lattice with no norm-2 vectors, and provides among other things the densest known packing of 23-dimensional spheres in $\mathbb{R}^{24}$. Many of its properties are discussed throughout [13]. So lamination provides us with a sort of no-input construction of the Leech lattice, and a good example of the mathematical meaning of 'natural'. After dimension 24, it seems chaos results from the lamination procedure (there are 23 different 25-dimensional lattices that have an equal right to be called Λ_{25}, and over 75 000 are expected for Λ_{26}).

It is natural to ask about Moonshine for other groups. There is a partial Moonshine for the Mathieu groups M_{24} and M_{12} (which have about 2×10^8 and 10^5 elements resp.), the automorphism group .0 of Λ_{24} (which has about 8×10^{18} elements), and a few others — see e.g. [49]. These groups are either simple or almost simple (e.g. .0 is the direct product of $\mathbb{Z}_2$ with the simple group .1). More generally, there will be some sort of Moonshine for any group which is the automorphism group of a vertex operator algebra; the finite simple groups of Lie type should be automorphism groups of VOAs closely related to the affine algebras except defined over fields like $\mathbb{Z}_p$.

There is a geometric side to Moonshine, associated to names like Lian-Yau and Hirzebruch. In particular, Hirzebruch's 'prize question' asks for the construction of a 24-dimensional manifold on which $\mathbb{M}$ acts, whose twisted elliptic genus are the McKay-Thompson series. This is still open.

It should be emphasised that Monstrous Moonshine is a completely unexpected connection between finite groups and modular functions. Although there has been enormous progress in our understanding of this connection (so much so, that Richard Borcherds won the 1998 Fields medal for his work on this), there still is mystery at its heart. In particular, that $\mathbb{M}$ is associated with *modular functions* can be explained mathematically by it being the automorphism group of the Moonshine VOA $V^\natural$, and physically by the associated RCFT, but what is so special about $\mathbb{M}$ that these modular functions should be genus 0? We will come back to this in §2.9.

2.5. FORMAL POWER SERIES

Vertex (operator) algebras (VOAs) are a mathematically precise formulation of the notion of *W-algebra* or *chiral algebra*[30] which is so central to conformal field theory (see §1.1). VOAs were first defined by Borcherds, and their theory has since been developed by a number of people (Frenkel, Lepowsky, Meurman, Zhu, Dong, Li, Mason, Huang, ...). Because our primary motivation here is Moonshine, I will only focus on one aspect of their theory (the connection with Lie algebras). Useful to consult while reading this review are the notes [27] — they take a more analytic approach to many of the things we discuss, and their approach (namely that of CFT) motivates beautifully much of VOA theory.

In quantum field theory the basic object is the quantum field, which roughly speaking is a choice of operator $\hat{A}(x)$ at each space-time point x. 'Operator' means something that 'operates on' functions or vectors. E.g. an indefinite integral is an operator, as is a derivative. The operators in the QFT act on the space spanned by the states $|\star\rangle$, and together form an infinite-dimensional vector space (e.g. a C^* algebra) — this infinite-dimensionality of QFT is a major source of its mathematical difficulties, and QFT still has not been put on completely satisfactory mathematical grounds.

---

[30] An alternate (and much more complicated) mathematical formulation of chiral algebra is due to Beilinson and Drinfeld, and belongs to algebraic geometry. See [28] for a good — but still difficult — review.

But another difficulty is that the quantum field $\hat{A}$ really isn't an operator-valued *function* of space-time. 'Function' is too narrow a concept. For example, one of the most familiar 'functions' in quantum mechanics is the Dirac delta $\delta(x)$. You see it for example in the canonical commutation relations: e.g. for a scalar field $\hat{\varphi}$, we have $[\hat{\varphi}(\vec{x},t), \frac{\partial}{\partial t}\hat{\varphi}(\vec{y},t)] = \mathrm{i}\hbar\delta^3(\vec{x}-\vec{y})$. $\delta(x)$ has the property that for any other smooth function f,

$$\int_{-1}^{1} f(y)\,\delta(y)\,\mathrm{d}y = f(0)\ , \qquad \int_{-1}^{1} f(y)\,\delta'(y)\,\mathrm{d}y = f'(0)\ ,$$

etc. The problem is that $\delta(x)$ isn't a function — no function could possibly have those properties.

One way to make sense of 'functions' like the Dirac delta and its derivatives is distribution theory. Although it was first informally used in physics, it was rigourously developed around 1950 by Laurent Schwartz, and uses the idea of test functions. See e.g. [15].

What I will describe now is an alternate approach, *algebraic* as opposed to *analytic*. These two approaches are not equivalent: you can do some things in one approach which you can't do in the other. But the algebraic approach is considerably simpler technically — no calculus or convergence to worry about — and it is remarkable how much can still be captured. This approach is the starting point for the VOA story described next section, and was first created around 1980 by Garland and Date-Kashiwara-Miwa. Keep in mind that what we are trying to capture is an operator-valued 'function' on space-time. Space-time in CFT is 2-dimensional, and so we can think of it (at least locally) as being on the complex plane $\mathbb{C}$ (more precisely, we will usually associate the space-time point (x,t) with the complex number $z = e^{t+\mathrm{i}x}$). Good introductions to the material in this section are [23,39,31].

Let W be any vector space. We are most interested in it being an infinite-dimensional space of matrices (i.e. operators on an infinite-dimensional space), but forget that for now. Define $W[[z,z^{-1}]]$ to be the set of all formal series $\sum_{n=-\infty}^{\infty} w_n z^n$, where the coefficients w_n lie in our space W. We don't ask here whether a given series converges or diverges — z is merely a formal variable. We will also be interested in $W[z,z^{-1}]$ (Laurent polynomials). We can add these formal series in the usual way, and multiply them by numbers (scalars) in the usual way.

Remember our ultimate aim here: we want to capture quantum fields. So we want our formal series to be operator-valued. The way to accomplish this is to choose W to be a vector space of operators, or matrices if you prefer. A fancy way to say this is '$W = \mathrm{End}(V)$', which means the things in W operate on vectors in V. If we take $V = \mathbb{C}^m$, then we can think of W as being the space of all $m \times m$ complex matrices. We are ultimately interested in the case $m = \infty$, but we won't lose much now by taking $m = 1$, which would mean formal power series with numerical coefficients.

Because our coefficients w_n are operators, we can multiply our formal series. We define multiplication in the usual way. For example, consider $W = V = \mathbb{C}$, and take $c(z) = z^{21} - 5z^{100}$ and $d(z) = \sum_{n=-\infty}^{\infty} z^n$. Then

$$c(z)\,d(z) = \sum_{n=-\infty}^{\infty} z^{n+21} - 5\sum_{n=-\infty}^{\infty} z^{n+100} = \sum_{n=-\infty}^{\infty} z^n - 5\sum_{n=-\infty}^{\infty} z^n = -4d(z)\ .$$

So far so good. Now try to compute the square $d(z)^2$. You get infinity. So the lesson is: you can't always multiply in $W[[z, z^{-1}]]$. We'll come back to this later.

But first, look again at that first product: $c(z)\,d(z) = -4d(z)$. One thing it tells us is that *we can't always divide* (certainly $c(z)$ and -4 are two very different power series!). But there's another lesson here: if you work out a few more multiplications of this kind, what you'll find is that $f(z)\,d(z) = f(1)\,d(z)$ for any f, at least for those f for which $f(1)$ exists (e.g. any $f \in W[z, z^{-1}]$). Thus $d(z)$ is what we would call the Dirac delta $\delta(z-1)$! (You can think of it as the Fourier expansion of the Dirac delta, followed by a change of variables). Unfortunately, the standard notation here is to write it without the '-1':

$$\delta(z) := \sum_{n=-\infty}^{\infty} z^n$$

and that is the notation we will also adopt. Similarly, $\delta(az)$ and $\delta'(z)$ etc (which are the formal series defined in the obvious way) act on $W[z, z^{-1}]$ in the way one would expect: $f(z)\,\delta(az) = f(\frac{1}{a})\,\delta(az)$ and $f(z)\,\delta'(z) = f'(1)\,\delta'(z)$. So of course it makes perfect sense that we couldn't work out $d(z)^2$: we were trying to square the Dirac delta, which we know is impossible!

A similar theory can be developed for several variables z_i, with identities such as $f(z_1, z_2)\,\delta(z_1/z_2) = f(z_2, z_2)\,\delta(z_1/z_2) = f(z_1, z_1)\,\delta(z_1/z_2)$.

But we must not get too overconfident:

Paradox 1. Consider the following product:

$$\delta(z) = \big[(\sum_{n=0}^{\infty} z^n)\,(1-z)\big]\,\delta(z) = (\sum_{n=0}^{\infty} z^n)\,\big[(1-z)\,\delta(z)\big] = (\sum_{n=0}^{\infty} z^n)\,\big[0\,\delta(z)\big] = 0\ .$$

When physicists are confronted with 'paradoxes' such as this, they tend to respond by keeping them in the back of their mind, by treading with care when they are involved in a calculation which reminds them of one of the paradoxes, and otherwise trusting their instincts. Mathematicians typically over-react: they kick themselves for getting overconfident and walking head-first into a 'paradox', and then they devise some rule which will absolutely guarantee that that paradox will always be safely avoided in the future. We will follow the mathematicians' approach, and in the next few paragraphs will describe their rule for avoiding Paradox 1: to forbid certain innocent-looking products.

Remember that we are actually interested in the vector space $W = \mathrm{End}(V)$. Suppose we have infinitely many matrices $w_i \in \mathrm{End}(V)$. We will call them *summable* if for every column vector $v \in V$, only finitely many products $w_i(v) \in V$ are different from 0. In other words, only finitely many of the matrices w_i have a nonzero first column, only finitely many have a nonzero second column, ...

We will certainly have a well-defined sum $\sum_i w_i(z)$ if for each fixed n, the set $\{w_i(n)\}$ (as i varies) of matrices is summable. All other sums are forbidden. We will certainly have a well-defined product[31] $\prod_{i=1}^m w_i(z)$ if for each n, the set $\{w_1(n_1)\,w_2(n_2)\,\cdots\,w_m(n_m)\}_{\sum n_i = n}$

---

[31] m here will be finite: we permit infinite sums but only finite products.

(vary the n_i subject to $\sum_i n_i = n$) is summable. All other products are forbidden. This is reasonable because the sum of those matrix products $w_1(n_1)\cdots w_m(n_m)$ will precisely equal the nth coefficient of the product $\prod_{i=1}^m w_i(z)$.

Note that there are certainly more general ways to have a well-defined product (or sum). For example, according to our rule, we cannot even add $\sum_n 2^{-n}$! This way has the advantage of not touching the more complicated realm of convergence issues. We are doing *algebra* here, not *analysis*. The way out of Paradox 1 is that $(\sum z^n)(1-z)$ doesn't equal 1 — rather, it's a forbidden product.

An interesting consequence of the fact that we are doing algebra instead of analysis is that the product $z^{\frac{1}{2}}\delta(z)$ here does not and cannot equal $1^{\frac{1}{2}}\delta(z) = \delta(z)$ — their formal power series are very different. In hindsight this 'failing' is understandable: algebraically, it seems artificial to prefer the positive root of 1 over the negative root.

Paradox 2. Expand $\frac{1}{1-z}$ in a formal power series in z to get $\sum_{n\geq 0} z^n$. Next, expand $\frac{1}{1-z} = \frac{-z^{-1}}{1-z^{-1}}$ in a formal power series in z^{-1} to get $-\sum_{n<0} z^n$. Subtract these; we presumably should get 0, but we actually get $\delta(z)$!

The analytic explanation is that the first expression converges only for $|z| < 1$, and the second for $|z| > 1$, so it would be naive to expect their difference to be 0. We see from this 'paradox' that *it really matters in which variable we expand rational functions.* For instance, at first glance the identity

$$z_0^{-1}\delta\left(\frac{z_1 - z_2}{z_0}\right) - z_0^{-1}\delta\left(\frac{z_2 - z_1}{-z_0}\right) = z_2^{-1}\delta\left(\frac{z_1 - z_0}{z_2}\right)$$

is nonsense; it only holds if you expand the terms in positive powers of z_2, z_1, and z_0 respectively. The procedure of expanding a function in positive and negative powers of a variable and then subtracting the results, yields what are called *expansions of zero*; it is possible to show that expansions of zero will always be linear combinations of Dirac deltas $\delta(az)$ and their various derivatives $\delta^{(k)}(az)$, as we saw in Paradox 2.

2.6. INGREDIENT #3: VERTEX OPERATOR ALGEBRAS

We are now prepared to introduce the important new structure called vertex operator algebras (VOAs). They are essentially the chiral algebras of RCFTs — see [26,27] for excellent motivation of the 7 axioms below. A more detailed treatment of the basic theory of VOAs is provided by e.g. [23,39,31]. Although VOAs are natural from the CFT perspective and appear to be an important and rapidly developing area in math, their definition is not easy: Borcherds is known to have said that you either know what they are, or you don't want to know.

A VOA is a (infinite-dimensional) graded vector space $V = \oplus_{n\in\mathbb{Z}} V_n$ with infinitely many bilinear products $u *_n v$ respecting the grading (in particular $V_k *_n V_\ell \subseteq V_{k+\ell-n-1}$), which obey infinitely many constraints. 'Bilinear' means that for any $a, a', b, b' \in \mathbb{C}$ and $u, u', v, v' \in V$, $(au + a'u') *_n (bv + b'v') = ab\, u *_n v + ab'\, u *_n v' + a'b\, u' *_n v + a'b'\, u' *_n v'$ — i.e. that the products are compatible with the vector space structure of V. The subspaces V_n

must all be finite-dimensional, and they must be trivial (i.e. $V_n = \{0\}$) for all sufficiently small n (i.e. for $n \approx -\infty$). Note that we can collect all these products into one generating function: a linear map $Y : V \to (\mathrm{End}V)[[z, z^{-1}]]$. That is, to each vector $u \in V$ we associate the formal power series (called a *vertex operator*) $Y(u, z) = \sum_{n\in\mathbb{Z}} u_n z^{-n-1}$. For each u, the coefficients u_n will be functions from V to V. The idea is that the product $u *_n v$ will now be written $u_n v := u_n(v)$. The bilinearity of $*_n$ translates into two things in this new language: that $Y(\star, z)$ is linear, and that each function u_n is itself linear (i.e. they are endomorphisms).

The constraints are:

VOA 1. (*regularity*) $u_n v = 0$ for all $n > N(u, v)$;

VOA 2. (*vacuum*) there is a vector $1 \in V$ such that $Y(1, z)$ is the identity (i.e. $1_n v = \delta_{n,-1} v$);

VOA 3. (*state-field correspondence*) $Y(u, 0)1 = u$;

VOA 4. (*conformal*) there is a vector $\omega \in V$, called the *conformal vector*, such that $L_n := \omega_{n+1}$ gives us a representation of the Virasoro algebra $\mathcal{V}$, with central term $C \mapsto cI$ for some $c \in \mathbb{C}$;

VOA 5. (*translation generator*) $Y(L_{-1}u, z) = \frac{d}{dz} Y(u, z)$;
